Bombay.—There are several very distinct varieties or races of this pulse met with in Western India. These might be grouped into garden and field varieties. The former (as with the other provinces) can be spoken of as late kharif plants, since they come into season about December to January. Mollison (Textbook Ind. Agri., 1901, iii., 80) furnishes an interesting account of this Bombay crop. He says that the form known as suri pàpdi is grown extensively in gardens in the Surat district. The beans are plucked early and eaten like French beans. The field variety of Surat is a second crop, bitter to taste and called kádeo vál, but in Southern Gujarat there is still another field form that has smaller pods and is drilled with rice and tzewer (Cajanus indicus) during June–July. The principal crop is the rabi, which usually follows rice. It is sown alone or with castor-oil (the dwarf variety). Vál is also grown among other pulses subordinate to juar or bájri. When the juar is reaped, a long stubble, 3 to 4 feet high, is left. This, with the vigorously growing castor-oil and tzewer, affords support to the climbing vál, and heavy successive crops of green beans may be plucked from November to March. The most suitable soil for rabi vál is a heavy black clay retentive of moisture. When the leaves turn yellow and begin to drop off, the crop of ripe beans may be gathered. Mollison adds that on good soil and with careful cultivation 1,300 lb. of pulse and an equal weight of useful fodder per acre may be obtained, off the same field from which a crop of rice has been previously harvested. And this is supplementary to the supply of green pods that may have been collected as a fresh vegetable in the early months of growth. The Department of Land Records and Agriculture, Bombay Presidency, in their Season and Crop Report for 1903–4, gave 94,993 acres as the total area under this crop; and for 1905–6,
DURIO ZIBETHINUS

Durian

52,969 acres, with, in addition, 232 acres in Sind. The chief localities are usually—in Gujarat, Surat; in the Deccan, Poona; in the Karnátak, Belgaum and Bijapur; in the Konkan, Thána and Kolába.

Madras. Garden Crop.

_Madras and Mysore._—Very little can be said regarding this crop in South India except that it is grown in gardens, being sown from June to August, and reaped from October to March. In the _Dictionary_ will be found a selection of passages from the _Madras District Manuals_, and these may be consulted. Rice (Mysore Gaz., 1897, i., 112) says it is always cultivated with ragi (Eleusine coracana). When the plant is cut it is exposed for one day to the sun and then beaten with a stick to separate the seed. [Cf. Buchanan-Hamilton, _Journ. Mysore_, etc., i., 103; ii., 220, 290, 314, 323, 384.]

Burma. Food.

_Burma._—Mason (Burma and Its People, 1860, 466, 768) says "the Burmese and Karens grow several varieties of one or two species of Lablab, which occupy the place of kidney beans in Europe."

_Food and Fodder._—It is difficult, if not impossible, to estimate the actual area under a garden crop such as the present. It is grown all over India more or less, but is comparatively rare in Northern India, becomes abundant in Central, Western and Southern India, and is extended through Bengal and Assam to Burma. As already indicated, it is grown as a green vegetable (corresponding very largely with French beans and as a ripe pulse with the broad bean) and also as a fodder crop. The ripe pulse is eaten by certain classes only or is employed as a cattle food. Church (Food-Grains of India, 1886, 161, t. 31) gives the following, deduced from the chemical analyses of the ripe bean:—Nutrient ratio 1 : 2.5, nutrient value 80. The percentage of albuminoids is rather variable. Leather, in an article on Cyanogenesis in Plants (Agrí. Journ. Ind., 1906, 1, pt. iii., 224), states that he has obtained prussic acid from the seeds of _vdld_ by simply allowing the crushed seeds to remain a few hours in cold water. [Cf. Leather, _Agrí. Ledg._, 1901, No. 10, 361; 1903, No. 7, 152, 155, 166.]

Nutrient Value. Poison.

_D.E.P._, iii., 198. 

Durian, _duren_, _duyin_. A large tree native of the Malay Peninsula, though wild and cultivated in Tenasserim. The earliest European mention of this fruit appears to be that of Nicolò Conti (Ind. in the 15th Century (ed. Hakl. Soc., Major, transl.), 9), and the first botanical drawing of it would seem to be that given by Jacobus Bontius, 1629 (Hist. Nat. et Med. Ind. Or., in Piso, Ind. Ûtr. re Nat. et Med., 1658, 118), though a crude representation of the tree and its fruit was given by Acosta (Tract. de las Drogas, 1578, 231). García de Orta (1533, Coll., xx) very correctly describes the fruit as agreeable to some, repulsive to others. Linschoten (Voy. E. Ind. (ed. Hakl. Soc.), 1598, ii., 31–3, 68) remarks that no fruit in the world is to be compared with it, and Pyrand (Voy. E. Ind. (ed. Hakl. Soc.), 1601, ii., 366) affirms that the Indians "esteem this fruit to be one of the best and daintiest in the Indios." A similar opinion is given by Mandelso (Travels, in Olearius, Hist. Muscovy, etc., 1639, 149), while Herbert (Travels Ind., 1677, 334) mentions it among the fruits of Mangalore. In size it is 10 inches by 7, has a cream-coloured fleshy aril or pulp enveloping the seeds. The smell is most offensive, but the fruit is highly prized, even by Europeans, when the prejudice against it is once overcome. [Cf. Wallace, Malay Arch., 57.] The plant thrives well in Burma, where it is cultivated both in gardens in or near the villages and on the hillsides. The garden cultivation is largely in the hands of the Chinese, but the fruit produced is inferior to that from the hills. It sometimes sells in Moulmein at Rs. 20–30 per 1,000. [Cf. Rept. Sett.
ELETTARIA
CARDAMOMUM
Cardamom

ELÆOCARPUS GANITRUS, Roxb.; Fl. Br. Ind., i., 400; Gamble, Man. Ind. Timb., 113; TILLIACEÆ. Utrasum Bead Tree, rudrak, rudrákya, rudra-chalú, rudráksha. A large tree found throughout various parts of India.

The hard tubercled nuts are cleaned, polished or even stained, then made into the rosaries and bracelets worn by Brahmins and Sinyásis, and sold at such places as Benares, Allahabad and Hardwar. An effort has recently been made to organise a European trade in buttons and hatpins, etc., made of these nuts.

In a letter from the Deputy Conservator of Forests, Lakhimpur, Assam, to the Reporter on Economic Products in 1900, the price for a maund of nuts in Dhuragarh was said to be Rs. 10, and Rs. 12-8-0 landed in Calcutta. Cooke (Fl. Pres. Bomb., 1901, 152) remarks that the stones are imported from Singapore, where the tree is abundant.

E. serratus, Linn.; Fl. Br. Ind., i., 401; jatpí, perinkara, meralu, utraccham, etc. A rather small tree, occurring on the North-East Himalaya up to 3,000 feet in East Bengal, and in the evergreen forests of North Kanara and the west coast down to Travancore; also the low country of Ceylon. The fruit is known as "wild olives," the fleshy outer portion of which is eaten in curries by the Natives, and pickled in oil and salt like olives.

The Cardamom is the true Cardamom, the so-called Greater Cardamom of most writers (Amomum Subulatum, p. 65) being in reality a substitute for the true spice. The Cardamom is a perennial herb, with thick fleshy rhizomes, having erect leafy stems 4 to 8 feet in height, and long much-branched inflorescences which arise near the ground. It is indigenous to West and South India, growing in the rich moist forests of the hilly tracts of Kanara, Mysore, Coorg, Wynaad, Travancore and Madura. It is fairly extensively cultivated, within the regions indicated, at altitudes of from 500 up to 5,000 feet. Although there are no botanical specimens in the Kew Herbarium to support the opinion held by some writers, namely that it is also wild in Burma, there would seem little doubt that it is cultivated in that province, especially in the Bhamo district.

Varieties and Races.—There are apparently two well-marked cultivated plants which it seems must be regarded as deserving of separate recognition as at least varieties. In Rees' Cyclopædia (1819, xxxix., suppl.), the subject of Elettaria is discussed and divided into two sections (a) E. Cardamomum, the

Two Forms.
ELETTARIA
CARDAMOMUM
Cardamom

Lesser or Malabar Cardamom, and (b) E. major, the Greater Oblong Cardamom. The authorities mentioned for the second form can hardly be accepted as definitely denoting any particular plant, but rather one or other of the many cardamom substitutes. Moreover, the so-called form designated major is spoken of as a native of Java. This subject might not have been here mentioned but for the fact that Schumann (in Engler, Pflanzenr., 1904, iv. (46), 209) describes the Ceylon Elettaria as a distinct species, and cites the above authority (Smith in Rees, l.c.). Hooker (Trimen, Handboob Fl. Ceyl., iv., 261) makes reference to var. major and gives it the Sinhala name of enrail, the Malabar plant being ruta-ensal. But Thwaites tells us (Enum. Pl. Zeyl., 1861, 318) that after a careful comparison of growing specimens, he was satisfied that the round and long fruited cardamoms of commerce were not obtained from distinct species. The forms above indicated may therefore be stated thus:—

Var. a minor.—Leaves linear-lanceolate (much smaller and narrower than in β), the under-surface with a more or less complete coating of short white silky hairs. Inflorescence arising from the very base of the stems and creeping on the surface of the ground around the clumps, bracts shorter than the spikelets, acute. Fruits white, sub-globular, angled, somewhat coarsely veined.

This is the Malabar cardamom of Indian planters, and is admirably figured and described by Bontius, Rheede, Sonnerat, Maton and White, and also by Ludlow. An unpublished plate by Roxburgh shows the creeping inflorescence, bracts shorter than the flowers and fruits elliptic. It is, therefore, typical of this plant. He gives no drawing of the next form. Bontius claims to have been the first person to study in Java the living plant and to distinguish the lesser from the greater cardamom. There are good examples of the present form in the Kew Herbarium from Kanara, the Wynaad and Ceylon—the last mentioned being more hairy than the Indian, but said by Trimen to be "the Malabar cardamom of Ceylon planters." The present plant is, however, the lesser cardamom; the one which follows, being much larger fruited, is very possibly in consequence, the greater cardamom of the early writers, though as already stated that name has been frequently assigned to the Nepal cardamom (Annona subulatum).

Var. β major, Thwaites, l.c. 318; Fl. Br. Ind., 251.—Leaves oblong lanceolate (broader and larger than in minor), usually quite destitute of silky hairs (one Ceylon sample in Kew is sparsely hairy). Inflorescence at first erect, bracts larger (longer) than the spikelets and obtuse or apiculate. Fruit oblong, fusiform, minutely veined, twice the length of that of minor.

This is the Mysore cardamom of planters, who speak of two forms of it, viz. uru (cultivated) and kadu (wild). It is a larger, more robust plant than the so-called Malabar. In the Kew Herbarium there are, however, examples of it from Malabar, Palghat, Ceylon, Mauritius and the Gold Coast. Byal and Baker say it is indigenous in Ceylon. Bontius observes that it occurs in the woods of Java, and he figures it as differing from the lesser cardamom by having an erect scape, longer pods and more hairy leaves. Some few years ago a large cardamom was regularly seen in the European markets and known as "Ceylon Cardamom." At the present day the Malabar form is grown in Ceylon and has displaced the former plant. Thus a large-sized true cardamom has been a well-known plant for many years, and it would almost seem as if it had been carried even further afield by cultivation (perhaps because harder), than the smaller and finer spice. This, therefore, very possibly may have to be accepted as the Greater Cardamom proper.

Origin.—Whether both these forms exist as wild plants and whether they originated respectively in Malabar and Mysore, as the planters' names would denote, are points which more careful study in the future can alone determine. It has been suggested that the Malabar is simply a higher state of cultivation than the Mysore and Ceylon. The plants are at all events sufficiently distinct to justify belief that they have been known to the Indian people for many years. It is significant also that the earliest faithful illustrations (such as the admirable plates given by Rheede) denote in every particular the Malabar, not the Mysore plant. So far as can be judged, the Malabar Cardamom, three centuries ago, differed in no respect from that of to-day. But no botanist (if Bontius' somewhat doubtful figure be disregarded) appears to have illustrated and described the Mysore form even down to the present time. These circumstances are opposed to belief in the ancestral stock of the Malabar having been the long-fruiting Mysore plant. Lastly, Rheede makes no reference to either having been cultivated in Malabar.
during his time; on the contrary, he says the cardamom is not sown nor planted, but springs up after the forest is burned down. He then tells us of three being forms on the mountains, thirty miles inland from Cochlin and Calicut. It will be found below that Garcia de Orta, a century before Rheede's time, made practically the same observation except that he regarded the cardamom as cultivated. Rheede describes one of his plants as having round white fruits, another with longer but less valuable fruits, and the third pointed fruits, the least valued of all. It is thus quite possible that the two forms, the small round fruit and the elongated fruit, were both known to Bontius, as also to Rheede. Sonnerat, a century later, gives two admirable plates, one being undoubtedly the Malabar cardamom, and he speaks of its fruit as a round capsule with three angles or edges lengthwise, having many parallel nerves and divided within into three compartments, each with several black seeds. The Ghats (or coast mountains) of Malabar take the name, he adds, of "The Mountains of the Cardamom," from the abundance there of the plant, which grows wild and supplies the cardamoms of all the Indies. Farther on Sonnerat (Voy. Ind. Or., 279) discusses a greater cardamom (under the name of Amomum angustifolium)—a plant which he says is wild in the island of Madagascar. It grows on marshy soils, and its cultivation has been undertaken in Mauritius. It has a reddish capsule, oval-oblong, almost triangular. He does not describe nor figure it as winged, like the "bungali elachi"—the greater cardamom of the Calcutta shops (see p. 65)—though it is doubtless another of the many large fruits of which $A.$ maxiumum of Java, the nutmeg cardamom of the Arabs (Pharmacog. Ind., iii., 436) and of the Bombay shops, as also the prickly cardamom of Tavoy—$A.$ canthoides—are cardamom substitutes that have been all at times designated Greater Cardamoms. [Cf. Kew Mus. Guide, ii., 9.]

History.—It is hardly necessary to attempt to furnish a detailed account of the early history of the Cardamom. Garcia de Orta was the first European who studied the plant practically in India (1563, Coll., xiii.). He speaks of two kinds—major and minor, furnishes an accurate series of Indian and Ceylon vernacular names, and mentions that the Arabs knew the two forms and had separate names for them. It is highly unlikely that the Nepalese greater cardamom was carried to the west coast of India to be traded in by the Arabs at the time of Garcia's residence there, and it is certainly not so traded in to-day. Far more likely is it, therefore, that he alluded to the large and small fruited forms of Elettaria, above described. But there are many surprises for the student of this subject, in Garcia's brief account. He says it was cultivated. Both varieties are found in India, chiefly in Calicut as far as Kananor and other parts of Malabar and in Java. An especially large kind, but less aromatic, was produced in Ceylon and carried to Hormuz and Arabia. This was doubtless the var. major above discussed—a plant also said to be indigenous to Ceylon. But it is significant that Garcia, after apparently a personal study of the plant and of the fruit, should have arrived at the emphatic opinion that the eléttari or elachi of India was the cardamom of the Greeks, whatever that may have been (see Capsicum, p. 204). He says that the descriptions given by Galen, Dioscorides and Pliny do not agree with the Indian cardamom. Bontius, while agreeing that Pliny was wrong, takes exception, however, to Garcia's statement that it is cultivated and bears the fruits on the top like peas. In Java, Bontius says it is produced abundantly and its fruits are formed near the ground while the greater cardamom produces its fruits above. In this view Bontius and Garcia were practically followed by Clusius and the two Bauhins. Until the appearance of Rheede's account (approximately 100 years afterwards), the plant could not, however, be said to have been fully known in Europe. It is surprising that errors committed by Commelin (Pl. Malab., 1696, 18), Burmann (Thes. Zeyl., 1737, 54) and Linnaeus (Pl. Zeyl., 1747, 2) should have continued to disfigure the literature of the subject, during the succeeding century or so, until Maton and White established the genus Elettaria.

THE CARDAMOM PLANT

Cultivation.

Few recent writers have furnished either so interesting or so detailed accounts of the cardamom cultivation as those written during the first decade of the 19th century by White for Malabar and Buchanan-Hamilton for Mysore. It would occupy much space to deal with the centres of chief production separately, or the variations in method of cultivation and preparation that prevail. All that can be here attempted is a brief review of the salient points collectively. A fairly deep rich loamy soil, resting on rock, seems indispensable, and if possible this should be within undulating land, not too remote from running water. Shade and a humid atmosphere are essential—it luxuriates in mists and fogs and cooling sea-breezes. Northern and western exposures are in South India accordingly considered the best. But all these conditions are not often conveniently combined, and hence the localities of successful production are somewhat restricted. Even within Malabar there are only certain tracts that can be spoken of as specially favourable.

1. Forest Production.—The system described by Rheede still prevails. Small plots of land within the forests (called élá-kandies) where the wild or acclimatised plant is known to exist are cleared during February and March. The brushwood is cut down and burned, and the roots of powerful weeds torn up so as to free the soil. The shade, if too dense, is regulated by a certain percentage of trees being felled, thus admitting diffused sunlight; and, curiously enough (from the most ancient times to the present day), the disturbance or shaking of the soil, by the fall of heavy timber on it, is in itself deemed beneficial. At all events, soon after clearing, cardamom plants spring up all over the prepared plots; but if any reason exists for doubting the abundance of the future crop, young plants are deposited in the soil at the required distances apart. The plots are then left alone for a couple of years, and by that time the cardamom plants will have eight to ten leaves, and be a foot in height. In the third year they may be four feet in height. In the following May–June the ground is again weeded, and by September to November a light crop may be obtained. In the fourth year weeding is again given, and if the cardamoms are found growing nearer than six feet apart, a few are transplanted to new positions. A full crop is now obtained, and the plants may bear for three or four years; that is to say, the life of each plantation is eight or nine years. The seasons in Malabar are a little later than in Mysore, and according to some reports a full crop may even be obtained in the third year. It is also believed that above 2,000 feet the cardamoms grown are of a better quality than below that altitude.

Plants may be raised from seed or by division of the rhizome. They may be prepared in special nurseries. In about a year the seedlings will be a foot in length, and are then ready for transplantation. When raised by division of the
rhizome, it should be seen that each cutting contains at least three perfect shoots. Holes a foot deep and six or seven feet apart each way are now dug all over the specially cleared plot or garden, and the seedlings or sets are deposited within these, but they must not be buried too deeply as they are liable to rot off. The flowering season is April to May. It is a good plan to bank up around the clumps all leaves and rubbish obtainable, since this helps to support and encourage the growth of the creeping racemes. If at this stage the flowering branches (racemes) get submerged, the soil is washed away, the roots exposed, and the flowers and fruits ruined with the water and mud. The fruit should not be allowed to ripen fully, as the capsules will then burst and the seeds be lost. They should be collected just as they begin to turn from green to yellow. In August and September they swell, and by the first half of October have usually attained the desired degree of ripening. The crop is accordingly gathered in October and November, and in exceptionally moist weather the harvest may be protracted into December. A dry day is best for harvest. The scape or shoots bearing the clusters of fruits are broken off close to the stems and placed in baskets lined with fresh leaves. At night time they are carried to the temporary hut used by the men. After partaking of a meal and often working far into the night, the men separate carefully the capsules from the shoots, placing them as removed into a pit dug on purpose in the middle of the hut. In the morning the women arrive and carry the produce off to the homestead, where the further treatment is conducted. The fruits are spread out on carefully prepared floors, sometimes covered with mats, and are then exposed to the sun. At night they are carried within doors, as also during showers. Four or five days of careful drying and bleaching in the sun are usually enough, but in rainy weather artificial heat may be necessary, though the fruits suffer very greatly in colour when this course has to be resorted to, and are in consequence sometimes bleached with steam and sulphurous vapour or with ritha nuts (see p. 979). The sun-dried cardamoms are the best, and in trade are spoken of as "green cardamoms." The capsules are now rubbed by the hand or shaken within mats, in order to brush off the pedicles, calyces, particles of dust, etc., then are winnowed, hand-picked and assorted according to size, colour and degree of ripeness, etc.—for on the racemes there must always be a percentage of overripe as also of underripe fruits.

2. Agricultural Production.—Very little of a satisfactory nature can be learned of the systems pursued or of the extent of agricultural production in India. Mollison (Textbook Ind. Agri., iii., 262) gives a brief but instructive account. He there speaks of the crop being extensively grown in the betel-palm and pepper gardens of the Sirsi and Siddapur Talukas of Kanara. It thrives under the same conditions of soil, etc., but by preference is grown in a cool, very shady garden with soil kept continuously moist. In Kanara the crop is chiefly raised from seed. The sowing season is September–October. But the beds require both shade and shelter from the sun and rain. If the seeds germinate too thickly they should be thinned out and the seedlings transplanted into rice seed-beds, but shaded by a temporary protection of palm-leaves. When four feet high and fifteen to eighteen months old, they may be carried to their permanent positions and finally transplanted from March to June, or again from September to October. Pits 18 inches square and 18 inches deep are dug in the same lines as the betel-palms and intermediate between two trees. Into these pits the cardamoms are deposited and supplied yearly, in March and April, with leaf-manure. They come into bearing but do not yield much during the first year after transplanting. The flowers appear somewhat irregularly in April and May, and the fruits form in June and July. The capsules are in season in September and October. Each should be severed from the scape and not plucked. If plucked, the pressure of the fingers may burst the capsule. After being dried in the sun for two or three days the fruits are hand-rubbed to remove the attached stalk and calyx. A too hot sun or too long exposure to the sun may dry the fruits (capsules)
too quickly and thus cause them to burst and thereby to be lowered in value. In a fully stocked betel-nut garden there can be 300 to 400 cardamom plants to the acre. A well-grown plant may yield up to half a pound of dry cardamoms. Light showers in April and May are favourable. The fruits are dried and bleached in particular ways, according to the market for which destined. The waters of certain wells are moreover supposed to produce particular colours and flavours. The system above briefly reviewed is that also followed in Mysore—viz. production in betel-palm plantations.

Yield.

**AREA AND YIELD.**—Ludlow observes that when from one stem four scarces are thrown out, the crop is regarded as full; if only three, it is a three-fourths crop; if two, a half crop; if only one, a quarter crop. "One raceme will have from eight to fourteen branches, and each branch from three to six pedicels. When the crop is good, the branches are close together; when bad, the racemes are long and the branches far apart." "Fruit is occasionally borne on the upper part of the stem, but this is very rare." He further estimates that a garden of 484 square yards in area would give on an average 40 seers of green cardamoms or 10 seers of dry fruits. The actual yield, as published, by plantations is variously stated, and seems to range so greatly that the differences would be best accounted for by supposing that returns of green fruits had been contrasted with dry, or that they denoted diversities in stock rather than of soil or methods of cultivation. In Mysore 28 lb. are spoken of as the yield per acre, and in Ceylon 170 lb., although even as much as 400 lb. have been mentioned. In a circular issued by the Madras Government in 1903, the yield per acre is recorded as from 11 lb. to 700 lb. Omitting the extremes, the more important returns given in that circular were Dindigul, 93 lb.; Palni, 125 lb.; Kodakánal, 250 lb.; Wynaad, 42 lb.; Calicut, 50 lb.; Uppinangadi, 49 lb.; and Kasaragad, 56 lb. The difference between green and dry pods has been expressed as four to five bushels shrinking to one.

Total:

**Area:**

_Madras._

Very little can be stated regarding the total area under cardamoms. There may be stated to be two Indian areas, viz. the Madras and Bombay Presidencies. The former, which is often given the wider significance of South India, may, so far as cardamoms are concerned, be split up into (a) under British Indian Administration, or Madras proper; (b) the British Administration of Coorg; (c) under the Native State of Mysore; and (d) under the Native State of Travancore. Such particulars as are available regarding these areas are disjointed, and often do not refer to one and the same year. Cardamoms are of course returned under "spices and condiments," and it is only occasionally that the provincial details for these are forthcoming. The Madras Government published, however, in 1903, a statement of the cardamom area for the year previous. This showed _Madura_—(Dindigul, Palni, Periyakulan, and Kodakánal)—as possessing 3,714 acres with a yield of 649,281 lb. _Malabar_—(Chirakkal, Kotayam, Kurumbránáli, Wynaad, Calicut, and Ernad)—with 1,586 acres and 24,496 lb. yield. _South Kanara_—(Cundapour, Uppinángádi, and Kasaragad)—with 1,260 acres and 68,828 lb. yield. These give grand totals of 6,660 acres and 742,605 lb. In the small British Province of Coorg there are said to be about 60,000 acres retained for cardamom-growing, with, in 1902–3, 1,107 acres actually under the crop and say 50,000 lb. production. Turning now to the Bombay Presidency: in the official _Season and Crop Report_ it is stated that the area in 1903–4 under cardamoms in the Kára district came to 3,837 acres, or roughly half the area devoted to it in South India. If, for the purpose of comparison, the yield be accepted as on the same ratio, the production of Bombay should be 370,000 lb. In 1905–6 the area had increased to 4,573 acres.

Bombay.

The available information regarding Mysore and Travancore outturn is even more unsatisfactory than for the British districts. A few years ago the Travancore Cardamom Hills Planters' Association was established, a direct indication of the industry having in South India (as in Ceylon) passed to some extent into the hands of European planters. Of 1903 it has been said that 4,000 acres of cardamoms were owned by European planters. According to Mr. Bourdillon there are some 26,000 acres returned in Travancore as the cardamom area. Doubtless only a small proportion of that is in any one year actually under the spice. The produce of the Travancore plantations has been given as 650,000 lb., or just a little under that of Ceylon, which is obtained from an area of 10,000

acres. The yield of the Mysore plantations would seem to be about 200,000 lb., and the cultivation would appear to be mainly in Kadur district.

The figures given above (if reliance can be put on them) would show a total production in all India of close on 2,000,000 lb. per annum. But that figure is mentioned purely and simply as suggestive, and must not be seriously accepted. In the Annual Review of Forest Administration for British India, issued by the Inspector-General, returns are given of cardamom production within Forest Reserves. The volume for 1903-4 shows the value of the cardamoms exported to have been Rs. 3,37,000 as compared with Rs. 4,16,000 the previous year.

TRADE.—In the European markets cardamoms are spoken of under the terms “Shorts,” “Short-ongs” and “Long-ongs.” The “shorts” are from a quarter to nearly half an inch in length, and the “long-ongs” an inch and over in length. The “long-ongs” of modern commerce, it has been contended above, would seem to be the greater cardamom of early writers and the produce of the plant designated by planters the “Mysore or Ceylon cardamom.” They are finely ribbed, of a pale colour, and the seeds are grey or almost white, and shrivelled when dry. The “shorts” are the Malabar or Wynaad cardamoms, and accepted as the finest grades, the ripe seeds of which are black.

In most recent reports the statement occurs that overproduction has lowered very seriously the price. It would appear that in many of the abandoned coffee plantations of Coorg, cardamom and orange cultivation has been attempted, and with some degree of success. There has all over the cardamom area been for some years past a steady expansion of production, so that no doubt there is some truth in the story of overproduction. Still, it cannot be exactly said that the limits have been reached of the world’s demand for this spice, and a fall in price is naturally the first incentive to increased consumption. The EXPORTS to foreign countries during the undermentioned years have at all events shown an expansion in quantity and a shrinking in price. They were in 1889-1900, 191,120 lb., valued at Rs. 3,27,750; in 1902-3, 302,940 lb., valued at Rs. 4,16,242; in 1905-6, 295,390 lb., valued at Rs. 2,97,513; and in 1906-7, 202,374 lb., valued at Rs. 2,19,172. Of that traffic Bombay and Madras are the chief distributing ports. The coastwise returns, moreover, show that Bombay drew on Madras for its supplies. Of receiving countries the United Kingdom usually takes the first place, and is followed by Arabia, Aden, Germany, Turkey-in-Asia, Persia and Egypt. But perhaps the most surprising feature of the traffic is the fact that India IMPORTS cardamoms very largely from Ceylon. In 1903-4 these imports came to 269,132 lb., valued at Rs. 1,98,710, and in 1905-6 to 435,407 lb., valued at Rs. 2,58,083—as much in weight, but comparatively less in value than the corresponding exports. We thus learn that India is itself by far the most important consuming country for cardamoms in the world.

ELEUSINE CORACANA, Gaertn. : Fl. Br. Ind., vii., 294; Duthie and Fuller, Field and Garden Crops, ii., 10, pl. xxviii.; Gramineae.

It has been established by Sir J. D. Hooker that E. indica, Gaertn., is the wild form of which E. coracana is the cultivated state. There would therefore seem no urgent necessity to discard for the present the time-honoured name by which this millet has been known to those interested in the food supply of India. The wild plant is said to occur all over the low country and to ascend to altitudes of from 5,000 to 8,000 feet on the Himalaya. It is distributed throughout the tropical regions of the Old World, but only introduced into the New. As an Indian cultivated plant, however, it
might be more correctly spoken of as met with chiefly on the hilly tracts. With the hill tribes of Southern, Western and Northern India it is an important article of daily food. It is mentioned in *The Bower Manuscript*, of the 8th century, and is the rájika and rágí of Sanskrit, and known in almost every vernacular language by names either derived from these or from what are possibly even more ancient aboriginal names:—*marwa*, *mandund*, *makra*, *mandal*, *mandwa*, *meruya*, *nángli*, *náchui*, *nághi*, *kodé*, *kodou*, *koda*, *kodra*, *kayur*, *kévar*, *kelvaragú*, *kutra*, *kurakan*, *rotka*, *rágí*, *rágulu*, *tamiélu*, *taindulu*, *bávto*, etc.

**Names.**

**Origin.**

Varieties and Races.—There is perhaps little or no doubt that as a cultivated crop this originated in India. There are at all events three or four allied wild species regularly resorted to as articles of food in times of scarcity and famine. And moreover, of the cultivated plant there are in India several fairly distinct forms which almost of necessity denote antiquity of cultivation. *E. stricta*, Roxb., has the spikes quite straight and more numerous; is in consequence a very productive plant. Roxburgh, speaking of Rajamundry (*Fl. Ind.*, i., 344), describes this as the *pedia* (or great) *solu* and says it is a later crop than the ordinary *ponassa* (or early) *solu*. He then adds that there is still a third and even more productive form than either, namely the *maddi ruba solu*. It requires a rich soil but gives an increase of 500-fold.

**Forms.**

Other writers refer similarly to early and late forms of this millet. Mollison (*Textbook Ind. Agri.*, iii., 56–60), for example, observes that in the Konkan and the Ghats districts the early crop is *haloi* and the late *garvi*; the former ripens about the end of September or early October, the latter at end of October or early November. It is therefore a rainy-season crop, and is usually sown on land that is too shallow or too poor for rice or too steep for terracing. But if the rainfall be well distributed it succeeds even on clay loams. The variability of the plant may in fact be regarded as a direct consequence of the class of soils on which grown. On stony and sandy soils the form that approximates most nearly to the wild state (*E. indica*) can alone be produced, and it is an inferior early crop. From that to the large and vigorous late forms of richer agricultural regions, an endless series of adaptations may be chronicled.

**Early and Late.**

**Adaptations.**

**Bengal.**

*CULTIVATION.—*Bengal.—Until it is recollected that Bengal has large tracts of mountainous country it cannot be realised why this province holds the second position of importance in the cultivation of the present millet. The Bengal districts of production may be given here in sequence of value:—Darbhanga, Bhagalpur, Hazaribagh, Muzaffarpur, Patna, Gaya, Shahabad, Sarun and Monghyr have each from 250,000 down to 40,000 acres under the crop. The normal total acreage under it is about one million acres, and the outturn has been put at 10 maunds an acre. Buchanan-Hamilton (*Stat. Acc. Dinaj.*, 1833, 175, 182) describes the method of cultivation as a mixed crop with summer rice and *Cajanus*. In connection with Bihar he says it is grown as a summer crop broadcasted or transplanted, but of Bhagalpur there are two crops, one gathered in November–December, and the other three months earlier. Basu (*Agri. Lohardaga*, 1896, 63–5; also *Palamu*, 28–9) calls *mária* an upland cereal. *There are two main varieties, an early red *láká* and a late white *charkhá*; the former is a *bháddo* crop which is harvested from August 15 to November 15, according to the season of sowing, the race of plant grown, nature of soil, and degree of rainfall. It is usually transplanted and has this advantage, that harvest can be deferred to suit the convenience of the culti-

vator. Col. J. J. Wood speaks of the *marúa* as widely and extensively grown in Chota Nagpur. Banerjoi (*Agri. Outack*, 1893, 74–5) remarks that the *mandua* is an upland cereal and attains a height of 4 to 5 feet and bears grains of a reddish colour. The fields are prepared in May to July and the plants

The normal area under it in the British districts comes to close on two million acres, but in Mysore State alone the area is usually well over two million acres, so that the total for South India might be put at 4 1/2 million. The British
THE RÁGÍ MILLET

ELEUSINE CORACANA
Rágí

districts of greatest importance are Salem, Coimbatore, Cuddapah, North Arcot, South Arcot, Trichinopoly, Anantapur and Vizagapatam, in the order enumerated.

Mysore. Preserving Utilisation.

The Mysore districts are Mysore, Támkur, Bangalore, Kolar, Hassan, Chitaldrug and Kadur. As with other economic products so with this millet, Buchanan-Hamilton (Journ. Mysore, etc., 1807, i., 100–3, 285–6, 297, 369, 375–8, 403; ii., 103–4, 254) is a valuable writer. The Deccan Mussulmans, he says, call it rágí, the Tamil people keevir, and the farmers say there are three varieties—

the cari, kempu, and huluparia. It is, near Seringapatam, customary to sow all three kinds in the same field. When the rains begin in June the field is drilled and Elesine and Cajanus sown as a mixed crop. To appreciate the value of Buchanan-Hamilton’s account of this millet, the passages indicated above must be consulted. They have, however, been reviewed and amplified by Lewis Rice (Mysore Gaz., i., 1807, 107–12, a work which is probably more accessible than the original). Rágí is by far the most important single food crop of this State, especially on dry soils. It supplies the lower ranks of society with their chief food. The total area under food crops is usually 5½ million acres, of which rágí alone occupies fully half.

Very little, however, can be added regarding the South Indian cultivation of this millet, to the account given in the Dictionary. Stuart (Man. N. Arcot, 1895, i., 267–8) says it is a favourite four-month crop, the grain being largely used by the labouring classes. It is not a dainty food, but very nutritious. There are four varieties. It is grown both on irrigated and unirrigated land, but most commonly in that which is commanded by a well. When dependent upon rainfall alone it is sown so as to get the benefit of one or other of the monsoons, that is from May to June and from October to December. Under wells and tanks it is sown and reaped throughout the year. Only the ears of rágí are cut as they ripen, and, being heaped together for two or three months, the grain is beaten out with sticks or trodden underfoot by cattle. It should be kept some months before being used.

Utilisations. MANUFACTURES.—Incidental allusion has already been made to some of the edible preparations of this millet. It has the advantage not only that it may be left standing on the fields till a convenient time for harvesting, but the grain improves by being stored and may be preserved for many years without either being attacked by insects or becoming mouldy. These are circumstances of the greatest possible value, and have justified this millet being accepted as the most desirable for storage against times of scarcity and famine. It is moreover one of the most productive of grains and one which will give a paying crop on soils from which hardly any other food can be obtained. It is essentially, therefore, to large tracts of India, the staple food of the poor, and, though not appreciated by fastidious tastes, is nevertheless wholesome. The seeds are milled and the tailings (the bran formed of the seed-coats) constitute an article of food with the very poor and one which is fairly largely used by the lower classes of South India. [Cf. Agri. Ledg., 1899, No. 4.] The husked grain is reduced to flour and baked into cakes or boiled into puddings (about the consistency of blanc-mange). This is often improved by being cooked along with one-third rice or cholam flour. Church (Food-Grains of Ind., 1886, 89) has given attention to the chemical composition of both the grain and the tailings of this millet. Lastly, numerous writers allude to a beer and spirit prepared from the grain. One of the earliest and most curious passages on this subject is that given by Babor (Memoirs, 283, 294). This has already been alluded to, but the Emperor’s remarks regarding the people of Sewad, Bajour and the neighbouring countries, who make a peculiar kind of buzeh (or beer) may be here quoted:—“There is a substance which they call kim composed of the tops of certain herbs and of various drugs. They make it round like a loaf, and then dry and lay it up. This kim is the essence from which the buzeh is made. Many of the potions composed of it are wonderfully exhilarating, but they are terribly bitter and ill-tasted. I had thought of taking this buzeh, but, from its extreme bitterness, was unable to swallow it: I then took a little májum.” The Emperor repeatedly refers to his special drinking-parties, held not infrequently on board pleasure boats, and the gusto with which he narrates his experiences might easily enough have originated the English expression “bousing”—or deliberate intoxication with buzeh (beer). Mr. (now Sir Arthur) Wollaston tells me that buzah or buzah is Turkish, meaning a drink prepared from corn, and that it had been adopted into Persian with the meaning ale or beer. Shaw (Travels, 1757, 407) says: “Besides the use that is commonly made of barley to feed their cattle, the Egyptians, after it is dried and parched, make a fermented.
intoxicating liquor of it, called 

"bouza", the same, probably, with the oinos kritinos of the ancients. This is very copiously drunk by the lower rank of people. (See remarks regarding boza and māra under Cannabis sativa, p. 257). In the Marathā country the fermented liquor of Elesinus is called bojah or bojjal, and 100 years ago it was perhaps more extensively made than to-day. Hove (Tours in Gujarāt, etc., 1787, 21) speaks of the adulteration of mowra liquor with Acornus root. The liquor in question may have been the marua (Elesinus), or of course it might have been mahuia (Bassia), which Hove in another passage calls mowra. In Kumāon it is called daru (Bassia, see p. 119). A similar beer is made here and there all over the Indian area of Elesinus, and throughout the Himalaya from Kashmir to Sikkim. It is, however, displaced in Assam and the Naga hills by the beer made from cotex (Izu, see p. 396), also more recently by European Malt Liquors (see pp. 757–8).

Area, Yield and Trade.—The total area for all India devoted to this crop averages from 5½ to 6½ million acres, of which nearly two-thirds are in South India. It is possible that were returns for Hyderabad (Deccan) and other States (not at present obtainable) added to the returned area, the grand total would not be far short of 7,000,000 acres. The yield is variously stated at from 5 to 10 or more maunds per acre. If a yield of 400 lb. be accepted as a safe mean average, expressed to the estimated acreage that would show an annual production of 25,000,000 cwt. of edible grain—a by no means insignificant item in India’s food supply. To South India, which approximately consumes two-thirds of that amount, it is an exceedingly important article of diet. There is no mention of this millet in the foreign trade of India, so apparently the produce is entirely consumed within the country.

ERIOBOTRYA JAPONICA, Lindl.; Fl. Br. Ind., ii., 372; Firminger, Man. Gard. Ind. (ed Cameron), 250; Rosaceá. The loquat or Japan Medlar.

A tree indigenous in China and Japan; cultivated in Northern and Eastern India, and, like the litchi and other Chinese plants, is most successfully grown in Assam. The fruit is much appreciated and comes into season about the middle of March, and may be purchased almost everywhere in India for six weeks or two months thereafter.

ERIODENDRON ANFRACTUOSUM, DC.; Fl. Br. Ind., i., 350; Malvaceá. This is the White Silk-cotton Tree, the Kapok Tree of the Dutch, and in India is the safed sinal, senibal, katan, hatian, sham-eula, katsawar, slavam, buruga, pur, kadami, dúdi mara, pania, etc. Is a moderate-sized tree fairly plentiful in some parts of Western and Southern India and Burma, but doubtfully indigenous. Largely planted around villages and temples, and if a demand arose for it, of sufficient importance, its production might be greatly extended.

History.—Jacobus Bontius (Hist Nat. et Med. Ind. Or., in Piso, Ind. Utr. re Nat. et Med., 1658, 105) was perhaps the earliest author to figure and describe this tree. He lived in Batavia in 1629, but it is not quite clear whether his Abor Lanigera (which he identifies with the Gosampines of Pliny (bk. 12, ch. 10, 11) had been seen by him in the Malaya or in India. His engraving though quaint, is unmistakable, but he describes the tree so minutely that without his figure even, there would be little difficulty in identifying the plant as Eriodendron. The oblong pods produce wool that cannot be carded as it is too short, but throughout India it is sought for as a material with which to stuff couches and cushions. It is in passing worthy of remark that Bontius makes no mention of the true cotton, nor of the red-silk-cotton tree, both of which he must have seen in India at least. From this silence it may be inferred that the Abor Lanigera was a Batavian tree. Rheede (Hort. Mal., 1682, iii., tt. 49–51) gives a sketch of it not unlike that of Bontius, but his other pictures might be described as quite as
ERIODENDRON ANFRACTUOSUM

Kapok

WHITE SILK-COTTON TREE

good as many others produced up to two centuries later. He tells us that it occurs everywhere in Malabar and bears fruit in January and February and puts on fresh leaves in March and April. Hence if it be not indigenous to India it must have been introduced at a very early date.

Properties and Uses.—From the bark a medicinal Gum is obtained; the wood is employed as a TANNING material for leather, and from the bark an inferior bast FIBRE is sometimes prepared. The seeds yield 28 per cent. of an OIL that much resembles cotton-seed oil, and the cake is found to be a highly beneficial cattle food. The oil is used in Holland as food and in the manufacture of soap. It dries more rapidly than cotton-seed oil. The Wood is of poor quality, and is only of use in the construction of boxes. But interest in the plant may be said to be concentrated in the Floss or SILK-COTTON obtained from the fruits. This is known to commerce as kapok, a Dutch-Malay word derived apparently from the Sanskrit karpaśi just as the most general Indian name for the tree is hatian, a word derived from the Arabic katian, and thus its names suggest the similarity of the floss to cotton. Gamble (quoting Trimen) very properly remarks that the kapok cotton is obtained, not from the tests of the seed but from the wall of the capsule. This is perhaps more than a botanical peculiarity, and doubtless accounts for some of the characteristics of the floss, which is used in nature as a packing material for the seeds, but is not, like cotton, formed from the seeds themselves. Kapok is of better quality than the corresponding cotton of Bombay as it is more elastic, and when used for upholstery is less liable to knot. Both Bontius and Rhede (as already shown) mention that the cotton is used in stuffiug couches and cushions and is held in great esteem because of its softness. Rumphius (Herb. Amb., i., 196, t. 80) tells us that in his time (1750) the tree was very abundant in Java and had been introduced from there to most of the Malayan islands. He further remarks that although the fibre is too short to spin, it is largely used for filling cushions and has the advantage of not being, like ordinary cotton, easily rolled into balls. During the Colonial and Indian Exhibition of London (1885–6) I showed samples of Indian kapok and other silk cottons and urged the claims of this particular fibre to attention. It is only within the past decade or so that the subject seems to have attracted the notice of Indian merchants as being something more than a curiosity. It would thus almost seem as if the plant had been in India more highly esteemed over two centuries ago than to-day. And it is precisely in upholstery that the fibre has in Europe come into prominence. Fairly largely exported from Java. In 1898, for example, the traffic came to 51,919 bales, and in 1901 to 74,123 bales. Of the last-mentioned year’s consignments 45,631 bales went to Holland, 23,192 bales to Australia, and 5,300 bales to the United States. The supply received by Holland in 1903 was 51,918 bales. Ceylon also appears to have commenced to export this fibre. India exports none, and the local demand even is insignificant, Bombay floss (see p. 108) taking its place.

According to some writers the increasing demand for this floss in Europe necessitates belief that it is being used for textile purposes. But it is too fine, light, smooth and slippery to be easily spun, unless used as an admixture with other flosses. It is reputed to be employed in Bordeaux for the manufacture of soft non-conducting felts. Attempts have unsuccessfully been made to blend it with the fur fibre of the coney and hare, in the production of the “nap” of silk hats. The Kapok Supply Company of London announce that they are now using it very largely in the construction of life-belts, lifebuoys, etc., and that it is regarded as superior to cork or hair since much more buoyant, softer and cheaper. Life-jackets may be padded with kapok and rendered waterproof by being lined with waterproof cloth. It is, however, as already mentioned, in upholstery mainly that kapok has found its most important use. It is largely worked up for cushions, pillows, chairs, bedding, etc., in Holland, Germany, Australia and the United States, but only to a comparatively small extent in England. For these purposes its non-hygrosopic character, its softness and resiliency render it peculiarly suitable. It is also less absorbent, less liable to harbour insects, and can be sterilised by heating at least three times without being seriously damaged. With so much to recommend it, the apathy preserved in India is remarkable; but there is this to be said as possibly explanatory, viz. that so far the Indian floss has fetched less than that of Java. This is by some believed to be due to defective methods of collecting, cleaning, packing, pressing, etc.; by others, and perhaps with greater reason, as due either to climate or stock of plant grown. Certainly the opinion advanced by some writers (in the Indian press particularly) that
kapok is but a Dutch name for the well-known _semen_ cotton—the floss of _Bombax_—is quite erroneous; the floss of _Kriodeudron_ is far superior to that of _Bombax_, and the two must never be confused with each other. The best qualities of Java kapok are said to fetch from 7d. to 9d. per lb., the Indian not much more than half these sums. The double profile of floss and oil-seed should make the cultivation of kapok profitable in all hotter moist tracts of India that possess an insular climate. The subject is being vigorously taken up in both the French and German colonies, and is well worthy of special consideration in India. [Cf. Watt, _Select Rec. Govt. Ind._, 1888, 329–39; Mooden Sheriff, _Mat. Med. Mad._, 1891, 66; Cameron, _For. Trees Mysore and Coorg_, 1894, 30–1; Morris, _Kew Bull._, 1896, 204–7; also Cantor _Lect. in Soc. ---

**ERYTHROXYLON COCA**

_semen_ COCA

---

**ERYTHROXYLON, Linn.**; _Lineae_. A genus of shrubs or trees of about fifty species, natives of warm countries, six of which are Indian.

**E. Coca, Linn.**; De Candolle, _Orig. Cult. Plants_, 1884, 135; Warden, _Erthyroxylon grown in India_, _Journ. Agri._, 1907, 25, 109, etc. This is found in various parts of South America, but according to De Candolle is indigenous only to Peru and Bolivia.

**Introduction into India.**—The Coca plant was introduced into Ceylon from Kew in 1870. At a committee meeting of the Agri.-Horticultural Society of Madras in May, 1870, a letter was read from Mr. Joseph Stevenson in which he suggested the propagation of the plant, in view of the probability of its becoming an important article of commerce. No steps, however, were taken till 1885.
Cultivation.—Various attempts have, however, been made to grow E. Coca in India. Those in the Sikkim (Cinchona plantations) were a failure, but on the slopes of the Nilgiris and other parts of the Madras Presidency the plants have thriven much better. The slightest degree of frost appears to be fatal, and for this reason cultivation on the higher Himalaya has been abandoned, but at lower altitudes, from about 100 to 2,000 feet above sea-level, more encouraging results have been obtained. It is said that in Assam and Sylhet the plant has been grown satisfactorily. But it is affirmed that several species, besides the one here specially indicated, are employed as sources of cocaine, in addition to not a few well-recognised varieties of the true cocaine plant. From the leaves the crystallisable drug is obtained. Some of the species contain a large quantity of the drug not in a crystallisable form, and in consequence are comparatively valueless. It is, therefore, essential to obtain the correct plant, and to know whether the climate and soil of a proposed new plantation favour the formation of crystallisable cocaine. It is usually affirmed that for that purpose a rich and light soil is required. In other words, the plant is grown most successfully on well-drained moist loams, rich in humus; but as it exhausts the land, manuring is necessary after heavy cropping. There are said to be two chief varieties, one with small, the other with large leaves. These may be raised from cuttings, but if cultivated to any extent, seedlings should be produced in nurseries and the young plants put out into the fields when from 8 to 10 inches high. A writer in the Journal of the Agri.-Horticultural Society of India urged the necessity of a liberal supply of water to aid in germination. High rainfall is essential for the growth of the plant. In the Andes the only climatic variation is in degrees of humidity, and it rains more or less every month. The first harvest may be expected eighteen months after the time of planting, and once successfully established, the shrubs yield for forty years.

Anaesthesia.

when, owing to the discovery of the value of cocaine as an anaesthetic, the demand in Europe for the Coca leaf was rapidly increased. About then the Agri.-Horticultural Society of India distributed young plants from their Calcutta Gardens to the various tea-growing districts, and in the same year the Government of India addressed the Secretary of State for India, with a view to ascertain the method of preparation of the leaf as pursued in South America.

The leaves are ready for gathering when they become rigid and break on bending. Two, three or even four crops may be obtained in one year from strong plants in rich soil. The leaves are picked singly, but care must be taken not to pluck leaves nor shoots too young. A dry day should be chosen for harvesting and the picking should not be carried beyond noon, so that the leaves may be exposed several hours in the sun to dry. In India various methods of artificial drying in tea-driers or charcoal chulas have been experimentally tried. The dried leaves should be put aside for a day or two, and then packed. The better method of packing the leaves is to put them up in small, airtight packages, similar to those used for tea. Shipping should take place as soon as possible, for the leaves keep in good condition a much longer time in temperate climates than in the tropics. No commercial attempt has as yet been made to separate the alkaloid and its salts in India, though reports have appeared of the results obtained in the laboratory with Indian leaf. Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1900-1, 20-1), records, for example, the results of his examination of samples from Assam and the Wynaad. It was found that the leaves rapidly deteriorate if kept for any length of time, more especially if imperfectly packed.

The leaves have the property when masticated of communicating a remarkable sustaining power, due to their containing cocaine. On this account they are chewed by the Peruvian Indian, and are to him what betel pani is to the Hindu, kava to the South Sea Islander, and tobacco to the rest of mankind. Both the alkaloid and its salts are stimulant and restorative. Injected hypodermically or painted externally, they produce local anaesthesia, and are much used in minor operations, particularly in ophthalmic and dental surgery. Its employment in this form was first recommended by Dr. C. Koller of Vienna in 1884, though the anaesthetic action was known twenty years previously. [Cf. Kew Bull., 1889, 1-13; 1894, 151-3; Pharmacop. Ind., 1893, iii., 131-4, app.; Garsed, Brit. and Colon. Druggist, 1901, xl., 413; Lenton, Pharmacuet. Alkaloids, 1904, 232-7; White and Humphrey, Pharmacop., 1904, 136-40.]
COCAINÉ LEGISLATION

Trade and Cocaine Legislation.—The records of the traffic in the drug are very meagre. The world’s supply comes chiefly from South America, but recently Ceylon has begun to export a small amount. India is thus mainly interested in the import traffic, and the repressive measures of the Government. The quantity imported was returned in the official statistics for the first time in 1903, when it amounted to 1,400 oz., valued at Rs. 18,442. In 1904–5 it was 5,431 oz. (Rs. 59,910), and in 1906–7, 1,771 oz. (Rs. 19,999). Hooper has published a graphic sketch of the growth of the Indian habit of cocaine indulgence. This has also been fully discussed by Dr. K. C. Bose and other writers (Ind. Med. Gaz., Oct. 1901; March 1903). The Bengal habit seems to have originated in Bhagalpur, and spread to Calcutta. Shortly after it was carried to Bombay and Rangoon. So rapidly and alarmingly was this new vice being taken up that the Government of Bengal, with most praiseworthy zeal, in which it was also followed by the other Governments and Administrations, adopted repressive measures. In a notification of October 24, 1900, cocaine was included in the definition of “intoxicating drugs.” In February 1902 the sale of the drug without a license became illegal. A further enactment of December 1, 1903, limited the amount that could be held or sold at one time. In consequence importations that would have exceeded the limits of possession were seized by the Customs authorities, and returned to the countries from whence procured. It can thus be affirmed that a wholesome check has been given which it is hoped may in time completely repress this most pernicious utilisation of an otherwise valuable medicinal agent.

E. monogynum, Roxb., Fl. Ind., ii., 449; Fl. Br. Ind., i., 414; Talbot, List Trees, etc., 53; Gamble, Man. Ind. Timbs., 110–7. The Bastard Sandal or Red Cedar, dévadáram, nát-ká-deódár, simpulicca, sammanathi, thasadaram, chemblichan, bendde, huli, kurwakumara, jievadali, kumbulukay, devadru, adavigóránta, qathiri. A shrub or small tree found in the dry forests of the Deccan, Kārnātak and Ceylon.

The wood is said to yield an Oil, used as a preservative for Native boats. It resembles tar, and is known in Ceylon under the name of dummele. It is extracted by packing pieces of the wood in an earthen pot inverted over a similar pot which is surrounded by fire.

As a Medicine, Moodeen Sheriff (Mat. Med. Mad., 73) describes the plant as possessing stomachic, diaphoretic and stimulant diuretic properties. In several parts of India the leaves and fruits are used as food in times of famine; in fact they might almost be said to be regularly eaten as a green vegetable. It is reported (Ind. For., 1900, xxvi., 619) that during a recent famine in the Mysore Province the leaves had been largely eaten by the poorer classes. The time for gathering varies from June to December. They are boiled and mixed with salt and chillies. Dr. Bidie suggested that “probably the leaves contain some principle like that of E. Coca,” but specimens analysed by the Government Quinologist in Madras were proved to have no anaesthetic property, but to possess a bitter tonic principle which might serve to mitigate the pangs of hunger. [Cf. Cameron, For. Trees, Mysore and Coorg, 1894, 44; Biscoe, Hyderabad Trees, 1895, 6; Ind. Pharmacol., 1896, 55.]

EUGENIA, Linn. This genus of Myrtaceae embraces over 700 species, 120 of which are trees met with fairly plentifully in India. A few (such as the Clove, the Rose-apple and the Jaman-plum) are of considerable importance. Most modern botanical writers break up that vast assemblage of plants into three genera (or sub-genera) under the names Jambosa, Zyzgium and Eugenia. The less important Indian species may be disposed of at once and the major portion of the available space devoted to the clove, which although not a native of India, is nevertheless traded in all over the country so universally as to make it one of the most important of spices, and one which the future may see produced very much more largely by Indian planters.

**E. (Zyzygium) Jambolana, Lam.; Fl. Br. Ind., ii, 499;** the Black plum, Jaman-plum, jāmbu, jāmān, jām, jāmbul, kuda, naval, nerale, zebri, thabyebu, etc., and perin-njara, according to Rheede (Hort. Mal., 1676, v., t. 29).

A small evergreen tree met with throughout India and Burma, ascending the hills to about 6,000 feet. It is chiefly found along river-beds and is specially cultivated for its fruit in gardens (topes) and in avenues. There are several varieties that yield much flavoured fruit than others, but as a rule it is astringent, and only serviceable when cooked in tarts and puddings. In Goa a wine is prepared from it, and a spirit (jambava) is spoken of, by recent Sanskrit authors, as distilled from the jāmbu. Some years ago brandy was made at Monghyr from the fermented fruit. The jāmān is extensively used all over India in the manufacture of vinegar (see pp. 1109–10). Recently attention has been directed to the seeds as a cure for Diabetes Mellitus (Christy, New. Comm. Pl., 1893, No. 8, 77; Pharmacog. Ind., ii., 25–9). The tasar SILKWORM is said to feed on the leaves of the tree. The timber is fairly durable and is largely employed for building purposes, for agricultural implements and for well-work, since it resists the action of water. It gives a good fuel. The jāmbu is one of the trees held in veneration by the Buddhists (Monier Williams, Buddhism, 576), and is often planted near Hindu temples because regarded as sacred to Krishna. [Cf. Baber, Memoirs, 325; Garcia de Orta, Coll., xxviii.; Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), ii., 29; Taleef Shereef (Playfair, transl.), 65; Buchanan-Hamilton (Stat. Acc. Dinaj., 156), etc.]

Rose-apple.

**E. (Jambos) Jambos, Linn.; Fl. Br. Ind., ii., 474.** A small tree cultivated here and there throughout India, and probably wild in Eastern Bengal and Assam. The Rose-apple, gulab-jāmān (i.e. rose-jāmān) and nati-schamhu, according to Rheede (Hort. Mal., i., t. 18).

This fruit is met with throughout Northern and Eastern Bengal, Assam, Manipur, and the Naga hills, and has in these countries all the appearance of having been long acclimatised, if not indigenous. The fruit is produced during the rainy season, and is about the size of a small apple. By many persons it is highly esteemed on account of its delicate flavour, but is not juicy enough to be a universal favourite. The tree is very ornamental, and is often seen in gardens even where the fruit is not appreciated. [Cf. Boyum, Fl. Sin., 1656, pl. F.; Buchanan-Hamilton, Lc. 196; Robinson, Dis. Acc. Assam., 1841, 43.]

D.E.P., iii, 288.  
Malay Apple.

**E. (Jambos) malaccensis, Linn. ; Fl. Br. Ind., ii., 471.** The Malay Apple, the kavika tree, malaka jāmrum, and malacca-schamhu, according to Rheede (Hort. Mal., i., t. 17).

A handsome tree, native of the Malay peninsula but cultivated in Bengal, South India and Burma on account of its fruits—which are large and juicy, though rather insipid. [Cf. Garcia de Orta, Coll. xcviii.; Acosta, Tract. de las Drogas, 1578, 268; Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), ii., 29; Forster, Pl. Eex., 1786, 36.]

D.E.P., iii, 289.  
Rai-jāmān.

A moderate-sized tree of the Sub-Himalaya from the Panjāb to Assam, Orissa, N. Circars, Burma and Ceylon. It yields an edible fruit which ripens toward the end of the hot weather. It is a valued tree in reclothing the grassy banks in the sol and mixed forests, especially of North India. The timber, while not as good as jāmān, is employed for building and in the construction of agricultural implements.

**History.**—The name Clove denotes its resemblance to a nail (clavus), hence clavo (Sp.), clou (Fr.), nelken (Germ.), and mekhak (Pers.). In later Sanskrit it...
is *lavanga*. Mr. F. W. Thomas (whom I have had the pleasure of consulting on this subject) tells me that the earliest occurrence of the name is in the Ramayana; Charaka is the first medical writer who alludes to the clove. But the word *lavanga* has passed into most of the more recent languages of India, and become *lavanga*, *lavinga*, *labang*, *laung*, *langu*, *long*, *raung*, etc., thus showing a common source. Mr. Thomas, commenting on the possibility of *lavanga* being a Sanskrit word, says, "I should think that the chance of its being Malay is the greatest. It has a Malay appearance. . . In Malay *bunga lavang* is the term used, *bunga* meaning gay or variegated, especially a flower. *Lavang* by itself seems to be used for 'mace.'" [Cf. Reinwardt, *Reis in den Indischen Archipel.*, 1833, 465; Uhlenbeek, *Sanskrit Etymology*; *Encyclop. van Nederlandsche Indië.*] But, in addition, the clove bears in South India the names *kiranbhu*, *karampu*, etc., words which Dymock (*Mat. Med. W. Ind.*, 1855, 328) suggests may have been the source of the carophyllon. But it is probably more safe to assume that those South Indian names were derived from the Greek, through the Arabic *karanfal*. The Tamil name for *Cinnamomum zeylanicum* is *lavanga*, and Crawfurd (*Dict. Ind. Islands*, 1856, 215) gives that as the Borneo name for the clove-bark—a species of Cinnamon. In another passage (101-2) Crawfurd observes that *lavang* is a name used by the Malays for the clove, but brought to their country by the traders from India. Another name for the clove (in the Malay), he says, is *gaumed*, a word which Prof. Wilson, it would seem, translated "Cow's marrow" and regarded as of Sanskrit origin.

The Clove thus bears no undoubted Indian aboriginal names, and was probably not known in India much before the 5th century. The clove is not mentioned in the *Periplus* (63 A.D.) among commodities carried from India. There would seem, moreover, no doubt that it is the *caryophyllon* of Paulus Aegineta (Adams, transl., 1847, 100)—a Greek physician who wrote about the close of the 6th century A.D., and who speaks of the spice in such terms as to imply that it was well known. Passing over several centuries, it may be observed that Caspar Bauhin (*Pinax Theat. Bot.*, 1623, 410) was correct when he pointed out that Serapion was in error citing Galen. The account of the *garriosulus* given by Serapion (9th century), Avicenna (10th century), and by other Arabs is literally transcribed from Paulus.

It is a well-established fact that the Chinese traded with Amboyna and India at a time anterior to any definite knowledge of these countries being possessed by the inhabitants of Europe. The Arabs also had a direct commerce of their own with India and the Malay Islands. In consequence various commodities came to be known to the Indians, Egyptians, Greeks, etc., at earlier dates than might be otherwise easily accounted for, and moreover were sometimes spoken of as Chinese, Indian, Ethiopian, Arabian, etc., in consequence of the nationality of the traders, rather than the countries of supply. Hence very possibly the statement of Paulus Aegineta (and of most of the early writers) that cloves "were brought from India." As a matter of fact the clove even down to the present day can hardly be said to be systematically cultivated anywhere in India. Marco Polo (*Travels*, 1290 (ed. Yule), ii., 217) speaks of the cloves of Java, but his observation must be interpreted to denote the extensive traffic that even in his time had been established, since the clove did not then grow in that island. Barbosa (*Coasts E. Africa and Malabar* (ed. Hakl. Soc.), 184, 219-20) visited Malabar and the "spice isles," and wrote, "The clove grows in the islands called Molucche, and from these it is brought to Malacca and thence to Calicut, a country of Malabar." So again, speaking of Pegu, he remarks there is much trade in cloves and mace and other Chinese goods. Varthéma (*Travels*, 1510 (ed. Hakl. Soc.), 245) also visited the Moluccas and gives a detailed description of the clove. Pigafetta investigated the clove plantations of Molucca in 1512, and wrote a full account of the methods of cultivation and manufacture of the spice. Garcia de Orta, who was in India from about 1535, and published at Goa in 1563 his *Colloquios dos Simples*, etc., says (Coll., xxxv.) that the possession of the Molucca Islands (and thus of the clove and nutmeg trade) was the cause of the war between the Spanish and the Portuguese. But it would be absurd to believe that cloves were not known prior to the discovery of the Moluccas. The price of cloves is stated in the *Ain-i-Akbari*, a work written in Agra (1590), so that they were by then regularly known and traded in all over India (Blochmann, transl., 64). Linschoten gives an exhaustive account of the spice about the same date, and Pyrrad (1601) also described it. In 1603 the East India
THE CLOVE PLANT

Company were trading in cloves (Birdwood and Foster, E.I.C. First Letter Book, 36), and a little later we read of the cultivation being rapidly extended all over the tropics. Rheede does not, however, apparently describe the plant, so that very possibly it was not being cultivated in India during 1686—the date of his great work—the Hortus Malabaricus. About that time, however, the spice was an important article of trade with India. Tavernier (Travels Ind., 1676 (ed. Ball), ii., 17), for example, discusses the Dutch monopoly and the clove traffic of Surat. [Cf. Acosta, Tract. de las Drogas, 1578, 30-4; Thevenot, Travels in Levant, Indostan, etc., 1687, pt. iii., 109.]

Rumphius figures and describes the clove plant (Herb. Amb., 1750, ii., 1-5, t. 1), and gives a long list of its vernacular names. He lived and died in Amboyna and was, in all probability, familiar with every aspect of the clove plant and trade. The Chinese, he says, called it thenghio (= sweet-smelling nails); the modern Malay name is jsianeke and the old Malay name bugulawan; in Amboyna it is bukulawan; in Ternate boholawa, and in Tidora goomde. Filet (Plantkundig Woordenboek) gives it the name bobolava. Crawfurd (l.c. 101) says, "It is very difficult to understand how the clove could have come first to be used as a condiment by foreign nations, considering the well-ascertained fact that it has never been used as such, and indeed hardly in any other way, by the inhabitants of the countries which produce it." He then proceeds to explain that the earliest names in the Moluccas for the clove are connected with the foreigners who came to their shores to procure the spice. The most frequent name, he says, is cangkek, which has not the sound of a native word, but is a corruption of the Chinese theng-kiu. There seems no doubt the Chinese procured the clove from its island home for several centuries before it had reached Europe. It had, however, reached that point to this traffic as early as 260 B.C. Crawfurd, however, mentions none of the names given by Rumphius, but if these be actually the local names of the tree they have not apparently accompanied the clove into the commerce of the world. Little astonishment need, however, be expressed at these names not having accompanied the clove, when it is recollected that it was not regarded by the inhabitants of the "spice islands" as of any value until the Chinese desired to be supplied with the "little sweet-scented nails." In that circumstance alone lay the interest taken by the people of Moluccas in the plant, and "nail" or "clove" became its name in most countries.

Sonnevat (Voy. Nouv. Guin., 1776, 195, tt. 119-20) tells us that he found the clove being grown in New Guinea, and it is well known that in 1770 M. Poirre, of the Isle of Bourbon, sent M. Prevost to Ceram in order to procure live plants of both the clove and the nutmeg. This enterprise was completely successful, and shortly after the plants flourished so well in their new home that seedlings were sent to Cayenne about 1784, and in an incredibly short time the plantations were extended and cloves regularly sent into market of such quality that they were pronounced equal, if not superior to those of the "spice islands." Very shortly after the date mentioned the clove was carried to the West Indies (Dominica in 1789), in fact throughout the tropical world, and was even cultivated by Sir Joseph Banks at Kew in 1797. It had been successfully acclimatised in Zanzibar and Pemba. Migration became imperative, through the short-sighted policy of the Dutch, who sought to secure for themselves an absolute monopoly in the world's supply. For this purpose they ruthlessly destroyed the trees in all the islands except those specially set apart by themselves for clove-production. Having trampled on the rights of the people, retribution became a natural consequence. It is not much to be wondered at, therefore, that when in time a more liberal policy prevailed, the new countries of clove-production had so securely established their positions that a restoration or concentration of the traffic in the original home of the clove became an impossibility.

Cultivation.—Clove are the dried unexpanded flower-buds of this tree. The corolla forms a ball on the top between the four teeth of the calyx, and the stalk is the immature ovary. They are at first green, then turn yellow, and finally bright pink or scarlet. In this last stage they are ready to be picked. If, however, to remain longer on the tree the flowers expand, become fertilised, and the stalk of the clove then develops into a succulent purple-coloured berry containing one or two seeds. This is known technically as the "mother clove." These are sown in
CULTIVATION AND PREPARATION

rich mould about 12 inches apart, and the fresher the better, since the seed when dried soon loses its vitality. They germinate within five weeks and when 4 feet high are transplanted from the nursery into their final positions, 20 to 30 feet apart. The soil must be porous, well-drained, and consist of mould with a fair proportion of sand. The plants will not thrive on clay nor pure sand, and marshy land is fatal. Even in the Malaya the clove tree does not luxuriate alike on all the localities on which grown, and seems to prefer a soil formed from volcanic rock (Craw福特, Lc. 101). In Pemba the soil most suited is a dark loam, having underneath a layer of dusky yellow earth intermixed with gravel, also a yellowish or reddish stiff clay (Kew Bull., 1893, 17-20). Although indigenous to islands it does not succeed well when exposed to the direct sea-breezes. It prefers confined valleys, though dense overhead shade is highly injurious. Protection from high winds is essential, and a tree hedge along the windward side of the plantation is very desirable. But in place of seed the plant may be raised by layering. Young branches laid across the ground take root in about six weeks. The young plants should be transplanted at the beginning of the rains. Shade is necessary for the first two or three years, and watering occasionally is advantageous during exceptionally dry weather, both before and after transplanting. By the end of the third year the shade should be removed, and by the sixth the plants will have come into bearing and be in full crop by the twelfth. By 20 to 25 years they are usually too old to be profitable, though they may yield up to 150 years. It is accordingly customary to renovate certain portions of the estate every 8 years. In the Moluccas the trees are topped at 8 or 9 feet, so as to secure low plants easy of being picked. Each tree should give about 6 to 7 lb. of dry cloves. The best course is to hand-pick the clusters of buds, but occasionally they are beaten off the trees and caught on cloths spread below, or the ground is swept clean, so as to allow of the cloves being picked up without being injured. Every third or sixth year a heavy crop is obtained, and now and again (especially if over-cropped or injured) the trees bear next to no flowers.

In the spice islands the cloves are sometimes cured by being smoked over a shallow wood fire, until they assume a deep brown colour, when the further drying is accomplished by the sun. Occasionally the buds are scalded in hot water before being dried. But if bright sunny days prevail artificial heat may be dispensed with and the buds sun-dried from first to last. The crop loses about 60 per cent. in drying.

Nicholls (Textbook Trop. Agri., 1892, 184-9) gives useful particulars of clove cultivation. A most interesting and instructive account of the production, manufacture and trade in this spice was also written by Mr. J. C. Sawyer in The Produce World (May 1896). Mr. R. N. Lyne of Dunga, Zanzibar, published a valuable report on the plantations of that island, now by far the most important single country of production. [Cf. Trop. Agrist., July 1901, 11-2; Der Tropenpflanzer; Journ. Soc. Chem. Indust.; Pharmaceut. Journ.; Chem. and Drug.; Dipl. and Cons. Repts.; etc.]

Uses.—It is needless to say that the clove, though not held in such high esteem as in former times, is still a spice of considerable commercial importance. Oil of Cloves will be found dealt with in great detail by Gildemeister and Hoffmann (Volatile Oils, 1900, 512-8). It would appear that it was first distilled in the 15th century. The cloves of Pemba are those chiefly used for this purpose. Those of Amboyna and
Reunion are richer in oil, but command, as a spice, too high a price to be used in distillation. The most expensive clove is that of St. Marie in Madagascar. Clove-oil is largely employed in perfumery. Its value is estimated by its eugenol content, which varies from 76 to 85 per cent.

Trade.—Zanzibar and Pemba yield four-fifths of the total clove-supply of the world. There is a small EXPORT of Indian-grown cloves from Madras, a circumstance that points to a certain amount of cultivation. The traffic is, moreover, an expanding one. In 1899–1900 these exports stood at 148 lb.; in 1901–2 at 3,329 lb.; in 1903–4 at 12,598 lb.; in 1904–5 at 25,537 lb.; in 1905–6 at 11,825 lb.; and in 1906–7 at 5,173 lb. As compared with these records, the IMPORTS were 7,815,486 lb., valued at Rs. 17,63,050, in 1899–1900; 6,983,582 lb., valued at Rs. 15,33,174, in 1901–2; 6,659,913 lb., valued at Rs. 17,03,296, in 1903–4; 8,345,521 lb., valued at Rs. 22,01,424, in 1905–6; and 5,062,783 lb., valued at Rs. 16,28,355, in 1906–7. Practically the whole comes from British East Africa, and is received by the town of Bombay. There is an increasing trade from Germany (? Colonies), which supplied 1,100,068 lb. in 1905–6 and 798,851 lb. in 1906–7. The traffic with the Straits Settlements and China is insignificant—under 100,000 lb. from each taken by India. From the imports, however, are drawn the re-exports, viz. 1,000,000 lb., the major portion going to the Straits Settlements and China (Hongkong). India is thus once more a large emporium for the cheaper grades of clove, but in the opposite direction to its ancient traffic.

**EUPHORBIA, Linn. ; Fl. Br. Ind., v., 244–66 ; Gamble, Man. Ind. Timbs., 590–1; Brandis, Ind. Trees, 557–8; Prain, Beng. Plants, ii., 923–5.**

**EUPHORBIACEAE.** This is a genus of herbaceous plants mostly, though a few assume the condition of useful hedge bushes or even small trees. There are in India some 53 species; 7 or 8 only are of economic value.

The English generic name Spargewort denotes their chief medicinal property, but their greatest potentiality lies in the utilisation of their milky sap as a source of gutta-percha. It will be seen from the brief specific review that follows that this subject has engaged spasmodic attention in India for the past century or more without any practical results having been obtained. Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1903–6, 28–9) gives the results of his examination of the latex of two species. They yielded large quantities of euphorbiun and resin to boiling alcohol. Many of the species are valued as manures in the reclamation of waste lands.

**E. antiquorum, Linn.**—A small tree of the dry regions of India generally. Is often used as a hedge plant, and best known by the following names:—vajri in Sanskrit, and in the vernaculars—nara sij or narsej, tekatÁE sij, tidhÁEra, shivdu, kalli, bonta kalli, tazuang, pyathat, etc. Fryer (New Acc. E. Ind. and Pers., 1672–81, 105) alludes to the Euphorbia hedges of the Deccan, which doubtless to some extent consisted of this species. In some parts of Eastern Bengal and Assam this tree is almost sacred, and is supposed to protect the gardens around which planted, and like **E. nerifolia, Linn.**, has the merit, so it is thought, of safeguarding the inhabitants against snake-bite. Both are, in fact, sacred to MansÁE, the goddess of serpents.

**E. nerifolia, Linn.—**A small tree wild on rocky situations in the Deccan, West Coast and Orissa, and often seen under cultivation, especially in Bengal. It is the mansÁE sij, pÁE-sij, sekund, thor, nivarang, minina, kalli, yellowkalli, shazuang. It has a more or less cylindrical stem (the allied form E. tigulattir, Roxb., being four- or five-angled) with stipular thorns on numerous tubercles.

The Milky Juice of this as also the foregoing species is used medicinally all over India; it is purgative and rubefacient. Is a popular application to warts and other cutaneous affections. Internally the juice is usually administered along with other purgatives and aromatics. In the **Indian Forester** (1891, xvii., 350) Gleadow tells the results of some experiments he performed to extract the
POSSIBLE GUTTA-PERCHA

rubber contained in the present species. His samples were sent to Europe and reported on in such terms as to discourage further effort.

E. pluriflora, Linn.—A small herb found throughout the hotter parts of India from the Panjab southwards. Is the dudhí, dedeí, burakeru, pusícu, gordon, nayetí, etc. Used in the affections of children—bowel and lung complaints. A fluid extract has been employed in asthma and in dysentery (Rept. Cent. Indig. Drug. Comm., i., 154).

E. Royleana, Bnls.—A large shrub common on dry rocky hillsides of the outer Himalayans from Kumaon westwards, and also in the Salt Range. It is a most conspicuous and characteristic plant in the tracts of country indicated. Its ascending fleshy branches (or stems) are five-angled and thorny. It is the thor, shakar pítan, sáli, chálla, cháí, sura, tsúi, suru, sókhund, etc. The milk contains a large amount of gutta-percha. When fresh it has a sweet odour and does not blister the fingers, but it is very injurious to the eyes and flavours anything handled even after the greatest care may have been taken to clean the fingers. Some few years ago a fairly extensive series of experiments were conducted with this milk, having in view its utilisation as a waterproofing material or as a paint for ships. The subject is alluded to because sufficient evidence was obtained to satisfy belief that (without contemplating the utilisation of the milk as a gutta-percha substitute or the establishment of factories beyond both the means and the capabilities of the inhabitants of the country where it Royleana is an abundant and at present useless plant) there might still be directions in which it might be possible to convert the limitless supply into a source of wealth. (See Gutta-percha, p. 627.)

E. Trucaill, Linn.—The Milk-hedge or Milk-bush or sekund, shir, serra, lanka sij, sejú, neuli, nival, kadu-névali, jemudu, thwar, yeta-guda, sirukalli, sha-shoog, etc. A small tree with round stems and smooth branches. It is generally believed to be a native of Africa, but has been for many years completely naturalised in India, especially in the drier tracts of Bengal, the Deccan, South India and Ceylon. Heyno (Tracts, Ist. and Stat. Ind., 1814, 243) discusses fully the possibility of utilising the milk of this and other Euphorbias. Drs. Riddle, Cheek and Falconer devoted much time and attention to the self-same subject about 1850. It was observed that after boiling, the milk of this species becomes brittle, though whilst warm it is ductile and elastic. Giberne (Ind. For., 1899, xxv., 84–5) has urged the desirability of the milk of this and other species of Euphorbia being put to some useful purpose. He found that nitric acid caused the separation of the rubber. Mixed with mud the milk is employed in North Arcot in the construction of the flat roofs of houses. It is, in Ganjam, said to be used to intoxicate and poison crowns: for this purpose a little is mixed with boiled rice and given to these birds. The acid juice is in India generally, well known as a purgative and counter-irritant (especially in the treatment of animals), and it is so very painful when to wounds or to the eye that cattle are fully aware of this fact and will not attempt to break down a hedge of it. (Consult the controversy regarding Angola (Almeidina) Rubber—E. vihpsa-lloides versus Trucaill.)

EXCECARIA AGALLOCA

Blinding Tree

Unfavourable Report.

EXCECARIA AGALLOCA, Linn.; Fl. Br. Ind., v., 472; Roxb., Fl. Ind., iii., 756–7; Gamble, Man. Ind. Timbs., 626; Brandis, Ind. Trees, 585; Prain, Beng. Plants, ii., 955; Euphorbiaceae. The Blinding Tree, gangwa, geor, geera, ugru, gnuu, phungali, geva, thillayo-maram, tili, chilla, tella-chilla, haro, kadwu-pal, tayau, yekin, tella kwiya. It may be the taggar wood of Sylhet alluded to under Aquilaria (p. 74). A small evergreen tree of the coast and tidal forests of both sides of the Indian Peninsula, Burma, the Andaman Islands and Ceylon.

The wood contains a milky juice which hardens on exposure to the air into a black caoutchouc-like substance. The sap which exudes from the fresh-cut bark is very acrid, some say poisonous, hence the name Blinding Tree or arbor ex-ccans (Rumph., Herb. Amb., ii., tt. 79–80). Hooper (Yearbook of Pharmacy, 1899, 408) gives an account of the chemistry of this latex, which he analysed with a view to ascertaining its value as a rubber. The Timber is useful for general carpentry purposes and for match-making. [Cf. Pharmacog. Ind., iii., 1893, 314–5; Ind. For., 1897, xxiii., 150.] 531

Spinach.

FAGOPYRUM, Gaertn.; Fl. Br. Ind., v., 54–5; POLYGONACEAE.
F. esculentum, Moench; Duthie and Fuller, Field and Garden Crops, 1893, pt. iii., 25, t. 83; Rec. Bot. Surv. Ind., i., 33, 40, 219, 262; Woodrow, Gard. in Ind., 1899, 430; Mukerji, Handbook Ind. Agr., 1901, 56, 260. This is best known as Buckwheat or Brank, phaphra, koto, kâlû, raśjîr, doron, uga, oga, bâres katû, bres, trîmba (trumba), etc. Extensively cultivated on the temperate Himalaya and lower hills of India, from Afghanistan and Kashmir to Darjeeling, Assam and Burma. There are many cultivated states, some grown for the grain, others as a vegetable, and these blend imperceptibly into the wild F. cymosum, Melsan.

F. tataricum, Gaertn.; Duthie and Fuller, l.c. 26–8, tt. 84, 96. This is the kaspât, kâla trîmba (black trumbo), chin, karmabres, uga, kâltû, tró rjîs, etc. It is usually known as Black Buckwheat, but as a rule phaphra denotes F. esculentum and uga, F. tataricum. This form is cultivated throughout the higher temperate Himalaya, especially on the western extremity between altitudes of 9,000 and 15,000 feet. It is a taller, coarser plant than the other species, having longer grains (nuts, as they are sometimes called) of a black colour, and with the angles rounded off and keeled toward the top, instead of being sharp. There are many cultivated forms, one from Kangra having been treated as a distinct variety under the name himalicae.

On the lower Himalaya, between 4,000 and 10,000 feet, F. esculentum is grown, being sown in July and reaped in October. In the lower reaches of its mountainous area it is usually raised more as a vegetable than a grain. Indeed in Northern and Eastern Bengal, Assam and Burma (and even in the Deccan, the Central Provinces and Bihar) it is often met with (on the plains) as a catch or garden crop, where it is exclusively used as a vegetable or fodder. Of the mountains of Assam, Manipur and Burma, it might be said that a climatic depression exists which admits of plants being grown two or three thousand feet below their normal habitats. Hence in these regions the grain-yielding buckwheat becomes an important article of food at altitudes even below 5,000 feet. In the higher reaches of its area buckwheat often becomes exceedingly important, more especially F. tataricum, which, following the spring barley or wheat, is sown in July and gives a supplementary crop before the early snowfall puts a stop to agricultural operations. It is frequently utilised as a first crop on new clearances, and in the most alpine tracts sheltered portions of the grassy slopes are utilised in giving a catch crop one year and left fallow for several succeeding years. It may also be grown on soils too poor for wheat and barley. It seems to succeed fairly well on rocky soils containing a high percentage of granitic detritus, but not on clay. Lawrence (Valley of Kashmir, 1895, 338) informs us that buckwheat (both species) can be grown late on almost any soil, and that in the higher villages F. tataricum constitutes almost the only food-grain of the people. In the lower valleys, he adds, irrigation is sometimes given. Mukerji urges the claims of buckwheat as a catch crop; it yields a return in ten weeks after sowing; it can be grown on poor soils and is able to withstand a greater extreme in heat and cold than can be said of any other known crop.

As a human food buckwheat does not hold a high place, since about 20 per cent. of the weight is lost in decortication. The nuts are husked and ground into flour, which is made into bread or eaten as porridge. The leaves and shoots are boiled as a spinach. For poultry and horses, however, the unhusked nuts are regarded as very superior, while the straw is more nutritious than that of cereal. F. tataricum, var. himalicae, is a better food than F. esculentum, as it is richer in oil and contains less indigestible fibre.

532
FERULA

Asafetida

FERULA, Linn.; Fl. Br. Ind., ii, 707-8; Aitchison, Trans. Linn. Soc. (2nd. ser.), iii, 67-9. A genus of umbelliferous herbs which contains some sixty species found in Europe, North Africa and Central Asia. They grow from perennial root stocks, and some attain annually a height of from 8 to 10 feet. They afford the various forms of Asafetida, Galbanum, Sambul, etc.

History. The silphion of the early Greek writers was an edible product derived very possibly from a species of Ferula, but was not asafetida as accepted in modern commerce. The laser (laserpitium) of later writers, on the other hand, was very possibly the medicinal drug of the present day. Though botanically quite distinct, the edible silphion is strongly suggestive of the edible hing of modern Indian commerce. [cf. Oersted, Silphium of the Ancients, in Journ. Bot., 1873, ii, n.s., 176-9.] Theophrastus (Hist. Pl., vi., ch. 3 (ed. Scaliger), 1644, 598-9) speaks of two varieties, one coming from the stem, the other from the root. Dioscorides mentions two kinds, one obtained from Cyrene, the other from Asia. Strabo contrasts the Asiatic gum with that known in Europe. Plautus (220 B.C.) makes frequent mention of laser, and Galen, Ætius, Oribasius and Paulus Ægineta all deal with its medicinal virtues. Celsus gives an interesting description, and Pliny bases his encomium on the account furnished by Dioscorides, but he lays special stress on the fact that silphion had disappeared and its place been taken by the much inferior laser of Persia. By Sanskrit medical authors the gum is hingu and the plant fatuka; by Arabic writers it is asa or hiltut, and by Persian angazan. But so far as can be learned there is no classic mention of the distinction between hing and hingu. References to the medicinal uses of the drug (hinga or hingu) will be found in The Bower Manuscript (5th century A.D.) (Hoernle, transl., 1893-7, 81, 85, 86, 180, etc.).

Myrepsicus was apparently the first writer who combined the Arab name asa with the descriptive word fetida, a new name, he tells us, used by the Italians. Ibn Sina (Avicenna), a Muhammadan, who lived in the 10th century, mentions two kinds of asa, viz. tyib (good) and muntin (fetid), while Ali Isakhri, who also lived about the same time, states that the drug was produced in the desert between Seistan and Makran. The geographer Edrisi, who wrote about the middle of the 12th century, says that asafetida was collected largely in Western Afghanistan. It is perhaps significant that Marco Polo, who marched (1290) through a great portion of the country where certain grades of this drug are produced, should make no reference to it. Garcia de Orta (1603, Coll., vi.; also Ball, Comment., Proc. Roy. Ir. Acad., 1889-91, 333) mentions that it was reported to reach India from Khorasan through Hormuz, but was also grown in Gujarat, and from Doly, a land bordering on Khorasan and Chimon. Acosta (Tract. de las Drogas, 1578, 362) gives many interesting particulars of the drug imported into India. Jacobus Bontius (Hist. Nat. et Med. Ind. Or., in Piso, Ind. Utr. re Nat. et Med., 1688, 41) relates that the plant from which asafetida is produced grows in Persia, between the States of Lara and Gamaron. Mandelslo (Travels, 1638, in Olearius, Hist. Muscovy, etc., 84) furnishes a similar account. Bontius also states that by the Javans and the Malays and other inhabitants of India it is called hing. Fryer (New Acc. E. Ind. and Pers., 1675, 239) intimates that asafetida is gathered at a place called Descoen, and says it differs from the stuff the Indians call hing, which comes from the province of Carmania.

No satisfactory account of the plant yielding asafetida was given till 1712 (Kemfiper, Aman. Eozo, 537 and pl.). Hove (Tours in Gujorat, etc., 1855, 133), who visited Bombay in 1767, describes the cakes flavoured with asafetida that he was given to eat. He also says there are two kinds—hing and hingu. Milburn (Or. Comm., 1813, i, 133) gives a description of the commercial drug of his day, and says it had been in use nearly 1,000 years. But he was in error when he supposed this to be the true asafetida plant. Aitchison, who travelled in Eastern Persia, Baluchistain and Afghanistan (with the Afghan Boundary Delimitation Commission of 1884-5) elucidated this obscure subject very largely.

533
He found the word *kema* generic, the asafetida plant being *anguza-kema*, and Ammoniacum *kandal-kema*. [Cf. Stapf, *Kew Bull.*, 1907, 375–88.] Commenting on this view, the authors of the *Pharmacographia Indica* (ii., 143) observe, “It would appear then that the kind of asafetida called *tyib* by the Arabs and their followers is the drug of European commerce, the product of *Ferula fetida*. *Regel*, and not that of *F. alliacea*, Boiss., which produces the *king of India.*” Holmes in the *Pharmaceutical Journal* (3rd ser., xix., 21–34, 41–4, 365–8), and the various Museum Catalogues of the Pharmaceutical Society of Great Britain, has afforded many useful particulars and focussed the practical results of recent research. A long account of the philology of the word “asafetida” is given by Prof. J. Attfield (*Yearbook of Pharmacy*, 1897, 351–6), who, after consulting Dr. Murray (editor of the *Oxford Dictionary*), had come to the conclusion that it should, both in English and Latin, be rendered “asafetida.” When discussing the *hing* and *hingra*, it seems probable that it would be more correct to assign these to groups of species rather than to say that they were each the product of one species. Indeed it would appear that the part of the plant from whence procured, the season of the year when collected, the methods of preparation and degrees and materials of adulteration, exercise considerable influence on the quality and flavour of the resulting drugs. It is, however, convenient to group the commercial resinous products of *Ferula* under three chief species:—

**F. alliacea**, Boiss.; Bentley and Trimen, *Med. Pl.*, 1880, ii., 126; Dymock, *Mat. Med. W. Ind.*, 1885, 381. In Khorasan it is called *angusheh*, in Kirman, *zendebjuk*, while it is also known by the following names—*hing*, *anjudán*, *vagári*, *abhushaharu* *hing*, *káyam*, *perun gayam*, *inuga*, *anguza*, etc. A herb which grows to a height of 2 to 4 feet. It is found wild (is not, at all events, cultivated) in Eastern Persia in the neighbourhood of Djendack and Yezd, and in Khorasan near Schardur, Nischapur, Meshed, Dehrachindian and Kerman. It prefers a stony, arid soil, and is found at an altitude of 7,000 feet. This plant is the chief source of the asafetida used in India and known as *hing* (which means pure or superior *hingra*), while that of European commerce is the product mostly of *F. foetida*—*hingra*.

Gum-resin. *Hing*.

This might be spoken of as the edible form. The *Gum-resin* is obtained by wounding the upper part of the root, from which a small quantity of a fine gum escapes and is collected. The living root is then sliced daily, or every two or three days, with the tiluxhahen adhesion, to its Kanausal. The whole mass, consisting of alternate layers of root and gum-resin, is then packed in a skin. As found in the market, the resin consists of a blackish-brown, brittle mass of extremely fetid odour, unadulterated with earth or gypsum, but always with slices of the root. In Bombay it is sometimes adulterated by the addition of gum-arabic, and the cheaper sorts contain an undue proportion of root. Adulteration with sliced potato also takes place.

The resinous mass contains an abundant essential oil which differs from that of *hingra* in having a reddish hue, a higher specific gravity, and a stronger rotatory power. An alcoholic tincture is not precipitated by acetate of lead, nor is the sulphuric-acid solution fluorescent. From earliest times the gum has been held in esteem by Eastern doctors. It is a carminative and antispasmodic, and taken daily is said to ward off malarial fever. It is also recommended as a vermifuge. [Cf. *Pharmacog. Ind.*, 1890, ii., 141–7; Ranny Lall Doy, *Indig. Drugs Ind.*, 1896, 127–8; Thorpe, *Dict. Appl. Chem.*, 1898, ii., 273.]

**F. foetida**, Regel; Drude, in Engler and Prantl, *Pflanzenfam.*, iii., 24; *Kew Mus. Guide*, 1907, No. 1, 115; *hingra*, *anguza-kema*, *kurnekema*, *khora-kema*, *vaghayani*, *hingu*, etc. A herb with a circular mass of foliage, springs annually from a perennial root stock. It grows in Southern Turkestan, Persia, and Afghanistan. This would appear to have been the Persian plant sent by Dr. Guthrie of Edinburgh, and grown in the Botanic Gardens there in 1780. [Cf. *Phil. Trans.*, 1785, lxxv., 36.]

**Gum-resin.**—This is the European drug of commerce, and is obtained from Laristan in Persia and from Herat in Afghanistan. It is collected in June,
the method pursued being briefly as follows:—The tap-roots are exposed for a couple of inches. A thick slice is cut from the top, from which a quantity of milk exudes. The root is then protected from the sun by a domed structure, 6 to 8 inches in height, called a khora, formed of twigs and clay and which has an opening towards the north. In five or six weeks' time a thick, gummy, reddish substance appears in irregular lumps on the exposed substance of the root. This is scraped off or removed along with a slice of the root, and placed in a leather bag. It was reported that the plants were sometimes operated upon more than once during the season. The gum is next carried to Herat, where it is deliberately adulterated. [Cf. Aitchison, Pharm. Journ. and Trans., Dec. 11, 1886.] Masson (Journ. Kalat, 1848, 451–3) speaks of the plant as flourishing in Seistan, the gum being collected as nushki. Bellew, in his account, says that after cutting the plant through, above the root, three or four incisions are made in the stump, and the operation of incision is repeated every three or four days, so long as sap continues to exude. A particular sort is mentioned by the same writer as being obtained solely from the node or leaf-bud in the centre of the newly sprouting plant. This kind is never adulterated, and may be the fine quality of the drug known as Khandahari-hing (Pharmacog. Ind., ii., 151). The common form is much adulterated by a kind of red clay (tawak), by wheat or barley flour, and by powdered gypsum. It is also mixed with slices of the root. All species of the drug have a powerful, garlicky odour, and a bitter acrid taste. Except Khandahari-hing, this variety of asafetida is not used in India.

Maynard and Prain, on the Botany of Baluch-Afghan Boundary Commission of 1896 (Rec. Bot. Surv. Ind., i., 130–1), furnish interesting details of the collections of the commercial article on the hills between Samuli and Robat. Asafetida, they observe, affects bare rocky hill-sides. It is the plant, or at least one of the plants, that people from Kandahar yearly visit the Koh-i-Sultan to collect. Sir Arthur H. McMahon described the collection of the gum from personal observation. The heads are cut down to within one or two inches of the ground. The cut ends are then covered with a little dry earth in order, the collectors say, to keep the wind off. After twenty hours the people collect what has exuded and cut the stalk down another eighth of an inch. But the milk is not allowed to dry in the sun; to obviate this the collectors build small stone tramps, open at one side, over each plant, in order to keep off the sun's rays. The juice when partly dried is mixed with some kind of earth, like fuller's-earth; this is merely to increase the weight, and not with any idea of improving the quality. Doubtless the precautions taken to prevent drying are mainly with a view to facilitate this subsequent adulteration.

Asafetida consists of resin, gum and essential oil in varying proportions, but the resin generally amounts to more than one-half. It is partly soluble in either or chloroform. The oil may be separated by distillation. It is light-yellow, with a pungent odour, and if exposed to the air evolves sulphuretted hydrogen. An alcoholic tincture of the drug is precipitated by acetate of lead, and a solution in sulphuric acid is fluorescent. Medicinally it is used in Europe as an antispasmodic and stimulant (see Vinegar, p. 1110). According to Bellew, Masson and Aitchison, the Natives of Bokhara employ the leaves as a green vegetable, while the white underpart of the stem of the full-grown plant is considered a delicacy when roasted and flavoured with salt and butter. [Cf. Borszczow, Ferulaceae, 1860, 3–26; Pharmacog. Ind., 1890, ii., 147–52; Gard. Chron., 1896, 330–1; Thorpe, Diet. Appl. Chem., 1898, ii., 273; Dutt, Mat. Med. Hind., 1900, 175–6; White and Humphrey, Pharmacog., 1904, 82–3; Tschirch, Die Harze und die Harzbather, 1906, i., 360–76.]

**F. galbaniflua, Boiss. & Buhse.**—This is the chief source of the drug known as Galbanum; bireja, ganda-birozo, bodra-kéma, barzed. It is a native of Persia (especially Shiraz and Kirman), from which the gum is imported into Bombay and re-exported to Egypt and Turkey. Around Gilan it is reported to be specially common.

**Gum-resin.**—There are three kinds known in commerce: Levant, Persian, Solid, and Persian Liquid. The first comes from Shiraz, and is known as khasenib; the second has an odour of turpentine, and the third is the gao-shir or jawdishir. As met with in India, gao (jao)-shir is a yellow or greenish semi-fluid resin, generally mixed with the stems, flowers and fruits of the plant. It is obtained from the

Banyan Tree.

A genus of trees, shrubs or climbers, sometimes epiphytic, which contains about 600 species. Most are tropical, and, according to Hooker, 112 are Indian. They have a milky sap which contains caoutchouc, and F. elastica is one of the chief sources of the India-rubber of commerce.

Trade in Asafetida.—The following figures are returned as the Trans-frontier imports of asafetida into British India from Afghanistan, Seistan, etc., for the years 1902-7:—1902-3, 1,368 cwt., Rs. 1,73,760; 1903-4, 2,055 cwt., Rs. 2,63,891; 1904-5, 2,036 cwt., Rs. 2,58,762; 1905-6, 1,106 cwt., Rs. 1,38,901; 1906-7, 1,820 cwt., Rs. 1,59,873. During the years 1903-4 the imports by sea were 13,343 cwt., valued at Rs. 4,89,538; and in 1906-7, 6,062 cwt., valued at Rs. 2,42,635. Practically the whole of the foreign imports came from Persia and went to Bombay. The exports are returned both as foreign re-exports and as Indian produce. The latter of course means asafetida brought to India by land routes. Of the foreign produce, 1,612 cwt. were exported in 1903-4, valued at Rs. 53,440; and 1,250 cwt., valued at Rs. 30,758, in 1906-7. Practically the whole went from Bombay. Of the so-called Indian produce, 332 cwt., valued at Rs. 13,548, were exported in 1903-4, but sank to 51 cwt., valued at Rs. 2,043, in 1906-7. The export figures should, however, be regarded as having reference to hingra, while the returns of imports are both hingra and hing. [Cf. Brit. and Colon. Drugg., 1905, xlvi., 96, 120, 479, 504.]
THE EDIBLE FIG

Banyan Tree, bor, bar, bargat, but, bai, ranked, kangji, barelli, wora, kurku, bangat, phagvari, vour, wad, ala, mari, ahlada, gilike mara, peralu, pyinyoung, maka-nuga, vata, etc. A large tree which throws down numerous aerial roots from the branches. It is found in the Sub-Himalayan forests from Peshawar to Assam; in the deciduous forests of Bihar, Chota Nagpur, Orissa, Circars, Central Provinces, Bombay Presidency and South India; less commonly in evergreen forests and in the low country of Ceylon. It is wild, but doubtfully indigenous, and is also largely planted throughout India for its shade. Indian Gardening gives an account of the famous specimen in the Botanic Gardens, Calcutta; described also by Sir George King (1895) in the Guide to these Gardens.

It yields an inferior RUBBER. According to Hooper (Rept. Labor. Ind. Mus. (Indust. Soc.), 1905-6, 25), the latex contains only 12-1 per cent. of caoutchouc and 82-2 per cent. resin. Is employed in Lahore in the oxidation of copper. As a MEDICINE the juice is applied externally for pains and bruises, and used as an anodyne in rheumatism. An infusion of the bark is regarded as a powerful tonic in the treatment of diabetes. The leaves are heated and used as a poultice. The fruits ripen from March to June, according to locality, and are eaten in times of famine; it would moreover appear, in addition, that in many parts of the country the young tender shoots and leaves, as also the bark, are eaten. [Agri. Ledg., 1904, No. 4.] The twigs and leaves are grazed as FODDER by cattle and elephants. The WOOD is of little value, but is durable under water and, therefore, utilised for well-curbs. If carefully cut and seasoned it can be made into furniture, and is sometimes employed for boxes and door-panels. The wood of the aerial roots is used for tent-poles, cart-yokes and banygy-poles. The banyan is one of the numerous hosts of the LAC insect. By the Hindus it is regarded as sacred, and plays a great part in connection with their religious ceremonies. [Cf. Pliny (Holland, transl.), i., 300; Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), ii., 53-8; Pyrard, Voy. E. Ind., etc., 1601 (ed. Hakl. Soc.), ii., 370, etc.; Tavernier, Travels Ind. (ed. Ball), ii., 198; Fryer, New Acc. E. Ind. and Pers., 1672-81, 105; Buchanan-Hamilton, Stat. Acc. Dinaj., 163-4; Hobson-Johnson (ed. Crooke), 65-7; Pharmacog. Ind., 1893, iii., 338; Yearbook of Pharmacy, 1899, 466-7; Agri. Ledg., 1901, No. 9, 212, 235, 263; 1902, No. 1, 53; Joret, Les Pl. dans L'Antiq., etc., 1904, ii., 291-2; Workman, Through Town and Jungle, 1904, 39-40; Dunstan, Imp. Inst. Tech. Repts. (on latices of F. comosa and F. indica), July 13, 1905; Cunningham, Plagues and Pleasures of Life in Beng., 1907, 55-86, 339, 359-60.]

**F. Carica, Linn.; Rec. Bot. Surv. Ind., i., 136; Woodrow, Gard. in Ind., 1899, 451-3; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 211-3.** This species is the Edible Fig of Europe, the Smyrna Fig, also anjir, kimri, fagu, fagari, shimai-atti, tihdie, ten. Several varieties are cultivated in many parts of India, especially in Baluchistan, Afghanistan and Kashmir.

A rich and mouldy soil is required with a considerable quantity of lime combined with thorough drainage. The trees are propagated by cuttings, of one-year-old wood, planted in shady beds in February. There should be about 10 to 12 feet between each root. As a fertiliser about 50 lb. of well-decayed village sweepings may be applied to each tree after the crop is gathered. The plant begins to bear FRUIT in the second or third year after transplantation and continues for twelve to fifteen years. It fruits twice a year. The first season commences in June-July, but it is not allowed to ripen lest it should injure the second crop, which commences in January and is by far the most valuable. Figs for drying should be cut from the tree and carefully placed in trays and boxes. To improve the colour and soften the skin, the figs, before drying, are sometimes exposed to the fumes of burning sulphur or are dipped in a hot solution of salt, saltpetre or lye; but the former practice gives the fruit a very unpleasant taste and is injurious to the health of the consumer. The drying ground should be a clean space outside the orchard where the figs may be exposed to the full rays of the sun. The figs should be turned twice a day at first, and once a day in the later stages. Drying within six or seven days yields the best quality. **So far as India...**
is concerned it would appear that the most approved variety is that found at the village of Khed Shivapur, 14 miles south of Poona at an altitude of about 2,200 feet, but the fruit of Baluchistan, Afghanistan and Persia is superior to the Indian. As a medicine, the dried fruit is demulcent, emollient, nutritive and laxative. [Cf. Pharmacog. Ind., 1893, iii., 342-5; Eison, Handling and Curing of Figs, [Ind. Agri., Nov. 1, 1897, 348; April 1897, 128; Feb. 1, 1898, 57; Dutt, Mat. Med. Hind., 1900, 291; Repis. Agri. Exp. Stat. California, 1894, 1896-8, 1900, 1903-4; Cyprus Journ, 1905, ii., 76.]

F. Cunia, Ham.; Rec. Bot. Surv. Ind., ii., 65, 139; iii., 103; Agri. Ledg., 1904, No. 4, 27-8. The khewna, dumbur, ri, kanchya, sangji kanai, poroh, ye-kha-ong, jonua, etc. A moderate-sized tree of the Sub-Himalayan tract from the Chenab eastwards ascending to 4,000 feet, Bengal, Orissa, the Circars and Burma, usually on the banks of streams or in ravines. LAC is produced on this tree. A fibre is obtained from the bark which is used for tying the rafters of Native houses. The fruit ripens about July to October and is eaten in India, though somewhat insipid. The wood is not used economically. The leaves are rough and sometimes employed in place of sandpaper.

F. elastica, Roxb.; see India-rubber (pp. 651-5).

F. glomerata, Roxb.; Rec. Bot. Surv. Ind., ii., 139, 188; iii., 103. The gulp, aroa tue, jaqya dumur, dumer, lowa, dimeri, tchomtay, thoja, panva, krumbal, babar, dadhuri, kim, umbar, ronudi, atti, moydi, kullakith, yetha-pan, udumbara, etc. A large tree noticeable from its being deciduous in the middle of the rainy season. It is found on the Salt Range, the outer Himalaya and Sub-Himalayan tract from Kashmir eastwards; in Assam, on the Khasia hills and in Bengal; in Burma, Central, Western and Southern India, and in Ceylon.

It produces a viscid Gum which is made into birdlime; Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1906-7, 6) mentions that the latex contains only 4-9 per cent. caoutchouc and 94-0 per cent. resin. It bears large fruits in profusion, which ripen all the year round, are eaten both ripe and unripe, and are considered a useful famine Food, being ground to a powder and mixed with flour. The leaves are used for cattle and elephant fodder. The Wood is not durable, but is utilised for well-frames and for rough purposes, such as outhouse doors and cross-pieces for carts. [Cf. Pharmacog. Ind., 1893, iii., 338-42; Duncan, Dyes and Dyeing, Assam, 1896, 25; Innes, Jungle Prod., 1897, 8, 11; Dutt, Mat. Med. Hind., 1900, 321; Agri. Ledg., 1902, No. 1, 53; 1904, No. 4, 28-30.]

F. infectoria, Roxb.; Rec. Bot. Surv. Ind., i., 94; ii., 138, 188, 340, etc. The gulpan, ramani, pakri, kam, pakar, baswesa, prab, sajat kobra, kangji, pepere, serilli, war, babar, jangli pipi, trimbal, bassari, jovi, tsjaka, nyaunggyin, kalaha, plaksha, etc. A large (at first often epiphytic) tree found in the Sub-Himalayan tract from the Salt Range to Sikkim, and thence throughout India, Burma and Ceylon. It is more commonly planted than wild. There are in India three varieties.

The bark is said to yield a fair Fibre. The bark is one of the five known as panchavalkala, or the five barks. The young shoots are eaten by the Natives, and the leaves make good elephant and cattle fodder. The Wood is sometimes used for charcoal, but not otherwise. [Cf. Dutt, Mat. Med. Hind., 1900, 235; Innes, Jungle Prod., 1897, 9.]

F. religiosa, Linn.; Cameron, For. Trees Mysoare and Coorg, 1894, 283-4; Rec. Bot. Surv. Ind., i., 70, 89, 185, 209, etc.; Ind. Gard., March 1899, 87; Woodrow, Gard. in Ind., 1899, 453. Known as the pipal or peepul, the asvattha of the classics, and by the following, among many other vernacular names:—pipal, asvatha, asvat, hesar, jari, mor-bur, al, arasa, rai, rati, basri, haspath, nyaung-baudi, bo, etc. A large tree (usually starting as an epiphytic) without aerial roots. It is found in the Sub-Himalayan forests from the Panjab eastwards; Bengal, Orissa.
and the Circars; Central India and Upper Burmania. Is extensively cultivated and held sacred both by Hindus and Buddhists.

The bark yields a tenacious milky juice, which hardens into a substance resembling caoutchouc. Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1905–6, 25) mentions that a sample examined by him contained only 12.5 per cent. caoutchouc and 84.8 per cent. resin. The stem has also been stated to afford a resinous gum, used as sealing-wax and employed by artificers to fill up the cavities of hollow ornaments. In the Ahmedabad Gazetter (iv., 24) it is said to give a wax which is used in staining ivory red, but as this tree is one of the chief sources of lac, this gum may simply be the excretion of the lac insect and not a gum at all. Among the Santals the milky sap is known as lorôt. A birdlime is prepared from it, called shelin in the Deccan. From the bark a fibre is extracted, which was formerly made into paper in Burma and employed in the manufacture of the umbrellas of that province. The bark is a useful tan and yields in boiling water a dye of a faint reddish-fawn colour. With other barks it is converted into a black dye, while the root boiled in water with alum gives a pale pink on cotton cloth. The leaves, bark and fruit are all used in Nativo Medicine. The small figs as also the bark are used as famine foods, and the twigs and leaves as elephant and cattle fodder. The wood is utilised for packing-cases and for fuel, occasionally also for charcoal. [Cf. The Bower Manuscript (Hoernic, transl.), 1893–7, 186; Duncan, Dyes and Dyeing, Assam, 1896, 25; Innes, Jungle Prod., 1897–9; Agri. Leag., 1902, No. 1, 53; 1904, No. 4, 31; Joret, Les Pl. dans l‘Antiq., etc., 1904, ii., 293–4.]

FISHERIES OF INDIA.—Day, Fa. Br. Ind. (Fish, 2 vols.); Pisces. The information available regarding the Fish and Fisheries and the associated industries of India is very extensive and varied. The space available here may perhaps accordingly be best utilised by furnishing as complete an enumeration of the more valuable works, reports and magazine articles as possible. This may be referred to (1) a citation of general publications, then followed by (2) a series assorted provincially:

FISHERIES OF INDIA

PRODUCTION.

Bengal.

Experts.

Calcutta.

Supply.

Tank Fish.

Upper India.

Poor Supply.

The following are some of the chief commercial headings under which particulars regarding fish and fish products may be found in this work:—Béche-de-Mer (p. 122); Fish and Fisheries (the present article); Fish-maws and Shark-fins (p. 542); Isinglass and Glue (pp. 542–3, 695); Oils and Fats—Animal (pp. 811–4).

Other kindred subjects are:—Pearls and Pearl Fisheries (p. 557); Shells: Conch, Chank, Mother-of-Pearl, etc. (pp. 558, 989).

If may be said that while the products afforded by fish are many and varied, the information available regarding them is fragmentary and unsatisfactory. The majority of fish are of course cooked and eaten either fresh or after being salted, sun-dried, smoked, pickled, preserved in oil, etc., etc. But unfortunately it is next to impossible to learn actual particulars of the fisheries and fish-curing industries that could be regarded as of a practical and commercial value. Much has been published, but either of a purely scientific character or of a most discursive nature.

PRODUCTION.—Bengal.—In the trade returns of Bengal, for example, repeated mention is made of exports in dried fish and prawns. It is also known that a fair business is done in smoked, pickled or otherwise preserved mango-fish, hilsa (sable), and begti (cock-up), the last mentioned being often prepared in the form known as "tamarind-fish," but nothing for certain is known of the sources of supply or the centres of manufacture in Bengal or even in Calcutta. It is recorded that Calcutta obtains fish from Goalundo, from East Bengal, from Diamond Harbour, from Mutta and other localities in South Bengal. Moreover, though repeated efforts have been made (and indeed are being made) to organise a systematic supply of sea-fish, the Calcutta market is almost exclusively met by fresh-water fish. The supply of excellent begti, procured both direct from the rivers or from special rearing-tanks, is very great and the quality excellent. During their respective seasons both mango-fish and hilsa are plentiful, the latter caught very largely in the Ganges and conveyed by special fish trains to Calcutta. Tank-reared fish may be spoken of as an important feature of the Bengalsupply. The sale of live fry for the purpose of annually stocking tanks is accordingly a fairly important special industry. The fry are caught on the surface of the shallow water near sandbanks in the rivers, and are carried inland in earthen pots to be sold to the owners of rearing-tanks.

Upper India may be spoken of as entirely dependent on its rivers for its supply of fish. At one time a great effort was made to convey sea-fish from Karachi as far inland as Simla, but the venture was evidently not profitable as it was discontinued. The military stations of the Panjab, however, do in some cases get fresh sea-fish from Karachi. Near the larger rivers the towns such as Lahore, Delhi, Agra,
PROVINCIAL SUPPLIES

Allahabad, etc., obtain a fair supply at certain seasons, but fish is by no means the important article of diet in Upper India that it is in the western, southern and eastern provinces. In Assam excellent river-fish may be had, one of the most highly prized being the *bassa*, which when smoked is an excellent addition to the breakfast table, and by some the King-fish—*Semiplotus muceellandi* (Day, *l.c.*, i., 281)—or *sundari* is even more highly prized.

Bombay and Sind.—The trade returns of Bombay frequently make mention of *bummele* ("Bombay duck"), "tamarind-fish" of various qualities, such as *seir* (white-pomfret)—the best quality. Bombay has an excellent supply of sea-fish, and accordingly fresh-water fish are nearly as rare in the western capital as sea-fish are in the eastern. Calcutta visitors to Bombay accordingly much appreciate the pomfret and sole they receive there, just as the Bombay visitors extol the Calcutta *beity* and mango-fish. Bombay oysters have, as a rule, an evil reputation among Europeans, but all the same there exist extensive beds for their production and a by no means unimportant traffic in that shell-fish. The exports to China of Shark-fins and Fish-maws (see p. 549) are by far the most important single item in the Bombay foreign trade in fish. Karachi holds, however, an even more important position in the fish trade of Western India than Bombay. The oysters of Karachi are regarded as the best in all India. The pomfret, sole and other fish procured in Karachi are excellent, and of a flavour only to be compared with those in the extreme south, such as at Cochin and Calicut. A large trade is at the same time done in shark-fins and fish-maws from Karachi, as also in Isinglass and Fish-oil (p. 545). The Persian Gulf traffic in salted and sun-dried fish is very ancient. Marco Polo (Travels, 1290 (ed Yule), i., 102, also n. 109) alludes to the people of Hormuz living on dates and salt fish. Date and dry-fish diet is alluded to also by Ibn Batuta.

Madras.—This is perhaps the most important province in the fish trade of India. From ancient historic times the sun-dried, salted and pickled fish of the southern Malabar Coast have not only permeated over a large part of India but been carried to foreign countries. Difficulties in the Indian fiscal regulations with salt have for some years been loudly proclaimed as having restricted if not curtailed that industry, and the subject has received (and is receiving) the most careful consideration not only of the local but of the Imperial Government. The tamarind-fish of Cochin is chiefly made from the *seir*, and the fish-oil—so much extolled over India—is made mainly from the sardine (see Oils, pp. 544–5). Under *Bèche-de-Mer* (pp. 122–3) reference has been made to the Madras traffic in sea-slugs. Oysters are specially cultivated at several centres, and the supply is both large and excellent. South India has thus a liberal stock of most admirable sea-fish (pomfret, sole, sardine, etc.) of all kinds, and in the vicinity of its large rivers a supplementary supply of fresh-water fish. Important fisheries exist, as well as valuable industries in Pearls, Conch, Chank and Mother-of-Pearl (see p. 557).

Burma.—Speaking of Further India, the trade returns show a considerable traffic in locally produced sea-slugs, as also in foreign slugs imported and to a certain extent again re-exported. There are also valuable local fisheries and fish-curing centres in Burma. The salting and preserving of fish have in fact assumed special forms more or less characteristic. The *Gazetteer of Upper Burma and the Shan States* (ii., pt. i., 433)
FISHERIES OF INDIA

FISH

Bombay Duck

gives, for example, a useful sketch of the fisheries and trade in fish on the Irrawaddy.

CHIEF INDIAN FISH AND FISHERIES.—The following are some of the more important aspects of the fish supply of India, of fish products, and of the special preparation of fish, met with in Indian commerce:

1. "BOMBAY DUCK" OR BUMMELO FISH.—This is the fish—Harpaon neheurus (Day, l.c. i., 412), known in the vernacular as nehara, bumalo, cucah sawahri, coco mottah, luli, etc. It is common in the seas and estuaries of India, more especially Bombay. It is highly esteemed as food when eaten immediately after being caught. Since it rapidly goes bad, it is at once salted and subsequently sun-dried, and in that condition alone is known to most people. It is the relish served with curries that bears the name "Bombay Duck"—a quaint and obscure name that has an analogy in "Digby chicks." Boswell (Tour to the Hebrides, 1773) compares the Bombay ducks to the sun-dried whittings of Aberdeen, known as "Spoldings."

River-fish.

2. FRESH-WATER FISH.—It would occupy much space to mention all the fish of this class that might be regarded as worthy of interest. A special feature of Indian rural life, and one that is capable of considerable improvement, is the rearing of fish in tanks, an industry already briefly alluded to. Tanks are necessities of life in large tracts of country in order to supply water, and that they are utilised as sources of edible fish is not only natural and economical but essential to the purity of the water. A large number of the Indian fresh-water fish naturally frequent backwaters of the rivers; in other words, they are not adverse to live in tanks. This has led to the traffic already mentioned of catching and selling live fry with which to stock tanks that are even remote from the rivers. The following are some of the better known river-fish, many of which can be reared in tanks:—Ammus scundens (Day, l.c. ii., 367), the Climbing Fish or cot, semnal, nga-pri, hardian, etc.; these are often carried alive by the boatmen of the Ganges, being killed and cooked as required. They may be kept alive for a long time in damp earthen pots and thus conveyed to a distance. Barbus, the Carp: various species, especially B. sarana (Day, l.c. i., 300), the sarana or durhie, and B. tor (l.c. i., 307), the mahasir; most highly prized of sport-giving fish and found in hill streams. Barilius bota (l.c. i., 352), the trout of Indian streams. Catla buchanani (l.c. i., 287), largely employed for stocking tanks in Bengal, United Provinces and Panjāb. Clupea ilisha (l.c. i., 376), the sable or ilisha, a sea-fish that passes up most of the rivers of India and Burma, and is one of the most important of the fresh-water fishes. Nematopsethys eel (l.c. i., 128), the bassa of Assam, is found in most of the larger rivers of India. Labeo (l.c. i., 256), the Kalban fish: several species are common in the rivers and much used for stocking tanks, such as L. calbasu (l.c. i., 259), Panjāb, Sind, Kach, Dacca, etc., L. goinii (l.c. i., 261), the cura, much used in the United Provinces, Bengal, Orissa, Ganjam and Kistna. L. rohita (l.c. i., 262), the ruhu or ru, an excellent fish, and accordingly carefully propagated in the tanks of Bengal. Ophicephalus (l.c. i., 360): several species of the so-called Walking Fish or Murray, such as O. haria (l.c. ii., 361); may be carried in damp vessels for great distances, sold alive, and cooked as required. O. megalops (l.c. ii., 360) and O. striatus (l.c. ii., 363) are excellent for stocking tanks. Pseudentropius laukree (l.c. i., 138), Poona and Dacca. Ritu buchanani (l.c. i., 165), found in the Jumna, Ganges and Irrawaddy, is valuable for its capability of retaining life long subsequent to the removal from water.

Shark-fins.

3. FISH-MAWS AND SHARK-FINS: ISINGLASS.—The trade in these articles is a fairly ancient one. Milburn (Or. Comm., 1813, i., 109, 283) makes reference to them. "Fish-maws," he says, "are an article of trade from various parts of China, where they are much esteemed." So again, "Shark-fins are an article of trade from the Arabian and Persian Gulfs and from thence to China; they are esteemed very strengthening by the Chinese." "They are likewise prepared on the Malabar and Coromandel Coasts and many of the islands in the Indian Ocean. In some of the commercial products given as the title of this paragraph are not, however, the only products afforded by the group of fish placed in this position. The flesh (especially of the young) is often valued as an article of food; the fins are employed in making jellies and soups, mainly by the Chinese; the livers afford an oil, which when carefully prepared (more especially of certain species) is spoken of as a useful substitute for cod-liver oil; and the skin of most species is made into the substance known as Shagreen. The group of fish here indicated might be

Oil.

Shagreen.
SHARK-FINS

defined as the Sharks, Ray-fish, Skates and Saw-fish. On the other hand, fish-maw, which in a purified form is known under the name of isinglass (or, to be more accurate, fish isinglass) is a substance usually obtained from a widely divergent assemblage of fish. It is simply the "sound" or "air-bladder" and might be prepared from almost any fish, though certain species are more highly valued than others. It may accordingly be desirable to refer these to two sections:

(a) Shark-fins.—Day (l.c. i., 3) wrote, "These fish are employed as food, and portions of them, especially the fins, are largely exported from the Indian to the Chinese markets. In China Dr. Cantor observed that the fins were not exclusively selected from the sharks—Selachioidei—but equally from the rays—Holocephali. Among those examined at Penang were found to be fins taken from the fishes belonging to the following genera:—Caranxius, Zygorn,Lagiostoma, Pristis, Rhinobatis, Trygon and Myliobatis. Gelatine is obtained from the larger fins, glue from the smaller. All except the caudal fins are cut from the fish at the root, so as to leave as little flesh as possible. The root is dipped into wetted lime (chunam) and then the fins are dried in the sun, and according to their value they are divided into two kinds: "white" and "black." The white consists exclusively of the dorsal fins, which are on both sides of a uniform light colour, and are expected to yield more gelatine than the other fins. The pectoral, ventral and anal fins pass under the denomination of "black fins"; the colour, however, varies from buff to grey or brown, and most of them are of two different colours, the upper surface being dark and the lower light. The black fins of course are the most numerous, and supposed to yield a comparatively small quantity of gelatine." In another passage Day (l.c. i., 5) remarks:—"The fins of the sharks are removed and dried in the sun. Strips of the flesh are also salted as food and the livers boiled down for the oil they contain." "Some forms of large sharks, as Galeocerdo, which have the edges of their broad teeth sharp or coarsely serrated, cannot be captured by nets, as they at once cut their way out. But nets are suitable for such species as possess conical teeth; these last may likewise be taken by baited hooks to cords composed of many strands, through which the teeth penetrate but do not cut." A curious circumstance regarding the special nets used on the coast of Karachin. Fish-maws are found there, and it is a matter of course that the people of Karachin may be here mentioned, namely that they are made very largely of the fibre derived from Ctenopus procera (see p. 208), a fibre hardly utilised in any other part of India; but the place of which is taken in Eastern India by rhea fibre (see p. 157), both fibres being selected on account of their great strength and durability under water.

The following are the chief Indian fish that afford "Shark-fins":—Tetoubatis narinari (Day, l.c. i., 59), the Devil Fish; Hapalurus guarellus (l.c. i., 194), the fresh-water shark, the bönch or gunch; Caranxius acutidens (l.c. i., 11), a shark of the coast of Sind and the Indian Ocean; C. ganselius (l.c. i., 13), one of the most ferocious of Indian sharks; C. imbatus (l.c. i., 17); C. menisnortes (l.c. i., 14), canali sorrah or raman sorrah; and C. menisnortes (l.c. i., 14); Pristis canipidatus (l.c. i., 37), the Saw-fish; Pieroplatea mira (l.c. i., 50); Rhynchochus angustolobatus (l.c. i., 41), the Mud-skate; R. rjuddensis (l.c. i., 40), the ulawi or ranja; Trygon septem (l.c. i., 50), the Ray; T. marnah (l.c. i., 53), the sanan, hankus; and Zygorn matiles (l.c. i., 22), the Hammer-headed Shark.

(b) Fish-maws and Isinglass (see Isinglass, p. 635).—Vulgarly the term isinglass is sometimes given to Mica. The English word is a corruption of the Dutch huisenblaas (=sturgeon-bladder). It may be obtained from many substances, and according to the Greeks it was ichtyocolla or fish-glue. As already explained, the finer qualities are the "sounds" or "air-bladders" of fish. The true isinglass of European commerce is the sound of the sturgeon (Acipenser), Brazilian isinglass is derived from one or two species of Silurus, and the Indian isinglass from one or other of the following fishes:—Aristmucor, brevianum, cervus, falcatus, faliparius, gogour, sona, and sugor (Day, l.c. i., 173-38). These are largely prepared and salted on the Western Coast (Karachi), but at the mouths of the Ganges there is also a fair and improving trade:—Ostegenousus militaris (l.c. i., 190); Otolithus maculatus (l.c. ii., 127), the burlali of Orissa; O. ruber (l.c. ii., 128), the jarang-gigi (or pééperpierre) of Pondicherry; Pristipoa guarea (l.c. i., 512), the gourds; Serranias crassentus (l.c. i., 449), the damos; Scomber scombrus (l.c. i., 145); and the Umbra lycosstris (l.c. i., 110)."—Roylo, Prod. Isinglass; Day, l.c. (Fish) i., 3, 5, 7-63; Hunter, Indian Gaz., iii., 494.)

4. FISH MANURE.—When procured in excess of demand for human food, large Manures.

543
quantities of fish are utilised as manure near the coast towns of India, very much as in some parts of Europe. Thurston (Bull. Mad. Mus., 1900, No. 2, 120-3) gives much information on the extent to which the sardine is employed as manure, the supply ranging from 2 to 515 tons a year. Fish manure is not unknown to the coffee planters, and Mollison says that for sugar-cane culture this manure is much valued. The Malayans consider the fish *Kathema uncinate* (L.c. ii., 214) as specially suitable as a manure for fruit trees. [Cf. Simmonds, Waste Prod., etc, 155-77; Lehmann, Rept. Agr. Cult. Chem. Mysore, 1901-2, 14; Mollison, Textbook Ind. Agr., i., 107-8.]

### 5. MEDICINE.

The bile of certain species of fish is believed to be a valuable medicine, especially that of the *ruhu or rui* (*Kabero voitiu*). [Cf. Taleef Shereef, (Playfair, transl.), 1833, 150.] The brine of pickled fish is alluded to by Paulus Egineta (Adams, transl., iii., 81.). Fish diet is by the Hindus considered safer for invalids than the flesh of other animals. The oil prepared from many species is used as an efficient substitute for cod-liver oil.

### 6. NGAPEE (*Ngapi*).

In an official report issued in 1902 (though not offered for sale) by the Government of Burma on the Inland and Sea Fisheries, reference is made to the account of this preparation as given in the Dictionary. The passage in question was reprinted direct from the description of Tenasserim, written by H. Fenwick in 1849—presumably an authority on Burmese matters of the date in question. The recent official publication enumerates and describes some eighteen different forms of *ngapi*, the particulars given occupying five pages of closely printed footslop. It concludes by asking the question, "Why does *ngapi* smell, it will be asked? Because, however carefully the stuff is made, there must be always a considerable proportion of uncured flesh, flesh that the salt cannot reach. This flesh decays and rots, but the rest is properly cured fish."

To many persons preserved fish in any form is objectionable. The danger of eating a proportion of rotten uncured flesh, however small, may be suggestive of poisons. It is sometimes dictated the apppellative "semi-putrid fish" used by Fenwick. The following passage from Nisbet (i.e. i., 361) fairly represents all that is known regarding the preparation of *ngapi*. "Immediately after being caught and brought to land the fish are either scaled by hand or have the scales roughly brushed off with a frayed bamboo, and are then thrown into a wooden trough, the larger being gutted and deprived of head and fins. After being rubbed with salt they are packed in baskets and pressed down by means of a board weighted with large stones. Next morning they are unpacked and again rubbed with salt, then spread out on thin bamboo mats to dry in the sun until the afternoon of the following day, when they are packed alternately with layers of coarse salt in large earthenware jars placed in the shade. To retard the process of liquefaction of the salt, the powdered bark of the ondon tree (*Litsa sebifera*) is mixed with it; but, during the three to five weeks this rough method of pickling is allowed to continue, the oily brine oozing to the top and eventually becomes so full of maggots before drying up that fresh supplies of salt have to be added. The scaleless siluroid mud-fishes are those most easily treated in this way."

"Greater care is taken in the preparation of *ngathalauk* (*Clupea paciaria*), the hilsa of Indian rivers, which are simply gutted but not otherwise cleaned, and then salted and sun-dried before being spread between thin bamboo mats and pressed for about three days. These dried fish (*ngachauk*), the daintiest of Burmese condiments, are both in preparation and in transport handled separately, whereas the stinkingly offensive *ngapi* is sold in bulk, in baskets and sacks. Both varieties are cooked by roasting or frying when used to flavour the meal of boiled rice."

"Along the Tavoy and Mergui coast a finer quality of fish-paste is made with shrimps and prawns, which are worked up with salt when half-dried in the sun. As this is eaten uncured, it is termed seinsar or 'raw food.' The more carefully prepared paste, made with selected small prawns, is frequently used with curry and rice as a chutney by Europeans all along the Malay coast, where it is known as *balachong*; and of recent years it has competed with caviare as a bonne bouche in the boulevard restaurants of Paris." [Cf. Mandelslo, Travels, 1639, in Olearius, Hist. Muscovey, etc., 121; Synnes, Emb. to Ava, 1795, ii., 371; Crawford, Journ. to Ava, 1834, ii., 176; Gaz. Upper Burma and Shan States, ii., pt. i. 433.]

### 7. FISH-OIL

May be referred to two sections:

1. **Shark, Ray and Skate Oils.**—These are sometimes treated separately or mixed (as procured). In the former case an oil is often prepared from some of the
SARDINE OIL

Liver Oils.

FISH OIL

species that might be used as a substitute for cod-liver oil. Thus, for example, Day (l.c.i., 5) says: 'At Calicut, medicinal fish-liver oil of an excellent quality was formerly manufactured, a small factory for this purpose having been constructed at that station in 1854, and the livers of sharks and saw-fishes were purchased from the fishermen. The abundance or paucity of these fishes evidently depended to a very great extent upon whether sardines were or were not present, for these latter forms of Clupeidae are very capricious, sometimes forsaking the coast for several successive years, and then as suddenly reappearing in countless millions. No livers under 40 lb. weight were accepted at the factory, as the larger ones gave proportionally a greater amount of oil than the smaller ones; sometimes livers of a great size were purchased. One weighed 290 lb. and another from a female saw-fish, 14 feet long, 185 lb.' The fish included in this paragraph have been enumerated under Fish-maws and Shark-fins above.

(b) Other Fish-oils.—The livers, or the whole fish, of certain species that do not belong to the above group are known to afford excellent oils. These are mainly used for illuminating purposes, but some are of superior quality and may be even employed as articles of food. Such oils appear to be made of saltwater fish, all along the coast of India, and from fresh-water species, along the channels of the chief rivers. The following are the fish most highly spoken of as affording oil:—Harpalus chola (l.c. i., 317), the Bitter Carp of the rivers of India; Clupea Ignumia (l.c. i., 373), the Sardine; C. Hilsa (l.c. i., 376), the Sable or Hilsa; C. longiceps (l.c. i., 373), the Malabar Oil Sardine; Cybium caumenssooii (l.c. ii., 211), the Seer or konam; Lubio rohita (l.c. i., 262), the ruhu of Indian rivers; Sillanda guatemeltia (l.c. i., 145), found in the estuaries of India and Burma, the oil of which is much valued as a medicinie.

Trade in Oil.—Thurston gives the fullest and most recent account of the Fish-oil trade of India. The following passage may, therefore, be abstracted from his most interesting and useful report:—'Hundreds of tons of fish-oil are said to have been annually exported from Cochin in former years, and I find that the average export thereof in the five years 1856 to 1861 was 19,630 cwt. The oil trade is, however, reported to be decreasing year by year. In some seasons the sardines arrive off the coast in enormous numbers, or, for several years consecutively, they may be present only in quantities sufficient for purposes of food. The result of this irregularity is that one very important element of success in commercial undertakings—regular supply—is wanting. In some years large shoals of sardines appear, and suddenly disappear. Contracts for the supply of oil are made on the arrival of the fish, and, in the event of their disappearance, the contractor loses heavily. The Natives of Cochin say that formerly the sardines always arrived regularly, and remained throughout the season. And the fishermen's belief is that they are at the present day frightened away by the numerous steamers which call at Cochin, and retire in search of a less disturbed spot. In addition to steam-boat traffic, noises in boats, ringing church bells, artillery practice, the erection of lighthouses, gutting fish at sea, using fish as manure, burning kelp, and the wickedness of the people, have been charged with being responsible for a falling off of the fish supply. But, as Mr. Fryer naively remarks, of these alleged causes, only the last, it is to be feared, has been, and is likely to be, a permanent factor in the case.'

'The preparation of the evil-smelling fish-oil is carried out in large iron cauldrons, in which the fish are boiled with a little water. The oil, as it exudes, rises to the surface, is strained through cloth, and stored in barrels. The residue in the cauldrons is preserved, and utilized as manure for cocoanut gardens, paddy (rice) fields, etc. A rougher and cheaper process of oil-extraction, by which the cost of cauldrons and firewood was saved, has practically been put a stop to as being an offensive trade. This process consisted simply in putting the fishes into a cau, and exposing them to the influence of the sun until decomposition set in. The oil then rose to the surface, and was removed with a coop. By this crude process a comparatively small quantity of the oil was extracted. A portion of the manufactured oil is consumed locally by boat-owners for smearing their boats, so as to preserve the wood and coir ropes (made from the fibre of the cocoanut husk) with which the timbers are stitched together. But the bulk is exported to Europe and some Indian ports. The Natives believe that the oil returns from Europe, masquerading in the guise of cod-liver oil.' [Cf. Eastern India, i., 229; Buchanan-Hamilton, MS, pub. by Day in Hunter, Stat. Acc. Beng., xx., 85; Japanese Sardine Oil, in Journ. Soc. Chem. Indus., 1887, vi., 372; Thurston, Bull. Mad. Mus., 1900, No. 2.]

545

35
FISHERIES OF INDIA

8. POISONS OR INTOXICANTS USED TO KILL FISH.—The following are the plants often used in India to kill fish:—Albizizia stipulata, and procera; Anamirta Coecientia, W. & A. (the seeds boiled in rice and made into a paste); Balanites Roxburghii, Planta; Barringtonia racemosa (Growth with saltpetre); Bassia batuvae, Roxb. (bark used in Sikkim); Bemeris arisiata, DC. (bark); Crotalaria paniculata, Willd. (according to Hooper, plant used); Dorris elliptica, Benth. (bark and flowers); Diospyros montana, Roxb. (fruits); Enophlia Barcella, Linn.; Flagaea Leucopyrus, Willd., and F. microcarpa, Bl. (the barks); Gymnocardia odorata, Br. (the fruit); Hydnocarpus venenata, Gaertn. (fruit used); Lasiosiphon ereiophalus, Dene. (bark); Miltitria Piscidia, Wight (powder of bark and flowers); Manduca acutiloba, Benth. (seeds and inner layer of bark); Randia dumetorum, Linn. (brusied fruits); Sapium indicum, Willd. (the seeds used); Spathotes Aemrella, Linn. (fruits); Strychnos Nux-vomica, Linn.; Walsura Piscidula, Roxb (bark thrown into tanks).

It has been pointed out that many of these contain saponin. All are more or less acrid and bitter. It is generally held that the fish taken by this process are quite wholesome. The practice is most reprehensible, since young and old are killed and more therefore destroyed than can be used. [Hooper, Drugg. Bull., Nov. 1890.]

9. ROE.—The roes of certain fish are highly prized. They are often specially prepared and sold by themselves, just as in Europe the cod-roe is a recognised marketable article. The fish most generally resorted to for this purpose are the Gard fish of Malabar (Hemiraniumthus bonnissi) (L.c. i., 427), a fish found plentifully in the seas and tidal rivers of Bombay, Bengal, and the Andaman Islands. So again the Corsula Mullet (Magill carcina) (l.c. ii., 349) or the undala, corsula, in-ge-ri, nga-sheng, etc., which Ainslie says affords a kind of caviar (caviare), as also the Common Mullet (Magill oure) (l.c. ii., 348), the kola-kende or muklah, yields roes that are much appreciated and are sold sun-dried.

10. SALTED AND DRIED FISH.—In official statistics this subject is dealt with under the following headings:—"Dry Unsalted Fish," "Dry Salted Fish," and "Wet Salted Fish." One of the most startling circumstances of the trade in fish is the fact that India is apparently not able to meet her own demands. Perhaps no other part of the globe (of a like magnitude) possesses so varied and extensive a series of marine and fresh-water edible fish, nor so many forms that lend themselves readily to artificial production in tanks and ponds. In spite of every advantage, however, the foreign imports far exceed the exports, thus showing that from one circumstance and another, India is not self-supporting in the matter of fish. Whether this proceeds from unskilled methods and imperfect appliances, or from the want of proper regulations and protective measures, in the form of a Fisheries Act, or from the restrictions that prevail in the supply of cheap salt for fish-curing, or from the climatic and social conditions of the country and people that are naturally opposed to the development of a fish-curing industry, are points of a highly controversial nature. The late Dr. Francis Day was of opinion that the Bengal supply had steadily declined, since the first decade of the nineteenth century; when Buchanan-Hamilton conducted his survey of that province and wrote his Fishes of the Ganges, owing, Day thought, to the selfish and destructive systems that were allowed to prevail. Be that as it may; it is certain that the past twenty or thirty years has witnessed the steady growth of an import trade in fish which has assumed no mean proportions.

The following, arranged in alphabetical sequence of their scientific names, are the more important fish sold in salted condition:—Albatiss marshi (l.c. i., 59), the Devil Fish; Arius catus (l.c. i., 174), A. sagor and A. sona (L.c. 178—9); Chitoceius cinerina (l.c. 380), the Indian Herring; Chrysophrys beda (l.c. ii. 44), the Grey Perch; Citharurus maculatus (l.c. i., 115); Cyphium gilladi (l.c. ii., 210), Seer or seir; Cynoglossus sp. (l.c. ii., 452), the Soles known in South India as manda; Equita daura (l.c. ii., 188), the acer karah, Cormandel; Gerres filamentosus (l.c. ii., 537), the Udah; Harpodon nebulosus (l.c. ii., 412), the Bummerai, already discussed; Lutjanus argentinianus (l.c. i., 472), the Red Rock-cod; L. jahangirah (l.c. i., 474), the purruwa; Magil carcina (l.c. ii., 349), the Mullet; Pristis cupepidus (l.c. i., 37), the Saw-fish; Rhynchobatus djeddensis (l.c. ii., 40), the ulavi; Saccobranchus fossils (l.c. i., 125), the Scorpion Fish; Sciaena bleckeri (l.c. ii., 112), the sol-hi; Scoller microlepidotus (l.c. ii., 203), the Mackeral or ila; Stromates cinerus (l.c., 198), the Silver Pomfret; S. nigra (l.c. ii., 199), the Black Pomfret; S. cincens (l.c. ii., 197), the White Pomfret; Trachynotus ovarus (l.c. ii., 179), the
TAMARIND-FISH

11. FISH SCALES.—The scales of the mahasir (Barbus tor) are said to be employed in the manufacture of playing-cards. They are cut into circular pieces about 1/2 inch in diameter, painted and varnished. The centre of the trade in this curious commodity appears to be Shahabad. In the Deccan the large scales of a carp are used in place of glass for windows. The scales of the Blak and the Dace are in Europe employed in the production of a substance known as Essence d'Orient which is utilised in the manufacture of artificial pearls.

[Ind. Art at Delhi, 1903, 202-5.]

12. SEA FISH.—So many of the fish that should fall into this position will be enumerated under other headings that it is hardly necessary in this place to do more than mention a few of the more important species:—Atherina forsalii (l.c. ii., 338), also Engraulis indicus (l.c. i., 394), both called Whitebait by Europeans in India; Chanos chanos (l.c. i., 403), the Milk Fish or White Mullet; Chelidus chamauda (l.c. ii., 386), the Indian Herring; Clupea harengus, true and longiceps (l.c. i., 373-4), Sardines; Cybium guttatum (l.c. ii., 210) and C. commersonii (l.c. ii., 211), seir; Cynoscion lamna (l.c. ii., 454), the Sole of Europeans in India, or kot-aralu, a fish highly esteemed in the coast towns of India; Hussosia indica acuta (l.c. i., 399), the Malabar Sardine; Harpodon nehereus (l.c. i., 412), Bombay Duck; Lates calcarifer (l.c. i., 440), the Cock-up or near, the begiti; Mugil cavata (l.c. ii., 349) and other species, the Mullet; Polynemus indicus (l.c. ii., 195), the Rowall of Vizagapatam, the sol; is one of the chief sources of the "Fish-maws"; Scomber microlepidus (l.c. ii., 203), the Mackeral; Sillago sihama (l.c. ii., 224), the Whiting of Europeans in Madras; Stromateus cinereus (l.c. ii., 198), the Silver and Grey Pomfret; S. niger (l.c. 199), the Black Pomfret; S. sinensis (l.c. 197), the White Pomfret; and Upeneoides vitattus, the Mullet (l.c. ii., 25).

13. SHAGREEN OR FISH-SKINS.—The rough skins of many species of fish are used as a kind of sand-paper, and that of certain sharks, rays and skates is made into the substance called shagreen. This is a thick skin covered with hard enameled papillose scales. After being cured and stained it is employed to cover boxes, scabbards, sword-handles and other such purposes. In some respects the shagreen from the ray-fish and certain species of dog-fish is regarded as superior to that of the shark. In Hunter (Imp. Gaz., x., 252) mention is made of shagreen manufactures at Nawamgar; also in Milburn (Or. Comm., ii., 511), Horse-skins. The following afford shagreen:—Pristis eugypti (l.c. i., 37), the Sawfish; Rhynchobatus monacolus (l.c. i., 41), the Mud-skate; Trygon sepheus (l.c. i., 58); the Ray; Zygogramma malleus (l.c. ii., 222), the Hammer-headed Shark. Hoey (Monog. Trade and Manuf. N. Ind., 1880, 94) describes the process of making horse or asses' hides into an imitation shagreen known as kimakht and kirkin.

14. SMOKED FISH.—While the art of curing fish by smoking them seems to have been known to the Natives of India from fairly ancient times, it cannot be said that it has assumed a position of such importance as in Europe. The hisla or Sable, Clupea hilsa (l.c. i., 376), is the fish most noted as being in India cured by being smoked. The Mango-fish, Polynemus indicus (l.c. ii., 105), is a fish that must be eaten immediately after being caught. Accordingly, to allow of its being carried to a distance it is sometimes smoked. The basea of the rivers of Assam, Bengal, Orissa, etc., is also a fish often smoked, but these and other instances are more a consequence of special demand by the Europeans than a regular Native industry. The smoke from burning refuse sugar-cane is that most generally used.

15. SOAP.—Several methods of utilising fish and fish-offal in the production of soap have been discussed by several writers, but no actual industry exists in India for this purpose. [Cf. Simmonds, Waste Prod., 148.]

16. TAMARIND-FISH.—Fish pickled in a preparation of tamarinds is known in Indian trade by this name (see p. 1067). The species most frequently treated in this way are Cybium guttatum (l.c. ii., 210), the see or seir fish, and Lates calcarifer (l.c. i., 440), the Cock-up or Nair fish, the begiti of Bengal. Thurston says: "In

Tamarind-Fish
the ordinary method of preparation, the fish is boiled, and, after removal of the bones, cut in thick slices, highly spiced and left to soak, packed in a jar. But the following account of a new and improved process has been sent to me by Mr. Sherman. "Fish of all sizes can be cured; but, for Colombo market, mackerel are preferred. The fish are not slit open, but neatly gutted by extracting the entrails through the gill-opening. They are then carefully washed and packed, with alternate layers of salt, in big casks, which are procured locally and sold in Colombo with the fish. To each maund of the fish about 7 lbs. of tamarind fruit (goookapuly) are used." "The casks are stored on end and filled to the full. The fish is allowed to soak and pickle for four days, and the brine is then drawn off until it is about a foot from the bottom, and thus leaving enough brine to keep the whole cask moist when closed. Under this new system 1,658 mds. 5 seers of mackerel, with 375 lbs. of salt are used; or 18 lbs. per maund against 12 lbs. used in the usual west coast method of curing."

TRADE IN FISH.—It has often been urged that India is most neglectful of her food resources in this direction. With a little care the rivers and tanks might become very much more important sources of supply, and indiscriminate and wasteful methods of fishing, both in fresh and sea water, account largely for the backwardness of the trade. It has accordingly been urged that both a Fisheries Department and Fisheries Act are much needed. Repeated efforts have been made and voluminous reports prepared with a view at least to secure for each province a special Act to protect its fisheries (see p. 546). The multifarious vested interests of a vast population of semi-educated people are the excuses for existing defects. It has been said that when the people have come to appreciate the value of measures to secure and protect their interests, then will be the time for special legislation; and further, that without a proper Act a Fisheries Department would have little justification for its existence. On the other hand, the claims of the fish-curing industries have already been recognised by the organisation of Government fish-curing yards where cheap salt may be supplied, under regulations that ensure its being restricted to the purpose intended, and these have been placed under the control of the Salt Department. But in the annual publication Financial and Commercial Statistics of British India, no factory or establishment that employs less than 25 persons permanently is recognised, hence the bulk of the fish-curing yards are excluded. Fish-curing in India, though important in the aggregate, is a domestic rather than a public concern. Nevertheless, in the publication mentioned, there were recorded 10 companies in 1901, 15 in 1903, and 13 in 1904, employing on the average about 1,300 persons annually. These were entirely in the Madras Presidency. In 1882 the prohibition against the use of natural saline earth in the preservation of fish was issued. This of necessity led to some provision to replace that material and method of fish-curing. This was met by the Salt Department concerning themselves with the provision of the fish-curing yards to which reference has been made. The salt issued to the fish-curers was at first given at cost price, but in consideration of the fact that the saline earths formerly employed were procured for the cost of collection, the salt was reduced to 6 annas 8 pies per maund (say 6\(^{2}/\text{d.}\) for 80 lb.). It was found, however, that all forms of salt were not equally serviceable for fish-curing; accordingly for some years complaints were general, and a decline in fish-curing having occurred, this was pointed to as a direct result of the Government's efforts at protecting its salt interests while at the same time raising the standard of fish-curing in India. This subject will be found dealt with in some detail by Thurston. [Bull. Mad. Mus., 1900, No. 2, 147-52.]
FISH-CURING

From the reports of the Madras Salt Department we learn that 136 curing yards had been organised at convenient centres along the west and east coasts of the Presidency. In 1902-3 the total amount of fish brought to them to be cured came to 50,374 tons, as against 68,992 tons in the previous year. The production came to 814,716 maunds of cured fish, of which it is stated 631,277 maunds were consumed in the Presidency.

Thurston gives the returns of the three most important fish as follows:—

<table>

It would appear that from 60 to 65 per cent. of the South Indian fish-curing is done in the Salt Department Sub-Division of Calicut (including Malabar and South Canara), such as Calicut, Cannanore, Mangalore and Malpe, etc. There are several other important centres such as Chicacole, Tinnevelly, Cocanada, Chingleput, Nellore, Naga
tapatam, etc. Malpe is interesting as the centre to which the fishermen of Ratnagiri and Goa come for the seir fishing season. [Cf. *Memo. prepared by Finance and Commerce Dept. Ind. on the Salt Dept., Sept. 1894, 42-3.*]

The internal traffic in fish, as in most other Indian commodities, can alone be studied by the perusal of the official statistics of Foreign and Coasting Trade. Fish do not appear in the returns of *Rail and River-borne Traffic*, so that very little can be learned of the internal transactions. The following are the headings under which they are recorded:—(a) Fish-maws and Shark-fins; (b) Fish, Dry Unsalted; (c) Fish, Dry Salted; (d) Fish, Wet Salted; and (e) Fish-oils.

**Trade in Fish-maws and Shark-fins** (see p. 542).—India imports on an average 5½ lakhs of rupees' worth. These come from Aden, Arabia, Mekran and Somniani, Persia and Zanzibar. The highest record during the six years ending 31st March, 1907, was in the year 1901-2, when the imports stood at 1,797,114 lb., valued at Rs. 6,58,200; of that amount Bombay took 1,755,877 lb., valued at Rs. 6,27,554, and the balance went to Sind, Madras and Burma. The imports during the years 1903-7 have been:—1903-4, 1,588,692 lb., Rs. 5,87,444; 1904-5, 1,330,326 lb., Rs. 5,05,193; 1905-6, 1,388,365 lb., Rs. 5,25,394; and 1906-7, 1,215,972 lb., valued at Rs. 4,84,465. Practically the entire imports are re-exported, and from 6 to 14 lakhs of rupees' worth of Indian produce exported at the same time. This may approximately be said to represent on the average a total export traffic of 20 lakhs of rupees in value. Thus, taking the year 1903-4, the foreign shark-fins and fish-maws re-exported came to 1,878,342 lb., valued at Rs. 14,36,580, and the exports drawn from Indian supplies came to 481,873 lb., valued at Rs. 5,14,006; and in 1906-7 the re-exports came to 1,350,020 lb., Rs. 11,73,345, and the exports 565,435 lb., Rs. 5,13,350. Bombay is of course the chief exporting province, and exported out of the totals mentioned, in 1903-4, 1,876,074 lb. foreign shark-fins and fish-maws and 49,520 lb. Indian; in 1905-6, 1,336,804 lb. foreign, but no Indian; but Bombay, however, is by no means the most important exporting centre for the Indian fish-maws and shark-fins. In the Indian produce traffic, Burma usually heads the list, and in 1903-4 exported 281,296 lb., in 1905-6, 243,592 lb.; being followed by Madras with 107,582 lb. and 153,614 lb.; Karachi with 14,923 lb. and 113,804 lb.; and lastly Bengal with 28,552 lb. and 14,768 lb. in the two years mentioned. The most important receiving country is of course

549
China (Hongkong) for the re-exported fish-maws and shark-fins, followed by the Straits for the Indian. It is perhaps a significant circumstance that the United Kingdom has for some years taken fairly large quantities and even the United States have obtained supplies of these products direct from India.

As giving a fuller conception of the Indian production, the following review of the traffic carried coastwise may be framed. In the year 1903–4 the total coastwise transactions came to 1,236,173 lb., valued at Rs.6,84,179, but showed a decrease in 1905–6 to 875,927 lb. Of the amount for 1903–4 Bombay alone took 1,160,667 lb., valued at Rs. 6,29,229. Of these coastwise imports two-fifths came from Madras, one-fifth from Sind, the remaining two-fifths equally from British ports and non-British ports within the Presidency of Bombay. The remainder, over and above the Bombay transactions on total coastwise trade, may be said to be imports taken in 1903–4 by Burma from Madras and Bengal, viz. 47,057 lb. Practically, therefore, the coastwise trade in shark-fins and fish-maws is concentrated in Bombay. It has been fairly constant for some years past, but if anything has manifested a tendency in the foreign imports to decrease and the Indian produce to expand, a satisfactory state of affairs.

Trade in Fish.—(b) to (d) above may be exhibited as follows:—

Foreign Imports.—In 1892–3 the imports of fish were valued at Rs. 28,80,269 (say £193,000). Of that amount the "Unsalted Dry Fish" (see p. 542) came to Rs. 3,55,893, "Salted Dry Fish" (see p. 546) to Rs. 18,08,491, and the "Wet Salted Fish" (Ngapi, p. 544) to Rs. 7,15,885. In the years 1894–7 a serious decline took place in the traffic, due, it is believed, to the conditions that then prevailed in Bombay.

</table>

Another very significant circumstance in the fish trade of India may be stated to be the fact that Bengal practically takes no part in the import traffic. Burma receives by far the major portion of all the fish imported by British India; and, what is most striking, its supplies come almost entirely from the Straits Settlements, and are uniformly returned at a much higher price than the classes of fish that go to the other provinces. Bombay is the chief receiving province for "Dry Unsalted Fish" and Burma for "Salted Dry" and "Salted Wet Fish." The imports of "Dry Salted Fish" come mainly from the Straits (into Burma) and from Arabia, Mekran and Sonniami (into Bombay).

Foreign Exports.—There exists a small re-export of foreign preserved fish which in 1905–6 came to Rs. 44,584, and in 1906–7, 22,686. But turning from these unimportant transactions to the traffic in Indian produced and preserved fish, it may be said that, if anything, the exports of "Dry Unsalted" and "Dry Salted Fish" from India have shown a tendency to improve during the past decade. In 1892–3, for example, they were valued at Rs. 8,97,406; in 1903–4 they came to Rs. 17,75,722;
and in 1906-7 to Rs. 15,64,747. The “Dry Unsalted Fish” goes usually in almost equal proportions and value from Bombay and Madras (in 1906-7, the Bombay share came to 1,206,656 lb., valued at Rs. 1,20,490; and the Madras to 4,162,854 lb., valued at Rs. 2,94,235). In the “Dry Salted Fish” trade Madras takes by far the most important position. Out of the total exports of 1906-7, Madras supplied fish of this class to the extent of 9,934,728 lb., valued at Rs. 10,44,465, and these went almost exclusively to Ceylon.

**Coastwise Traffic.**—But to attain a fairly comprehensive conception of the location and extent of the Indian fisheries, it is necessary to consult the returns of coasting trade. It is unfortunate that no particulars are published of the fish carried by rail and river, as these might have afforded some data upon which to judge of the transactions in the more interior tracts. So far as is known, there are no large fish-curing centres connected with the fresh-water fish and fishing, so that the coastwise traffic may be accepted as fairly representing the local trade. The coastwise transactions are recorded under two headings—“Dry Unsalted” and “Dry Salted.” Under each the traffic has fluctuated considerably, but on the whole forward. During the under-mentioned years the “Dry Unsalted” has manifested a satisfactory expansion, viz., Rs. 19,85,869 in 1899-1900; Rs. 29,30,971 in 1903-4; and Rs. 25,61,334 in 1905-6; while the “Dry Salted” have practically remained stationary—Rs. 7,87,774 in 1899-1900; Rs. 7,80,301 in 1903-4; and Rs. 7,50,975 in 1905-6. By far the most remarkable features are the immense traffic towards the town of Bombay in cheap fish, and the fairly large supplies drawn by Rangoon of highly priced fish. Thus, for example, in 1905-6 Bombay imported coastwise “Dry Unsalted Fish” to the extent of 15,040,751 lb., valued at Rs. 6,43,159, and Burma 7,219,489 lb., valued at Rs. 18,10,459. The Bombay town supply was procured from British ports within the Presidency (Rs. 2,92,757); from Kathiawar (Rs. 2,60,698); from Daman (Rs. 66,044); and from “Other Provinces” (Rs. 22,660). The Burma supply was drawn from Bengal (Rs. 5,03,765); Madras (Rs. 7,24,770); “Other Provinces” (Rs. 1,94,453); and from the British ports within the province of Burma itself (Rs. 3,86,946). Turning now to the subject of the coastwise traffic in “Dry Salted Fish,” the total for 1903-4 came to Rs. 7,80,301, and in 1905-6 to Rs. 7,50,975. But by far the most remarkable aspect in this traffic may be said to be the circumstance that the exports are almost exclusively into Bombay, Madras and Burma, in equal proportions and from their own provincial ports into their chief towns.

**Location of Fisheries.**—It may, in conclusion, be inferred, from these observations, that the fisheries of India are mainly along the west coast from Kathiawar to Travancore; that Burma is the least self-supporting of all the provinces and demands from external sources a superior, not an inferior quality of fish; and lastly that Bengal, while it takes very little share in the export traffic in fish, produces apparently enough for its own necessities, since it practically imports no fish either from foreign countries or from other Indian provinces.
The Gamboge Varnish

Cooke, Fl. Pres. Bomb., i., 572-3; Firminger, Man. Gard. Ind. (ed. Cameron), 166; Umbelliferae. The Fennel, saunj, bari saunj, sonp, mauri, pan-muhori, bari-shopha, variari, badishep, badisopu, azpa, badyan, sohikire, shombo, pedda-jila-kurra, sa-meit, madhurikā. A perennial which attains a height of 5 to 6 feet, commonly cultivated throughout India, at all altitudes up to 6,000 feet, and also found wild.

This plant seems to be grown only in small patches, on homestead lands, as a cold-weather crop. Firminger informs us that it thrives well in Bengal, and where once grown will come up each cold season afterwards, from self-sown seed. The seeds should be sown in October on the plains, and in March and April on the hills. Of the United Provinces, Duthie and Fuller intimate that fennel is extensively cultivated during the cold season in garden patches. In Bombay, the chief localities are Khandesh and Gujarat, but it is also grown in the Deccan.

Fennel fruit yields about 3 per cent. of volatile oil, which consists of anethol or anise camphor and variable proportions of a liquid isomeric with oil of turpentine. The oil is used in Europe in the manufacture of cordials and enters into the composition of fennery water, which is now sold in Bengal as muhori-ka-arak or arak badian. [Cf. Thorpe, Dict. Appl. Chem., 1900, iii., 12; Schimmel & Co., Semi-Ann. Rept., Oct.—Nov. 1897, 27-8; Oct.—Nov. 1902, 42-3.]

The fruits and oil are stimulant, aromatic and carminative, used largely as flavouring agents to medicines. The root is purgative and the leaves diuretic. [Cf. Pharmacog. Ind., ii., 1890, 124-7; Dutt, Mat. Med. Hind., 1900, 174; White and Humphrey, Pharmacop., 1904, 203.]

The exports are not very important. During the five years ending 1903-4 they ranged from 3,355 cwt., valued at Rs. 29,277, to 14,085 cwt., valued at Rs. 1,16,370, but have since declined to 10,974 cwt., valued at Rs. 1,09,735 in 1906-7. Ceylon is usually the most important receiving country, though during 1903-4 and 1904-5 the United Kingdom took the largest amounts, viz., 5,390 cwt. and 10,521 cwt., but in 1906-7 took only 532 cwt. Outside the British Empire, Germany is the only country that need be mentioned. In 1903-4 it took 1,424 cwt., and in 1906-7, 2,273 cwt. Practically the whole of the exports go from Bombay.

Garcinia Linn.; Fl. Br. Ind., i., 259-70; Roxb., Fl. Ind., ii., 618-30; Gamble, Man. Ind. Timbs., 49-55; Cooke, Guns, Resins, etc., Ind., 1874; Umbelliferae. A large genus of evergreen trees of the tropics, none of the species extending to the Panjāb or the United Provinces, and few even to the North-East Himalaya. There are thirty-six species, most of which contain a yellow juice, which generally gives a more or less useful pigment—the grades of Gamboge.

G. gambogia, Deer.; Talbot, List Trees, etc., 1902, 27; Cooke, Fl. Pres. Bomb., 1903, i., 77; Brandis, Ind. Trees, 51. The hila, aradal, manthuli, ponapu, wpugj māra, dharambe, ḍhorgupu, gorakkapu, goraka, etc. A small evergreen tree of the western coast and Ceylon, ascending to 6,000 feet on the Nilgiris. It is said to yield a yellow, very adhesive Gum, which is valueless as a pigment because insoluble in water. It is, however, soluble in spirits of turpentine, and thus forms a beautiful yellow Varnish. It also gives an Oil used in medicine. The Fruit is edible and of a pleasant acid taste. It ripens during the rainy season. The rind of the fruit is employed as a condiment and eaten with fish as a substitute for tamarind. The Wood is grey, sometimes patched with red, smooth and close-grained. Beddome remarks that it would be useful for common furniture. [Madras Weekly Mail, May 16, 1901.]

G. Cowa, Roxb.; Rec. Bot. Surv. Ind., 1893-1902, i., 56; 1903, ii., 82; Prain, Beng. Plants, 1903, i., 247; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 289; Brandis, Ind. Trees, 52. A tall evergreen tree with a round stem. It occurs in Bengal, Assam, Chittagong, Burma and the Andaman Islands. In Bengal it is the cowa, and in Burma the tawngthale, ma-dow. It produces
KOKAM BUTTER

GARCINIA MANGOSTANA

Mangosteen

A yellow Gum which is insoluble in water, but with spirits of turpentine gives a beautiful and permanent yellow Varnish for metallic surfaces. In certain districts the bark is employed to produce a light-yellow Dye used in colouring cloth for the garments of Buddhist monks. Duncan (Dyes and Dyeing, Assam, 1896, 25) mentions that its use in dyeing is unknown in that province. The Fruit ripens at the beginning of June, and is of the size and form of a small orange. It is acid in taste, but otherwise good, and makes a very fine preserve. The Wood is not used for any economic purpose.

G. heterandra, Wall. An evergreen tree of the hills of Burma up to 3,000 feet. It is the thanattaw or tha-nat-taw, and yields a superior quality of gamboge sometimes called Arakan. [Cf. Hanbury Journ. Agric.-Hort. Soc. Ind. (Proc.), 1859, x. 121.] A sample from Tavoy, when analysed, gave :—resin 76-5 per cent. ; gum 23-5. [Gamble, l.c. 55.]

This slender tree with its drooping branches is found in the forests of the Konkan, Kanara, Coorg and Wynaad, and is often planted, especially in the southern districts of the Bombay Presidency. It thrives particularly well on the lower slopes of the Nilgiris, and a writer in Indian Gardening (March 16, 1899, 108) recommends its cultivation for the fruit as a by-product on lower elevation estates. From the Seeds of the fruit a valuable Oil is extracted known as kokam butter. It is obtained in one of several ways by boiling, churning, or simply pressing the seeds in an ordinary oil-mill. In the Indian bazars it is found in the form of egg-shaped or oblong lumps, of a whitish colour, at ordinary temperatures, firm, dry and friable, yet greasy to the touch. Examination of the glycerine under the microscope proves it to be crystalline. Usually it contains a considerable amount of impurity, but by filtration it may be obtained perfectly pure, transparent, and of a light-yellow colour. It melts at 98° F. According to Flückiger and Hanbury it contains stearic, myristic and oleic acid. In medicine it is considered nutritive, demulcent, astringent and emollient. It is also used as a substitute for cod-liver oil, and in the preparation of ointments. The Fruit, sometimes called the wild mangoosteen, has long been considered an article of food. Garcia de Orta (1563) refers to it under the name of brindola, and in his note on Linschoten's account of Indian fruits Paludanus (1590) calls it brindotius and speaks of its sour taste—it is called brindao in Goa to-day. Woodrow mentions that a statement made by Graham in the Bombay Courier (June 12, 1830), to the effect that it is used at Goa for adulterating ghi, had been denied by a writer in The Indian Times. At the present day the dried fruit is used as a condiment in curries, and in the preparation of acidulous drinks. A considerable trade in kokam butter is carried on by the Goanese. [Cf. Pharmacog. Ind., 1890; i., 163-7; Moodeen Sheriff, Mat. Med. Mod., 1891, 45-6; Andére, Veg. Fats and Oils, 1897, 216, 219; Waring, Gaz. Med. Ind., 1897, 83-4; Wright, Am. and Veg. Fixed Oils, Fats, etc., 1903, 299, 553; Imp. Inst. Tech. Repts., 1903, 128, 132.]

G. Mangostana, Linn.; Nairne, l.c. 25; Woodrow, l.c. 173; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 289; Kew Mus. Guide, 1907, 21. Mangoosteen, mangústan, mustah, mengkot, mimbu, youngzalat, manggis. An evergreen tree of the Malay Peninsula, indigenous to the Molucca Islands. [Kew Bull., 1898, 26.] Fairly extensively cultivated in Burma (Tenasserim) and in a few special localities in India, such as the Barliar gardens, Nilgiri hills. Though frequent efforts have been made in Bengal and Western India to grow this tree, it has not been known to fruit successfully. In Ceylon, Trinidad and Jamaica better results appear to have been attained. A warm moist, insular climate seems essential to success. In the open plains it does not thrive so well as in valleys with light shade. Is liable to the disease known as gamboge canker.
THE MANGOSTEEN FRUIT

GAMBoge

It is propagated by seed, grafting or inlayering, and on rich loamy, well-drained soils. The tree is commonly said to begin to bear when from 7 to 10 years, or, according to other experience, not until it is 15 to 20 years old. It may continue to yield thereafter for 50 to 100 years. The fruiting season is June to September. Rich cultivation is essential, such as manure once a year. Care must also be taken in picking the fruit, since until the rind has hardened it is delicate—a fall may often be fatal to any idea of preservation. The yield has been variously stated. A writer in Indian Gardening speaks of trees planted 25 by 25 feet yielding 1,000 fruits an acre, with a net profit of £2. A writer in The Planter, on the other hand, affirms that each tree may give an annual income of £2 to £5. Gamble observes that according to Helfer one tree may yield 1,000 fruits yearly, valued at Rs. 3 per 100. At Barliar a tree has been reported to have given 1,200 fruits. The fruits are usually strung by a bast fibre, being tied between the thick, hard, calyx teeth and the fruit; bunches thus formed are hung up to mature. If intended to be transported, these bunches should be packed in baskets along with wet moss, and dispatched the day they are plucked. Some years ago a consignment of fresh fruits was sent to London from the West Indies, but apparently no trade has as yet been organised. As an article of food, the fruit is highly esteemed both by Europeans and Natives, and is considered by many persons the most delicious of Eastern fruits. Ships coming from the Straits bring it to Rangoon and Calcutta, but by the time they reach the latter port the fruits have lost their true flavour, and are often very bitter, through the formation of layers of yellow gamboge between the pips. A considerable trade is done, however, and the price ranges from Rs. 3 to as much as Rs. 10 a hundred, according to season and quality. Recently an attempt has been made to preserve the mangosteen, and a little more enterprise might make this an important industry. Traffic in mangosteen is, in fact, very ancient. Tavernier (Travels Ind., 1676 (ed. Ball), ii., 287) speaks of the fruit as abounding in Siam.

The rind is a powerful tanning material, and an attempt has been made to utilise the immense quantities available in Burma and the Straits. (Cf. Agri. Ledg., 1902, No. 1, 14.) The chemistry of the rind was investigated by Schmidt in 1855. It contains tannin, resin, and a yellow crystallisable principle, mangostin. In medicine the rind or entire fruit is employed in the production of a syrup that is used in chronic diarrhoea and dysentery. (Cf. Pharmacog. Ind., i., 167; Year Book of Pharmacy, 1892, 167; 1900, 399; Sett. Repts. Amherst, 1893, 47; Cult. in Singapore, Agri. Bull. Straits, 1902, i., 373; Nisbet, Burma under Brit. Rule and Before, 1901, i., 352; Hawaiian For., 1905, ii., 91; Trop. Agrist., 1905, xxv., 256-60.)

GAMBOge

G. Morella, Desr.; Talbot, List Trees, etc., 1902, 27; Cooke, Lc. 77-8; Gamble, Lc. 55; Brandis, Ind. Trees, 1906, 53. Indian Gamboge Tree. The vernacular names may be thus grouped:—the tree—arasinagurj mara, aradal, punar puli, kankutake, daramba, tha-men-gut: the resin—ghotdaghauvă, ausaraherevan, revachinnisră, maki, irvail-chinip-păl, sanato-st, rubbyrevand, jarfrar, etc. An evergreen tree of the forests of the Khasia hills, Eastern Bengal, the West Coast and Ceylon. The Gamboge of European commerce comes from Siam, and is obtained from G. Hanburyi, Hook., f. (Kew Mus. Guide, 1907, 20).

From the GUM-RESIN is produced the gamboge of medicine and the arts. That substance has been known almost from classic times. Of European writers it was first mentioned apparently by Chasius (1605). It is referred to in Chinese works as far back as the end of the 13th century. The gum is not collected to any material extent in the forests of India, and the chief supply comes, therefore, from Siam. Before the resin can be gathered, the trees must be some ten years old. Tapping is carried on during the rainy months, June to October, when the sap is vigorous, by cutting a spiral line round the trunk from a height of about ten feet above the ground. Down these grooves the resin trickles in a viscous stream into hollow bamboos placed at the base. From these it is decanted into smaller bamboos, and left for a month or so to solidify. To remove the gamboge the bamboo joints are placed over a hot fire, which causes them to crack, when a round stick of gamboge is obtained from each—the Roll or Pipe Gamboge of commerce. This method does not seem to be employed in India, where only
THE GAMBOGE PLANT

small incisions as a rule are made, and the resin collected in small tear-drops. In Ceylon it is procured by cutting here and there a thin slice off the bark and scraping away the resin which collects on the exposed surface. Cake and Granular Gamboe are thus obtained, but both these are less pure than Siam pipe gamboe. The best commercial samples of the pipe gamboe are of a rich brown colour externally, dense and brittle, with a conchoidal fracture of a reddish-yellow colour, odourless and tasteless at first, then acid. Mixed with water it forms a yellow emulsion. Hurst (Painters' Colours, Oils, etc., 1901, 461) gives an account of the chemistry. Analysis shows it to contain:—moisture, 2.50 per cent.; mineral matter, 1.05; resin soluble in ether, 66-05; wax soluble in alcohol, 4.31; gum, 26-03. Gamboe dissolves in ammonia with a yellow colour, and this solution produces yellow and red dyes with zinc, alumina, and lime mordants. The average London quotation for Siam gamboe varies from about £6 10s. to £10 per cwt.

In medicine, gamboe is employed as a hydragogue and drastic cathartic and anthelmintic. From the seeds a semi-solid Oill or fat is obtained, used as a lamp-oil or a substitute for ghi. [Cf. Milburn, Or. Comm., 1813, ii., 507; Cooke, Gums, Resins, etc., 1874, 41-4, 46-8; Mooden Sheriff, Mat. Med. Mad., 1891, 43-4; Pharmacog. Ind., 1890, i., 168-70; Trop. Agrist., 1895-6, xv., 216-7, 319; Yearbook of Pharmacy, 1897, 177-8; 1899, 164-5; Liveache, Manuf. Varnishes, Oil Crushing, etc., 1899, 77-8; Moritz Lowenthal, Uebcr das Gumbigutli, 1900; Chem. and Drugg., 1901, lix., 102; Allen, Comm. Orgon. Anal., 1901, iii., pt. i., 461-3; Barry, Legal Med. Ind., 1902, i., 532, 558; Mitchell, Animal and Veg. Fats, etc., 1903, 299; Blyth, Foods, 1903, 353, 491; White and Humphrey, Pharmacop., 1901, 543; Tsirich, Die Harze und die Harze-behalter, 1906, ii., 833-50.]

G. Xanthochymus, Hook., f.; Rec. Bot. Surv. Ind., i., 336; Talbot, l.c. 27-8; Cooke, l.c. 78; Prain, Beng. Plants, i., 247; Firminger, l.c. 290. The damphl, damphid, tepor, manhola, tauri, sicara memadi, nukki, janayi, madaw, etc. A medium-sized evergreen tree of E. Himalaya and E. Bengal; from Kanarasouth, through Coorg and the Nilgiris; also in the N. Cincara, Burma and the Andaman Islands. A large quantity of an inferior gamboe is obtained from the Gum-resin of this species. In Assam it is extensively used as a Dye. The Phakials of Lakhipur also employ the bark to produce a bright yellow. The mordant used is the green leaves of Symptocos grandiflora (bhomrat). [Cf. Duncan, Dyes and Dyeing, Assam, 1896, 26.] The Fruit is utilised in medicine either fresh or dried, and also eaten as a Food. It ripens in January and February, and is sometimes used in place of the tamarind for preparing curry, and this fruit, as also that of G. paniculata, are used in the preparation of vinegar (see p. 1109).

GEM-STONES.—Holland, Rev. Min. Prod. Ind., 1898-1903, in Rec. Geol. Surv. Ind., 1905, xxxii., pt. i., 106-9; also Imp. Gaz., 1907, iii., 160-3. Holland states that the most important of the precious and semi-precious stones of India are amber, jadeite and ruby. "The only precious and semi-precious stones at present mined in India are the diamond, ruby, sapphire, spinel, tourmaline, garnet, rock-crystal, and the various chalcedonic forms of silicon, jadeite and amber" (see p. 64). The Pearl, though not a mineral but an animal gem-stone, may be described here. In the present article, therefore, a classification into Major and Minor gems may be adopted advantageously. Under the heading of Major Gems will be taken up in alphabetical sequence—Beryl, Diamond, Pearl, Ruby, Sapphire, Spinell, Tourmaline, garnet, rock-crystal, and the various chalcedonic forms of silicon, jadeite and amber" (see p. 64). The Pearl, though not a mineral but an animal gem-stone, may be described here. In the present article, therefore, a classification into Major and Minor gems may be adopted advantageously. Under the heading of Major Gems will be taken up in alphabetical sequence—Beryl, Diamond, Pearl, Ruby, Sapphire, Spinell, Tourmaline; under Minor Gems—Garnet, Jade, Lapis Lazuli, the Quartzose minerals (Rock Crystal, Agate, Onyx, Jasper, etc.), and Tourmaline.

Total Trade.—The value of the precious stones found annually in India does not apparently equal the value of the unset stones and pearls imported. The Imports in 1903-4 amounted in value to Rs. 1,52,15,502, and in 1906-7 to Rs. 93,38,103, and came chiefly from the United Kingdom, Arabia, France and Persia. The share of Bengal was Rs. 94,62,278
in 1903–4, and Rs. 6,05,482 in 1906–7; of Bombay, Rs. 55,02,591 in 1903–4, and Rs. 84,49,271 in 1906–7. The balance on the totals of the years named went to Burma. In the same years the Exports (Indian merchandise, including Jade) amounted to Rs. 9,25,257 and Rs. 18,81,608, and the re-exports to Rs. 92,118 and Rs. 2,57,598.

1. MAJOR GEMS.

1. Beryl.—Ball, Man. Econ. Geol. Ind., 1881, iii., 520–2; Holland, l.c. 107–8. The sabzá, panooa, fastiki keriši.

Prof. Church writes me that beryl includes not only the rich green emerald, but also the sea-green aquamarine as well as the white, and the bluish varieties of a mineral species, which is a silicate of alumina and another earth, now generally called beryllia.

According to Holland, the palest varieties are common in the granite pegmatites of India, but the crystals are too fissured for use as gem-stones. The only places where attempts have been made to excavate pegmatite solely for its aquamarines are at Padyur (Pattalai) near Kangayam, Coimbatore district, and at different places in the Toda hills in Rajputana. [Cf. Linschoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), 1885, ii., 138; Tavernier, Travels, 1676 (ed. Ball), 1889, ii., 104; Milburn, Or. Comm., 1813, ii., 288; Watt, Min. Rev. Ind., 1894, 16; 1895, 39; 1896, 38; 1897, 36–7.]

Sources.—India was the first and for long the only source of diamonds known to European nations, and most of the great historic diamonds, the Koh-i-nur, the Orloff, the Pitt, etc., were obtained from that country. Many of the early Indian explorations by Europeans were primarily conducted with a view to learn particulars of the supply of diamonds and other precious stones. References to Indian diamonds accordingly occur in the writings of most of the early travellers. Marco Polo wrote of them in the 13th century. Varthéma (Travels, 1510 (ed. Hakl. Soc.), 1803, 107) deals specially with the diamonds of Cambay. The history of the Koh-i-nur, given by Tavernier (1676, l.c. 123–7), traces that gem back to the time of the Emperor Baber (Memoirs (Leyden and Erksine, transl.), 308). Jahangir (Memoirs (Price, transl.), 2–3, 51) gives an account of the diamonds in the crown and throne used by him. Garcia de Orta, who was in India in 1563 (Coll., xiii.; also in Ball, Proc. Roy. Ir. Acad. (3rd. ser.), 1890, i., 657–61) mentions various Eastern diamond mines, such as that of “Bienager” (Vijayanagar) and the “Decam” (Deccan). Ball, in his translation of Tavernier’s Travels, gives full particulars of all the Indian sources of diamonds, and the reader desirous of such details should, therefore, consult that work (app., 431–61). Tavernier—a diamond merchant—was the first European to critically examine the diamonds and the Court jewels of India. His work is, accordingly, highly instructive. Fryer (New Acc. E. Ind. and Pers., 1675, 188, 212–4) and Thovenot (Travels in Levant, Indostan, etc., 1687, pt. iii., 98–100, 104) speak of the diamonds of Golconda, etc. (Golconda mines, consult Ball, l.c. 453–6). Milburn (Or. Comm., 1813, ii., 79–81) furnishes particulars for the guidance of the purchaser and enumerates the more important historic diamonds that had been procured from India up to the beginning of the 19th century.

The following account by Holland gives concisely the chief facts of the modern production:—“Notwithstanding the reputation (stretching back even as far as Ptolemy in the European, and further in the Hindu, classics) which India has had as a diamond-producing country, the output of to-day is very small and comparatively unimportant. The places which, according to accounts, have been most productive in the past form three great groups, each in association with the old unfossiliferous rocks of probably pre-Cambrian age, now known as the Purána group, and distinguished locally as the Cuddapah and Kurnul systems in South India, and as the Vindhyan system in the northern

D.E.P.,

Diamond.
part of the Peninsula. The southern of the three groups of diamond-occurrences includes localities, with apparently authentic records, in the districts of Cuddapah, Bellary, Kurnul, Kistna, and Godavari. Loose stones have been picked up on the surface of the ground, found in deposits of alluvium and in the workings which have been undertaken in the so-called Banaganpilly stage of the Kurnul series of strata. In the second group of occurrences, in the Mahanadi valley, the stones have been found in the alluvium of the Sambalpur and Chanda districts, and though strata similar to those of the Vindhyans and Kurnuls are known in this area, no diamonds have been found in these older rocks. The third group of occurrences occupies a tract some sixty miles long by ten miles wide, with the Vindhyan conglomerates near Panna as the centre. The diamond-mining industry still persists in this area, both in the old conglomerate of Vindhyan age, and in deposits which, though described as alluvium, are possibly relics of Lameta (Upper Cretaceous) deposits."

3. Pearls, Pearl Fisheries and Mother-of-pearl.—Pearls are found in several mollusces which inhabit shallow seas and sandbanks in both the Old and New Worlds. The most productive is the so-called "Pearl Oyster," in reality a mussel—*Melleagrina margaritifera*, Lam. Modern classification, however, favours its reduction to *Ariella*: *moti, mutli, mulhu*, etc.

**Formation.**—It is now known that most pearls are formed by the presence of some foreign substance, which becomes embedded in the interstices of the molluscan mantle and constitutes a source of irritation. This irritation causes the mollusc to deposit nacreous matter in concentric layers until the foreign particle becomes completely encysted. It has been practically established, chiefly through the investigations of Dr. Lyster Jameson, that the irritating substance which induces the pearl-formation is very seldom a sand grain, but almost always a small parasite, in some cases a simple protozoan, in others one of the stages in the life history of a flat worm. Prof. Herdman of Liverpool, who was requested to examine the fisheries in the Gulf of Manar, states in his report that the majority of the best pearls contained as their nuclei the remains of certain Platyhelminthian parasites, which he identified as the larval condition of a Cestode or tape-worm. This cestode passes from the body of the pearl oyster into that of a file-fish and from the file-fish into some larger animal, possibly the large Trygon or ray.

Though pearls originate in the mantle, they nevertheless, when large, frequently work their way out and lie loose between it and the shell, or become attached by subsequent nacreous deposit to the "mother-of-pearl" surface of the latter. In this position a pearl may become so covered up as to form a hemispherical mass which when cut out forms the "perle bouton" of the jewelers. The hollow warty pearl, known as "blister pearl," is produced by a deposit of nacre in order to close an aperture arising from some injury.

**Indian Fisheries.**—The pearl fisheries of India have been famous from remote times. Garcia de Orta in 1563 (*Coll., xxxix.*) mentions the principal localities in the Persian Gulf where pearls were then obtained and says the pearls were cleaned and polished with pounded rice and salt. Linschoten in 1598 and Tavernier in 1676 describe both the Persian and the Ceylon pearl fisheries. At the present time the largest pearl fisheries in the East are those of Ceylon, for information concerning which the reader should consult the reports submitted to the Government of Ceylon in 1904 by Prof. Herdman, Mr. J. P. Lewis and Mr. Hornell; also Herdman's much fuller report published by the Royal Society (London, 1903-6, 5 vols.). In 1905 the total amount realised was Rs. 25,10,021, and the number of oysters fished up 49,250,189. These fisheries (it is understood) have been recently sold, or rather leased, for £20,000 a year to a company who are to work them. The only other pearl fishery of importance
is that of the Mergui district, Burma, which forms a considerable source of revenue to the Burma Government.

MOTHER-OF-PEARL (see p. 989) is procured in connection with the Pearl and Chank fisheries of South India. It is carried all over the country, but curiously enough is not worked up to the extent that might be anticipated, though a fairly large trade exists in exporting the shells (Watt, Ind. Art at Delhi, 1903, 206–8).

This name is applied by lapidaries and jewellers to two distinct minerals, the True or Oriental Ruby and the Spinel-ruby (see opposite). The former is a clear, crystalline form of alumina, coloured by some metallic oxide, chiefly that of chromium or of iron, while the latter is an aluminate of magnesium. In hardness the true ruby is inferior only to the diamond, a fact which affords the simplest test for distinguishing it from spinel, but it is also denser and dichroic.

Sources.—Rubies have been found in certain localities in Southern India, Ceylon, Afghanistan and Badakhshan, but the chief sources both of the Oriental and the spinel ruby are in the mines of Upper Burma. Garcia de Orta (1563, Coll., xliv.; also in Ball, Proc. Roy. Ir. Acad. 3rd ser., 1859–91, i., 665) gives some account of rubies, but remarks that under the name of "ruby" a great many stones are placed. Ball, commenting on Garcia, says that definite information of the occurrence of true rubies in India, at least the existence at any time of regular mines, is wanting. Tavernier makes numerous references to the ruby, and Ball in his edition of that work (1889, ii. (app. v.), 465–70) takes the opportunity to give a full account of the ruby mines of Upper Burma which should be consulted by the reader.

Mining.—At the present day ruby mining in India is confined to the province of Burma, the most important locality being near Mogok. Here the rubies occur in a clayey mass, an alteration product of a coarsely granular marble. According to Mr. Bennet Brough, the methods of mining in Burma are suited to the three conditions of its occurrence, in the limestone, in hill detrital material, and in the alluvial deposits in the valleys. The following account is taken from Brough. "During the period under review the ruby-mining industry in Upper Burma underwent a new and favourable phase, the mineral having become, next to petroleum, the most profitable source of revenue among the Burmese minerals. Various leases were granted in the ruby-bearing area near Nanyaseik in the Myitkyina district, and in the 'stone-tract' of the Sagin hills, in Mandalay district, and the results have been most profitless; but the returns for the Mogok area, where the Burma Ruby Mines Company is paramount, show that the industry has entered a most encouraging phase. The Company was granted the right in 1889 to mine for rubies and to levy royalties from persons working by Native methods, the lease being renewed in 1896 for fourteen years, at a rent of Rs. 3,15,000 a year plus a share of the profits. The result being, however, unsatisfactory from the shareholders' point of view, the rent was reduced in 1898 to Rs. 2,00,000, the share of the profits being at the same time raised from 2½ per cent. to 30 per cent. A dividend of 5 per cent. was paid for the first time in 1898, when the value of rubies obtained amounted to Rs. 2,57,950. In 1899 the Company obtained rubies to the value of Rs. 90,848, and paid a dividend of 12½ per cent.; in the year 1899 three unusually valuable stones were found, one of 77 carats.
being valued at 4 lakhs of rupees (£28,606). In the following year (1900) the value of the stones raised increased to £97,326, and the Company paid a dividend of 17½ per cent. The year 1901 showed the record output of stones, valued at £104,470, whilst in 1902 they brought £86,895. In the last year (1903) the Company's receipts were £98,575, and profits on the year's working £44,950.

Sources.—The sapphire is a transparent variety of corundum or native alumina, composed of oxide of alumina with traces of other substances to which its colour is due. The colour varies from the palest blue to deep indigo, while violet, yellow and green varieties are also met with. Both dark and light varieties are described by Garcia de Orta (1563, Coll., xlvii.), who says the latter are called safrira de agua (water sapphire) and that both varieties are found in "Calcit, Cananor and in many parts of the kingdom of Bissnagar." Ball (Rev. of Garcia de Orta, in Proc. Roy. Ir. Acad., 1889-91 (3rd ser.), i, 604), commenting on this subject, states that he has no definite information as to the former workings of sapphire deposits in India. In recent years the chief source of sapphire was at Zanakar in Kashmir, but the mines are now said to be exhausted. According to Holland (l.c. 109), the normal blue sapphire and rarer green, yellow and white varieties are occasionally found in the ruby-bearing gravels of Burma. [Cf. Thavenot, Travels, 1678 (ed. Ball), 1889, ii, 102, 465, 470; Thavenot, l.c. 99; Lawrence, Valley of Kashmir, 1895, 60-1; Min. Rev. Ind., 1895, 41; 1896, 40; 1897, 40; Bennet Brough, l.c. Jan. 14, 1904, 172.]

The spinel or Balas ruby differs from the true Oriental ruby by containing a considerable percentage of magnesium with traces of chromium and iron oxide. In hardness it is also inferior to the true ruby, of which it is a constant associate and for which it is frequently mistaken. [Cf. Thavenot, l.c. ii, 102, 467.]

7. Topaz.—Ball, Man. Econ. Geol. Ind., 1881, iii, 530-1. 

A fluo-silicate of alumina always containing a little essential water, and occurring only in metamorphic rocks or in the veins which traverse them. Of its occurrence in India there seems no authentic record. [Cf. Linschoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), 1885, i, 80; ii, 138; Thavenot, l.c. ii, 129, 449.]

8. Turquoise.—Ball, l.c. 435. 

The existence of the true turquoise in India is doubtful. Holland remarks that its only importance lies in the fact that India is one of the channels by which the material procured in Persia and adjoining areas reaches the European and Eastern markets. The art of manufacturing and colouring imitation turquoise has become a science with the traders in these stones. Recently a new industry has arisen in Kashmir in ornamenting metal wares with a layer of false turquoise embedded over the surface (Watt, Ind. Art. at Delhi, 1903, 50, 75). [Cf. Linschoten, l.c. ii, 141; Thavenot, l.c. ii, 103; Milburn, Or. Comm., 1813, ii, 543; Bennet Brough, Mining Non-Metall. Min., in Journ. Soc. Arts, Jan. 14, 1904, 174.]

II. MINOR GEMS.

9. Garnet.—Ball, Man. Econ. Geol. Ind., 1881, iii, 521-4; Holland, Garnet, Orig. and Growth of Garnets, etc., in Rec. Geol. Surv. Ind., 1896, xxix, pt. i,
GEM-STONES

Jade and Jadeite

Composition.

Garnets are silicates of alumina, iron, lime, magnesia or similar bases. They may be grouped in six sections as alumina-lime, alumina-magnesia, alumina-iron, alumina-manganese, iron-lime and lime-chrome garnets.

Sources.—The garnet is common in various localities in India, those of Rajputana being the most important. Some stones from Rajputana are said to measure a quarter of an inch to six inches in diameter, and are reputed to be the best in the world. In the Madras Presidency they occur in Vizagapatam, Godavari, Trichinopoly and Tannevally, and are fairly abundant in Burma. According to Holland, "The only garnets worked to any considerable extent in India occur in the mine schists of Rajmahal in Jaipur, and near Sarwar in the adjoining State of Kishengarh. Returns are not available to show the condition of the industry in Jaipur, but there is still a considerable industry in the Kishengarh State, though the yearly estimates are altogether too variable to permit of a fair average being drawn, varying from about £10,000 to £2,000."

Cut garnets in the form of necklaces and other small articles of personal adornment constitute an important section of the lapidary craft of India (Watt, Ind. Art at Delhi, 1903, 74–5). The chief centre of the production of these goods is Jaipur. The qualities known are the so-called amethystine or Oriental garnets, which are usually cut in the form of pendants for jewellery, and the more valuable noble or almandine garnets.

Jade, Jadeite, Jadestone.

Burma.

10. Jade and Jadeite.—Ball, Man. Econ. Geol. Ind., 1881, iii., 516–8; Fritz Noetling, Rept. Econ. Res. of Amber and Jade Mines Area, Upper Burma, in Rec. Geol. Surv, Ind., 1892, xxv., pt. iii.; Occurrence in Upper Burma, 1893, xxvii., pt. i., 26–30; Baner, Jadeite from Tamman, Upper Burma, 1895, xxviii., pt. iii., 91–5; Holland, l.c. 52–4. The yashm, sunq-yashab, sitashi, etc. Under the name jade several different minerals are included, not always easily distinguishable. True jade or nephrite is a native silicate of calcium and magnesius, and may be regarded as a crypto-crystalline variety of hornblende. Jadeite, commonly confused with true jade, is a silicate of soda and alumina, is harder and has a higher specific gravity and greater fusibility than jade. Both jade and jadeite are of economic importance and are comprised under the general term Jadestone.

Sources.—The chief source of the mineral is in Upper Burma. According to Holland, some of the best material is obtained as pebbles in the gravels of the Uru river, a tributary of the Chindwin, but most is obtained by quarriers near Tamman, in the Mogaung Sub-Division of the Myitkyina district. The jadeite here is enclosed in an eruptive rock closely resembling serpentine which pierces strata probably of Upper Miocene age. No jade (nephrite) of the kind which would be regarded as a marketable mineral is known in India, though a mineral having the essential composition and approaching jade in physical characters is known in South Mirzapur. Outside India it may be remarked that in South Turkestan true jade has been worked for many centuries.

Mining.—The method of extraction is very primitive. Before the discovery of the Tamman mines, the mineral was obtained only in the form of boulders in the Uru valley, mixed with other rocks in the alluvial deposits of the river. "The boulders are obtained either by digging holes along the bank of the stream or by diving to its bottom. The boulders brought to the surface are at once broken, and the jadeite separated from the useless stuff" (Noetling). In the Tamman mines the method employed is to heat the surface of the rock by large fires, the fall of temperature by night being sufficient to crack the rock. Crowbars are then inserted in the cracks and the big blocks thus obtained are broken by mallets into lumps of convenient size.

Manufactures.—Jade is highly valued by the Chinese, and also by certain classes in India. The best is of an intense bright-green colour, but red and pale pinkish varieties are also prized. In Burma it is employed chiefly in the manu-
AGATE AND CARNEILIAN

facture of finger- and ear-rings, bracelets, chains, etc. The chief seat of the manufacture of these articles is at Momein. All sort of cups, vessels, tables and other ornaments are made of it. [Cf. Watt, *Ind. Art at Delhi*, 1903, 73, 476-7.] Articles of spurious jado are also frequently met with. The most common of those in India is the Afghan jade-like serpentine, largely used in Bhera (Shahpur district) for making hafts of *peshquabz* (Afghan knives) and of hunting- or ordinary table-knives, small boxes, etc.

**Trade.**—In Upper Burma the export trade in jado-stone is very considerable. Some passes into South-West China by the overland route, but most finds its way down to Rangoon, whence it is exported to the Straits Settlements and China. During the six years 1897-1903 the exports averaged 3,911 cwt., valued at £44,770, giving an average value per cwt. of £11.45. The exports in 1906-7, according to the Official returns, were 2,998 cwt., valued at Rs. 8,02,270.

11. **Lapis Lazuli.**—Ball, l.c. 528-30. The *lajward, rajaviral.*

A mineral of complex composition, but consisting chiefly of silica, alumina and lime. It is commonly known as ultramarine from its blue colour. The mineral powdered was largely used in India for house decoration and book-illumination. [Cf. Paulus *Égineta* (Adams, transl.), iii., 200-1; Linschoten, *L.c.* ii., 144; Tavernier, *Travels*, 1670 (ed. Ball), 1889, ii., 156; Milburn, *Or. Comm.*, 1813, i., 138.]

12. **Quartzose Minerals.**—Quartz is the natural silicic anhydride, but hydrated silica also exists. This has led to the classification of the stones of this kind into:—crystallised or phanero-crystalline anhydrous quartz, represented by the rock-crystals; uncrystallised or cryptocrystalline anhydrous quartz, including chalcedony, jasper, agate, etc.; uncrystallised hydrated quartz. The opal is a type of this last group.

(a) **Rock-crystal.**—Ball, *L.c.* 502-3; Holland, *L.c.* 107. The *bilaur, phatak, tansal.*

**Sources.**—Rock-crystal is the name given to the transparent varieties of crystallised quartz, the different colours which are met with being due to the presence of small quantities of foreign minerals. These coloured varieties are known by various names, e.g. Amethyst, Cairngorm, Rose-quartz, Smoky-quartz, Milk-quartz, etc., and Holland makes the following statement regarding the occurrence of this gem and its use in India:—"In the Tanjore district, Madras Presidency, fragments of rock-crystal are collected and cut for cheap jewellery, being known as "Vallum diamonds," whilst the bi-pyramidal quartz-crystals found in the gypsum of the salt marl near Kalabagh, on the Indus, are to a certain extent used for making necklaces, and rock-crystal is similarly used for cheap jewellery in Kashmir." In *Indian Art at Delhi*, 1903 (l.c. 78), it is stated that rock-crystals are also largely cut and made into sword and dagger handles, beads, buckles, necklaces, etc. These are turned out fairly extensively in Jaipur. The so-called "rock-crystal" buckles, etc., of Kashmir are very largely made of paste diamonds. [Cf. Mandelslo, *Travels*, in Olearius, *Hist. Muscovy*, etc., 1662, 83; Tavernier, *L.c.* i., 389; Milburn, *Or. Comm.*, 1813, i., 360-1; *Min. Prod. Ind. Rev. and Agri. Dept.*, 1892, 3; Watt, *Rev. Min. Prod. Ind.*, 1894, 18; Nicholson, *Man. of Coimbatore Dist.*, 1898, ii., 150.

(b) **Agate and Carnelian.**—Ball, *L.c.* 503-4; Watt, *Ind. Art., l.c.* 73-5; Holland, *L.c.* 107; *yanmi, manka,* etc.

Agates are concretionary masses or nodules, which occur usually in hollows or veins in volcanic rocks. When cut across, the sections show layers. Their composition consists of 70 to 96 per cent. of silica, with varying proportions of alumina, coloured by oxide of iron or manganese. Various varieties are found, known as Mocha stones, Moss Agates, Bloodstones, Chrysoprase, etc.

**Sources.**—According to Holland, a considerable trade in agate and the related forms of silica, called *hakhik*, still exists. These are obtained from the amygdaloidal flows of the Deccan Trap, chiefly from the State of Rajpura, where the main source is a conglomerate near the village of Ratnapur. Here the right to collect *hakhik* is leased for a period of five years at an annual rental. The most
important place at which agates are cut is Cambay, but a certain amount of agate-cutting is also carried on at Jabalpur, and other places within range of the Deccan Trap. They are much used for ornamental and decorative purposes, being made into brooches, rings, seals, cups, etc. The ancient murrhine vases, famous from the time of Pliny, are supposed to have been made of agates from Broach and Cambay. While collecting the pebbles the miners divide them into two primary classes—those that are not improved in colour by burning, and those that are. Of the former there are three chief varieties: (1) the Onyx, known as mora or bhawa ghor; (2) the Cat’s-eye, cheshamaddar or dola; and (3) a yellow half-clear pebble called ror or lasania. All other stones are baked to bring out their colour. During the hot season, generally in March and April, the stones are spread in the sun in an open field. Then in May, a trench, two feet deep by three wide, is dug round the field. The pebbles are gathered into earthen pots, which, with their mouths down and a hole broken in their bottoms, are set in a row in the trench. Round the pots, goat or cow-dung cakes are piled, and the whole kept burning from sunset to sunrise. The pots are then taken out, the stones examined, and the good ones stowed in bags. About the end of May the bags are carried to the Nerudda and floated to Broach. Here they are shipped in large vessels for Cambay, and offered for sale to the Carmelian dealers.

By exposure to the sun and fire, among browns the light shades brighten into white, and the darker deepen into chestnut. Of yellows, maize gains a rosy tint, orange is intensified into red, and an intermediate shade of yellow becomes pinkish purple. Pebbles in which cloudy browns and yellows were at first mixed are now marked by clear bands of white and red. The hue of the red carnelian varies from the palest flesh to the deepest blood red. The best are of a deep, clear, and even red colour, free from cracks, flaws, or veins. The larger and thicker the stone, the more it is esteemed. White carnelians are scarce. When large, thick, even coloured, and free from flaws, they are valuable; yellow and variegated stones are worth little. It may be of interest to add in this connection that the burning of agates at Cambay is fully described by Barbossa at the beginning of the 16th century, so that it would appear to be a fairly ancient industry. And moreover other writers of an even earlier date allude to the agates of India without specially indicating their production.

Onyx.

The onyx is the general term for those varieties of agate in which the colours are arranged in flat horizontal planes. It is reported to be plentiful in the crystal pits in the Betul district, and to occur near Amerwara in Chhindwara. It was formerly in great repute for cameo work, and is employed for various articles of adornment. [Cf. Milburn, L.c., ii., 515; Watt, Rev. Min. Prod., L.c.]

Jasper.

A quartzose mineral, commonly of a red or yellow colour. The former occurs among the Cambay stones from the Deccan, and the latter in Tenasserim. A green variety is found in Burma, and fine specimens of ribbon jasper are met with in the Sandur hills, Bellary. [Cf. Garcia de Orta, 1563, Coll., xlv.]

Opal.

(c) Opal.—The dhididi pathar.

Compact uncrystalline semi-transparent to opaque hydrated silica. There are various varieties, of which the most valued is the Noble Opal, of a milky white colour, opalescent and exhibiting a rich play of colour. [Cf. Milburn, L.c. ii., 515; Bennett Brough, Mining Non-Metall. Min., in Journ. Soc. Arts., Jan. 15, 1904, 174.]

Cat’s-eye.

(f) Cat’s-eye. — The chush-maidar, laeniyâ or lahansiya.

A variety of chalcedonic quartz, presenting a peculiar opalescent reflection, said to be due to the presence of asbestos. It is called Cat’s-eye from its resemblance to the eye of a cat, hence also the Burmese name kyiung, which has that meaning. [Cf. Garcia de Orta, 1563, Coll., xlv.; Linschoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), 1885, ii., 141; Milburn, l.c. i., 361.]

Tourmaline.

GLASS AND GLASSWARE

A mineral of very complex and variable composition occurring in the granitic and metamorphic rocks of most countries. It is generally black, when it is termed schorl; red varieties (rubellite), dark-blue (indicolite) and white (achroite) also occur. The red variety is commonest in India, good specimens being of a deep crimson colour. White specimens have occasionally been found among the black stones from the Shan States, and green tourmaline has been mentioned as occurring in the Hazaribagh district of Bengal and in granite dykes in the bed of the Kauveri, Seringapatam. Holland states that various attempts have been made to work the red variety which occurs in the Ruby district of Upper Burma. In 1898 an output worth £230 was reported, in 1900 worth £1,340, and in 1903, £196, but returns for 1898 and 1902 are not available. [ Cf. Milburn, I.C. p. 1859, 82; Min. Rev., 1895, 42; 1897, 40; Scott, Gas. Upper Burma and Shan States, 1900, ii., pt. i., 227–30; 1901, pt. ii., 392.]

GLASS AND GLASSWARE.—Glass is known in India by the vernacular names of kanch, kunnadi, addannu, shishah, kizaz. It is a mixture of silicate of potassium or sodium, or of both, with one or more silicates insoluble in water, such as those of the alkaline earths, aluminium, manganese, iron or lead. The mixture is effected by fusion.

History.—Stein (Ancient Khotan, 1907, 372), in discussing fragments of glass picked up at Niya (3rd century), observes, "Glass was in the middle of the fifth century of our era known in China only as an import from To-Chin, the Far West (Hirth, China and the Roman Orient, 228 et seq.,), and it appears very improbable that the introduction of glass manufacture could have been delayed so long, if the making of glass had been an art practised in Eastern Turkestan when the latter was under Chinese control during earlier centuries. It is significant that, according to the Pei shih, the first makers of glass in China were traders from the country of the Great Yukh-chih, i.e. from the Old Indo-Scythian dominion, for whom the land route through Khotan was a more likely line of communication than the sea route."

In India glass is little employed for the purposes it is ordinarily used in other countries (windows, bottles, etc.), and the process of manufacture, as carried on by the Natives, is accordingly very crude and unscientific. The chief materials employed are carbonate of soda in its crude condition, called reh, and the impure sands of the rivers with certain special earths, etc. The ordinary Native glass is a coarse, impure, coloured or dirty mass, full of flaws and air bubbles, and suitable only for the manufacture of beads, coarse bangles and other minor articles. White glass is sometimes made (or rather re-made) by melting broken glass or glassware of European manufacture.

Indian Production.—The chief centres of the glass industry to-day are the Lahore, Karmál, Jhelam and Hoshiarpur districts of the Panjáb; the Bijnor, Lucknow and Saharanpur districts, United Provinces; Ahmednagar, Kaira and Baroda, Bombay; Seoni, Central Provinces; Patna, Bengal; lastly the State of Jaipur and the North Arcot district, Madras. The chief articles manufactured are bangles (chiris), beads, crude globes, silvered with mercury or tinfoil, coarse toys, small bottles, lamp chimneys, etc. The only glassware in India with any pretension to art is that produced at Patna. The articles are generally coloured and the shapes very elegant but exceedingly fragile. The industry is said to be dying out for want of demand. Special mention may be made of the glass mosaics seen in the palaces of some parts of Rajputana, the Panjáb and Burma. It was to meet this demand that the industry of blowing glass globes, silvered inside, sprang into existence. The globes are broken up into fragments of certain sizes, then set in cement (or in Burma in lacquer), and in that way constitute the chief decorative feature of shish mahals (looking-glass palaces). The smaller fragments of silvered glass are also worked up into the embroidered phulkari cloths of the Panjáb. There is in addition the true mosaic art where coloured glass elaborates a pattern, as seen in the palaces of Udaipur.

The influences that operate against the establishment in India of glass works on a commercial scale are the cheapness of the imported Western products, the want of enterprise on the part of capitalists, and the unfavourable climatic conditions. Recently several praiseworthy efforts to extend the manufacture of
GLASS WORKS AND TRADE

Trade in Glass.—The total imports into India of glass and glassware of all kinds, including Government stores, were in 1876–7 valued at Rs. 29,45,091; twenty years later (1896–7) they stood at Rs. 72,25,918. For the five years ending 1906–7 they were as follows:—1902–3, Rs. 96,15,631; 1903–4, Rs. 1,01,17,065; 1904–5, Rs. 1,14,21,397; 1905–6, Rs. 1,14,79,658; and 1906–7, Rs. 1,23,75,725. The analysis of the commercial returns (1905–6) might be given as follows:—13,769,052 superficial feet of sheet and plate glass, valued at Rs. 12,44,884; 22,520 cwt. of beads and false pearls, valued at Rs. 24,02,442; 65,785 cwt. of bottles, valued at Rs. 6,50,645; bangles, Rs. 42,78,558; lamp-ware, Rs. 6,94,138; other miscellaneous glassware, Rs. 28,43,441; Government stores, Rs. 1,61,767. The sheet and plate glass came chiefly from Belgium and the United Kingdom; the beads from Italy, Austria, Germany and the United Kingdom; the bottles from the United Kingdom and Germany; bangles from Austria-Hungary; lamp-ware from Germany, Austria-Hungary and the United Kingdom; and the other wares from Austria-Hungary, the United Kingdom, Belgium and Germany. Bangles and lamp-ware were returned for the first time in 1905–6. In the same year the Exports (Indian produce) amounted to Rs. 98,029. Bombay exported the largest amount, viz. Rs. 89,177, and the chief market was Persia, followed by Turkey-in-Asia, Arabia, Ceylon, Aden and the United Kingdom.

GLYCINE SOJA, Benth., Journ. Linn. Soc., viii., 266; Kew Rept., 1882, 42–3; Prain, Journ. As. Soc. Beng., 1891, lxvi., 403–4; Duthie, Fl. Upper Gang. Plain, 232; G. hispida, Maxim., Duthie and Fuller, Field and Gard. Crops, 1893, pt. iii., 3, 85; Leguminosae. (Following the suggestion made by Prain, the above name had better be adopted for the cultivated plant and G. ussuriensis, Regel & Maack, for the wild, which = G. Soja, Sieb. & Lucc.). The Soy Bean; in Indian vernaculars, bhat, ram, gari-kulay, hendedisom horec, pond disom, an-ing-kiyo, tsu-dza, bhainas, seta, musa, khajuea, etc.

A sub-erect or creeping annual native of China, Cochinchina, Japan and Java, comparatively recently introduced into India, though recorded as acclimatised and even seen as an escape from cultivation. It might, in fact, be described as extensively cultivated, though more as a garden than a field crop; is especially prevalent in Eastern Bengal, Assam (Barpeta Sub-division), the Khasia hills, Manipur, the Naga hills and Burma. It is not infrequent in the plains of India proper, especially in Busti, Gorakhpur, Patna and Purnea, etc. In Bombay and Madras, however, the Soy Bean has apparently hardly passed the experimental stage.

Cultivation.—Two chief varieties occur, one called white, the other black. On the plains it is generally grown by itself as a kharif (autumn) crop. The seeds are sown from June to September, and harvested from November to December. They should be placed at a depth not exceeding 1 to 1½ inches, and 18 plants
may be left, after weeding, to the square yard. A peaty soil, or one rich in organic matter, is preferred. A good manure for it is sulphate of potash, but nitrogen may be supplied with advantage in the form of nitrate of soda, or in the case of soils poor in organic matter, in the form of rape or mustard cake. In Assam it is sown with dhu (autumn rice) in April and May. The dhu crop is removed in July and August, and its stubble acts as a support for the bean plants, which are ready for harvest in December and January.

Church (Food-Grains of Ind., 1885, 140-3) gives the following analysis of the bean:—in 100 parts: water 11.0; albuminoids 35.3; starch and sugar 26.0; fat 18.9; fibre 4.2; and ash 4.6. Its chemical composition thus places it above other pulses as an albuminous food. It is eaten in India in the localities where it is cultivated, chiefly in the form of dāl or sattu. In Japan it largely used as a sauce, cheese (natto) or paste, and in China an edible oil is obtained from the seed. If cut when the pods are fully formed it makes a most nutritious fodder, and the seed-cake, as already stated, is an extremely rich cattle food. [Cf. Milburn, Or. Comm., 1813, ii., 519; Drug. Bull., Feb. 1890, 113; Trop. Agrist., 1893, xiii., 50; 1903, xxix., 175; King, Trop. Agrist., 1897, xvii., 460; Ind. Agr., March 1, 1899, 93; Ind. Gard., Feb. 9, 1899, 56; Agri. Ledg., 1903, No. 5, 137; König, Chem. Zusammensetz. der Mensch. Nahr., 1903, i., 1484; Rev. Mus. Guide, 1907, No. 1, 65.]

GOLD.

Occurrence.

Ball, Man. Econ. Geol. Ind., 1881, iii., 173-230, 608-10; Mallet, Man. Geol. Ind., 1887, iv., 1; Smith, Gold Mining in India, in Mining Institute, 1893; Watt, Min. Rev., 1894 to 1897; also Mem. Res. Br. Ind., 1894, 19-20; Bosworth-Smith, Rept. Kolar Gold-Field and its Southern Extension; 1889; Grundy, Repts. Insp. Gold Mines, Mysore State, 1894, 1895; Hatch, The Kolar Gold-Field, Quartz-Mining and Gold-Recovery, in Mem. Geol. Surv. Ind., 1901, 1-90 (numerous plates); Holland, Rev. Min. Prod., in Rec. Geol. Surv. Ind., 1905, 33; pt. i., 10, 12, 45-50. Gold has been known since the most remote classic times of India; it is indicated by the following vernaculars:—sona, gser, swarna, pucon, bungdrum, mas, kanchana, shwae, run, tibr, zahab, tilla, zir, etc.

Production.

Gold is known to occur throughout India—in the Bengal, Madras and Bombay Presidencies; in the Central Provinces, Panjáb, United Provinces, Burma and many of the Native States. The ultimate derivation is mainly the quartz reefs which traverse the metamorphic and sub-metamorphic series of rocks, but smaller quantities appear to exist in certain chloritic schists and quartzites and possibly also in some forms of gneiss. The only other sources in Peninsular India are the recent and sub-recent alluvial deposits which rest on the metamorphic and sub-metamorphic rocks. In extra-peninsular regions, gold is met with in rocks of different periods; in Ladakh in quartz reefs of carboniferous age; in Kandahār in cretaceous formations; while along the foot of the Himalaya the tertiary rocks which flank the base of the hills are more or less auriferous. Holland (l.c. 45) has pointed out that India occupies the sixth or seventh position among the leading gold-producing countries of the world, but that the total output is nevertheless insignificant, aggregating no more than 3½ per cent. of the world's annual supply. The following brief abstract of the available information regarding the occurrence and production of gold, province by province, may be useful:

Bengal.—Gold is obtained in Orissa, Midnapur, Bankura and in the Province of Chota Nagpur. In recent years attention has been drawn chiefly to the latter, where, under the control of the Geological Department, an extensive survey for gold has been conducted by several officers whose publications are mentioned below. The area examined covers part of the districts of Manbhum and Singhbhum, with the tributary States of Gangpur, Benal, Udepur and Jashpur. Commenting on Mr. Maclaren's final report, the Director says that though gold is

GOLD.

**Assam.**—For an account of the gold of this province the reader should consult Maclaren’s exhaustive paper on the Auriferous Occurrences of Assam (Ie. 1904, pt. iv., 205–32, with numerous plates and maps). In a brief notice on that paper, Holland (Rev. Min. Prod., 1905, xxxii., 140) remarks that the most striking feature of the gold deposits of the Assam valley is the universal distribution of the metal in extremely small percentages throughout the river-beds. This Maclaren holds to be due to two main causes, the wandering of the Brahmaputra over the plain and the wide distribution of the Tipam or Sub-Himalayan sandstones, which are certainly auriferous in places. The next characteristic feature is the general aggregation of gold at a point the distance of which from the hills is dependent on the strength of the current of the gold dust.

This point of general deposition is marked on the Assam rivers by the occurrence of gravels containing pebbles up to 6 inches in diameter. Above the point indicated the only deposition is that due to local diminutions in the velocity of the current, as on the beaches at the end of a long pool or on beaches lying parallel with the stream, and to which the gold is carried by the back eddies, where it is retained in the interstices between the large boulders.

The only gold deposits considered by Maclaren to be worthy of further prospecting are the Guri Mara, above the Sadiya and opposite the Chumpara Stockade; the Sibia Mukh on the Dihong river, and the Dorpari pool on the Subansiri river. The most promising deposit is that on the Subansiri. The gold in general is of good quality, but the individual gold grains, except in a few places on the Subansiri, are extremely small and much flattened.

**U. Prov.**—The production of gold in these provinces is comparatively unimportant. The only districts where it occurs in any quantity are Bijnor, Naini Tal and Garhwal, but the estimated production is only about 50 to 80 oz. per annum. The general method of working is the washing of auriferous sands found in the beds of certain rivers, most notably Ramganga, Suktar Sot, Phika and Khoh in the Nagina Tahsil of the Bijnor district.

**C. Prov.**—Gold-bearing sands occur in most parts of these provinces, but the output is comparatively insignificant. The chief localities are Nagpur Division, especially Bhandara, Balaghat, Chanda, etc. [Cf. H. Nunn, Monog. Gold and Silver-Ware, 5–10.] In Central India gold appears to be confined to the Ajmere-Merwara district.

**Panjáb.**—The districts where gold is found are Bannu, Peshawar, Hazara, Rawalpindi, Jhelum, Kangra, Ambala, Gurgaon, and Hoshiarpur. The most important are the Jhelum district, where gold to the value of £770 was produced in 1901, and a fair amount in the Hazara district. It is said that recently an application has been made to the Panjáb Government on behalf of a Syndicate in British Columbia for the grant of a dredging lease for gold in the bed of the Indus. [Cf. Maclagan, Monog. Gold and Silver Works, P5., 1888–9; Robertson, Sett. Rep. Rawalpindi, 1893, 15; Mem. Geol. Surv. Ind., 1897, xxvi., 287; Madras Weekly Mail, June 7, 1900, 502; Capital, Fed. 4, 1904.]

**Kashmir.**—Gold-washing is carried on in some villages, chiefly in the Skardu Tahsil and Kargil Tahsil, Baltistan. In the former, the chief locality is the sands of the Bashahr river, and in the latter along the left bank of the Dras-Sooroo river from Harra to Maimus, at Sher Alithang near Kharbu, and at Chuskor, some eight miles from Kargil. The market value of a tola is Rs. 20 and the State rate Rs. 18. [Cf. Drew, Jamnow and Kashmir, 1875, 409; Clarke, Skardu Tahsil and Kargil Tahsil, 1901, 10; Kaye, Note on Asses. Rep. of Kargil Tahsil, 1901, 45; Lawrence, Vindictive of Kashmir, 1901.]

**Bombay.**—Auriferous rocks occur in the districts of Dharwar, Belgaum, Kalladgi, in the South Marathá country, and in the province of Kathiawar, but the output of gold in late years has been very small. Recently, however, promising work

566
MYSORE MINES

in reef-mining has been commenced in the Dharwar district under the auspices of the Dharwar Reefs Company, Ltd.

MADRAS.—Gold is found in Madura, Coimbatore, Salem, Wynaad, the Nilgiris, Travancore, Malabar, Kanara, North Acreot and Bellary. In recent years, however, all the gold produced in the Presidency was from the Kangundi mines in the Kangundi Zemindari of North Acreot. Work was commenced there in 1898 and was continued with varying success until 1900, since when working has ceased. The highest yield was obtained in 1898, viz. 2,854 oz. Prospecting has recently been carried on at Wynaad and three of the old mines were opened during part of 1901, but did not yield any gold. [Cf. Hayden and Hatch, Gold-Fields of the Wainil, Mem. Geol. Surv. Ind., xxxiii., pt. ii.]

MYSORE AND HYDERABAD.—The gold of Mysore State is solely derived from the Kolar district, which occupies a small tract of country in the eastern extremity of the State. Roughly, the field is about ten miles long from north to south, two miles wide from east to west, and made up of synclinal folds of schistose rocks. Hatch says that the auriferous lodes of the Kolar gold-fields consist of a series of parallel quartz veins which occupy a central position in the belt of Dharwar schists. Although there are several parallel veins, it is on the Champion lode only that paying mines have been developed. "The attention of European prospectors was directed to this area by numerous Native workings of unknown age; and since operations commenced on a large scale, shortly after 1880, the gold extracted, up to the end of 1903, has reached a value of nearly 19 millions sterling. During this period five companies have paid £8,250,000 in dividends, while the Mysore State has received only one million as its royalty. The deepest workings, now somewhat more than 3,000 feet below the surface, show little diminution in the value or width of the auriferous quartz vein. During the past five years the amount of auriferous quartz crushed has increased from 337,636 tons in 1898 to 546,752 tons in 1903, and the value of gold extracted has increased from £1,576,000 in 1898 to £2,284,000 in 1903."

[Holl] Holland observes that various improvement schemes, with the object of reducing working expenses, have been introduced in recent years, one of the most important being the provision of electric power from the Kauveri Falls. The supply commenced about the middle of 1902, and has regularly furnished over 4,000 horse power to the various mining and metallurgical works. In The Madras Weekly Mail (June 1, 1905, 597) an account is given of a new discovery of gold in Mysore at Yellahanka, 22 miles north-east of Bangalore, which seems of future importance.

The citation of publications in the opening paragraph practically denotes those of Madras and Mysore, but may be added the annual reports of the various companies, of which, in alphabetical sequence, the following may be quoted:—1. Balaghat Gold Mining Company; 2. Champion Reef Gold Mining Company; 3. Coromandel Gold Mining Company; 4. Ooreum Gold Mining Company; 5. Mysore Reefs Company; 6. Mysore Gold Mining Company; 7. The New Kempinkote Gold Field; 8. Nine Reefs Company; 9. The Nundy-droog Company; 10. The Oriental Gold Mining Company; 11. the Road Block Gold Mining Company, etc.

In Hyderabad the only quartz mines producing gold are those of Hatti and Wundalì in the Nizam's Dominions. At the Wundalli mine 7,822 oz. of gold were recovered in 1899, but the mines were closed in 1900, and the Hatti mine was the only one at work at the end of 1903. In the latter mine the total output for 1903 was 3,414 oz.

BURMA.—The only reef mine of importance is the Kyankpezat near Wuntho in Upper Burma. Holland tells us that this mine yielded in 1898, 1,120 oz., and maintained and indeed increased its yield until 1902, when 1,984 oz., valued at £7,606, were produced, but in 1903 the auriferous chute was worked out and the mine closed. From recent exploration, however, Burma appears to be very rich in alluvial gold, and in 1903 a license was issued to a Company to dredge gold in the Irrawaddy above Bhamo. Gold to the value of Rs. 2,016 was produced, and the result was sufficiently successful to induce the Company to extend its operations. The greater possibilities of dredging on the Irrawaddy appear to arise from the fact that the waters of the river are derived from ranges where, even in the cold weather, there is a heavy rainfall.

[Cf. Imp. Gaz., 1907, iii., 141-3.] The Indian Agriculturist (Feb. 1905) gives the practical results of an interview with Lt.-Col. Mackenzie Foss, on the subject of the occurrence of tin and gold in Lower Burma, in which that gentleman apparently stated that, in his opinion, the district of Mergui was one

567
GOLD OF THE TRADE, Mergul.

Uses. —Gold is largely employed by the richer classes in India for the purpose of personal adornment or in the ornamentation of sacred buildings, palaces, etc. The most important art industries for which it is employed are, therefore, coins, jewellery, gold-leaf, gold wire and thread (used in the fabrication of cloth of gold (kinkhab), braids, lace, etc. Stein (Ancient Khotan), 1907, 192–4, 210, 224, 381, 496) discusses the gold-digging at Yotkan and mentions the instances where he found gold employed by the artists of the sand-engulfed ruins. These date from the 3rd to the 8th centuries. While he found gold-leaf extensively employed in the ornamentation of the idols, statuary, etc., he makes no mention of having come across an example of fabric with gold wire (thread). He met with Chinese and Tibetan brocaded silks, but no examples of the Indian kinkhab.

TRADE. —If Max Müller and others be correct in identifying India with the Ophir of Scripture, the present production is possibly only a tithe of what it has been. According to Napier (Metallurgy of the Bible), King David derived, through the trade of Ophir, gold to a valuation of £600,000,000. But another opinion fixes Ophir in West Arabia. Pliny speaks of Indian gold coming from the country of the Narees (the Nairs of Malabar), and thus practically the Mysore mines.

"Within the past few years the net imports of gold have apparently diminished. Thus the excess of imports over exports during the ten years ending 1891–2 averaged about 729,900 oz., while during the following ten years the average did not exceed 442,400. The reduction is mainly due to two causes. Large imports of gold had been made by banks to be exchanged for silver, and the accumulation of gold coin having been found inconvenient by Government—for gold does not circulate freely in the country—the surplus was shipped by the Government to London, where at the same time considerable purchases of silver were made for additions to the coinage. Secondly, the Mysore gold-mines now send to London large quantities of gold every year, and this export reduces the net imports shown in the trade returns. It is probable that on the whole there was no real decline in the demand for gold in India, which is in value about half of that of silver. In 1902–3 the net imports rose to 1,417,000 oz., and in the following years to 1,566,237 and 1,516,991" (Imp. Gaz. 1907, iii., 292).

Holland (Rev. Min. Prod., i.c. 47), commenting on Indian production, observes, "For the six years under review the value of gold extracted was £11,510,038 or 60 per cent. of the total value (£18,687,818) extracted in the twenty-one years since the commencement of work under European supervision. With the increase in output dividends have also increased, rising from £739,114 in 1898 to £1,019,347 in 1903, or an increase of 38 per cent. The total dividends paid during the six years were £4,988,793 or 60 per cent. of the dividends (£8,287,071) paid since 1882, indicating that dividends and output have advanced pari passu." [Cf. O'Conor, Rev. Trade Ind.,
GOSSYPIUM (Cotton); Watt, *Wild and Cult. Cotton Plants of the World*, 1907, 1-406, tt. 1-53. A genus of MALVAE.ZE, the species of which are widely distributed on both sides of the equator, and in both hemispheres. On the north they extend, under cultivation, to Crimea (45°), and on the south to the latitude of the Cape of Good Hope (34°).

Few cultivated plants are so difficult to understand or have been half so much confused through conflicting opinions regarding the existing forms as the cottons. Practically all the botanical names in current use were founded on cultivated plants, and these changed subsequently, and in some cases so rapidly that they are now mostly unrecognisable. Instead of rejecting a nomenclature thus hopelessly useless, one botanist after another has given his peculiar views and reassorted the published names.

The obvious duty of establishing species on the wild forms and grouping the cultivated states as near as may be possible under these, has been absolutely neglected and the literature of the genus become confusion worse confounded. Useless controversies have engaged attention, such as whether there are fifty or more species, or only three, or even only one in the whole world; another, whether a single characteristic of supreme value can be discovered, upon which a classification of the forms might be based.

The early authors divided the cottons into trees and bushes, or into perennials and annuals. It has now been established beyond dispute that all species of *Gossypium* under suitable environment are perennials if left alone, and may in time become large bushes or even small trees. Moreover, when cultivated they readily respond to environment, and when necessity exists become annuals or otherwise adapt themselves. On dry stony soils they are usually perennials, on rich loamy soils annuals, more especially if restrained by cold in the winter months or by a heavy periodic (monsoonic) rainfall or by infestations of pests. Some writers have placed confidence on the characteristics of the seed as affording a key to classification. If possessed of a double layer of wool, viz. an under-velvet or fuzz (as it has been called) and an outer layer or floss (the true wool or lint), such seeds have been regarded as denoting very different plants from those with a naked seed, that is to say, not possessed of the undercoating (fuzz). This conception originated the classification into *album* (white or fuzzy seeds) and *nigrum* (black or naked seeds). So again the fact of the seeds being free from each other or attached together into what has been called a "chain" or "kidney" mass, has been accepted as a further means of diagnosis. But as opposed to such views it has recently been shown that certain structural peculiarities have originated in consequence of adaptation to beneficial insects, such as the *kelep* ant of Guatemala, or as protective measures against enemies. Of this latter kind they very probably be the formation of the floss and of its special and varied peculiarities. Hence another set of writers have rejected all the distinctions based on the fruit or seed and have advanced the argument that selection should primarily be directed towards lowering the size and weight of the seed, and thus increasing the proportion of wool. No structural manifestations would accordingly be less constant than those based on the seed and floss. But the colour of the fuzz and floss have been even more frequently utilised as aids in classification than structural characters. The names *Nanking*
and religiosum were at first used to denote a red or kakhi coloured floss, and the belief was accepted that all woofs of that colour were obtained from one and the same species. As opposed to that view it may be mentioned that Fortune (Three Years' Wanderings in China, 1847, 264) says that the mie wha or yellow cotton of China cannot be separated from the white form, and that the seed may come up either white or yellow. [Cf. Liotard, Note, Nanking Cotton in India, 1883.] As a matter of fact it would now appear certain that most wild cottoms have a red-coloured fuzz or even a red fuzz and floss: accordingly, under negligent cultivation or as acclimatised escapes from cultivation, the woolly coating of the seeds, in the majority of species, may become reddish coloured. Conversely, red-coloured cottoms, if carefully cultivated, invariably lose their colour and become white. Lastly, still other writers have sought for a classification based on the shape and degree of hairiness of the leaves and bracteoles or the shape and colour of the flowers. But, as with most other cultivated plants, the classification of the forms of Gossypium is alone possible on the basis of the wild plants and through an aggregation of all natural characteristics, including geographic and climatological considerations, and not upon any arbitrary (single) standard.

In this view it may now be desirable to furnish the practical results of a special study of the genus Gossypium (restricting attention as far as may be possible to the Indian forms) and to draw up the history of the available information regarding the cotton industry, with special reference to the periods of discovery, the stages in cultivation, the improvement of the plants of commerce, and the progression in industrial knowledge:—

I. THE HISTORY OF THE COTTON PLANT AND COTTON INDUSTRIES.

It would not be far from correct to describe cotton as the central feature of the world's modern commerce. Certainly no more remarkable example of a sudden development exists in the history of economic products than is the case with cotton. The enormous importance of the textile to-day, in the agricultural, commercial, industrial and social life of the world, renders it difficult to believe that but little more than two hundred years ago cotton was practically unknown to the civilised nations of the West. But it is perhaps even still more singular that a fibre which, for many centuries apparently, had been a staple article of clothing in India and the East generally, should scarcely find a place in the early classical literature of these countries. Nearly all the beautiful and useful plants of India have their properties extolled by the Sanskrit poets, and indeed are frequently dedicated to the gods, but cotton—the plant above all others which might have been expected to have formed the theme of nature-worship—is hardly more than incidentally mentioned.

The Sanskrit word कप्रदाति, often rendered rendered cotton, is connected with the Greek and Latin carpesia or carbasus, and denoted a fine textile. That name was also known to the Phoenicians and Hebrews, but whether it originated in India or was imported there would be hard to say. Mr. F. W. Thomas, who has kindly permitted me to consult him on this point, informs me that "the earliest mention appears to be in the Asvalayana Sutra Sutra (say 800 B.C.), where the material is contrasted with silk and hemp, as that of which was made the sacred thread of the Brahmins. Probably the word was thus borrowed from India. The other words tula and picu are later—they denote the substance." "The Sanskrit dictionaries give four names (vadara, kaphasi, tundikeri and semudrantá) for the shrub, while the wild kind is called bharadvájí. They also mention that kaphási and vadara (the material) come from the fruit of the plant in question, while the Haracarita (circa 650 A.D.) twice speaks of the cotton (tula) from the pods of the śālāyā tree" (=-semul, Bombax malabaricum). In the Institutes of Manu injunctions exist that regulate the operations of the washermen and of the weavers, and these all point to a social organisation and industrial attainment in which a knowledge
THE OLDEST ASIATIC COTTONS

of cotton is essential, but it is taken for granted rather than expounded or justified. All this might of course argue antiquity, as it certainly does for the arts of spinning and weaving, but the word kâr̲paśi may have existed for centuries with a generic rather than a specific signification.

Similarly it is extremely difficult, if not impossible, to determine the earliest certain references to cotton in the Persian, Arabic and European classics. It is fairly clear that kûn, katân or kutun (the Arabic name from which we have derived the English word cotton) originally denoted flax, not cotton. So also in Greek, kár̲pasos, often rendered cotton, had, as already stated, the still earlier meaning of flax or simply of a fine textile. But cotton textiles had been carried to Europe, and were regularly traded in, long before any definite knowledge existed there regarding the fibre of which they were made. In fact the Greeks first learned definitely of the cotton plant through the group of explorers who visited India along with Alexander the Great and his immediate successors in Bactriana. Herodotus (450 B.C.) had written of India having wild trees that bear fleeces as their fruits. But right down to the middle of the 18th century the wool-bearing trees were divided into those with spinose and those with smooth stoma. The former were the silk-cotton trees, of which Bombax mutatbericum may be given as the type, while under the latter many of the botanical writers included kapok (Fulocarpus aviculaceus).

A large percentage of the earliest authors speak of cotton being used for quilts and mattresses, but are silent regarding its being spun and woven. Ktesias would appear to have been the first European who observed the spinning and weaving of the Natives of India, but his description does not necessarily denote cotton as the fibre. Theophrastus (350 B.C.) gives us the first definite conception of Indian cotton cultivation. He says (Hist. Pl. (ed. Schneider), iv., ch. 4, 132), "The trees, from which the Indians make cloths, have a leaf like that of the mulberry; but the whole plant resembles the dog-rose. They set them in the plains arranged in rows, so as to look like vines at a distance." He then adds that cotton cultivation may be seen both in India and Arabia. Indian cotton-bearing plants set in rows necessarily involves cultivation, but it would be equally applicable to the perennial as to the annual plant. The comparison to the dog-rose, with its open lax branches, however, brings to mind the perennial roji of Gujarat rather than the small compact bush of the ordinary annual cotton. (See below, under Roji, p. 581.)

Pliny tells us that cotton (carbaby) was in Tylos called Gossypine. He does not state whence he derived that information, but curiously enough by modern botanical writers that word has become the generic name for the cottons (Gossypium). In the Periplus of the Erythraean Sea (63 A.D.) we have the first commercial mention of Indian cottons. The raw cotton, as also the Indian cotton manufactures, were conveyed by the Arabs from "Patiala, Ariake and Barygaza" (the modern Broach) up the Red Sea to "Aduli." The Indika of Arrian, a work compiled (150 A.D.) from Nearchus, Mogasthenes, Strabo and Eratosthenes, as also other early Greek travellers, was professedly intended to supersede the inaccurate account of India given by Ktesias. After narrating the particulars above mentioned, Arrian adds that the cotton of India is whiter and brighter than that of any other country. Thus by the beginning of the Christian era we have a fairly vivid glimpse of India as a cotton-growing and cotton-manufacturing country. Stein (Ancient Khotan, 1907, 374, 412, 430, 442, etc.) mentions that cotton cultivation is very largely pursued around the modern Khotan, and in other passages he refers to fragments of cotton garments, etc., found in the ruins of the ancient city, which must be accepted as dating from the 3rd to the 8th century. These are doubtless the oldest authenticated examples of the Central Asiatic cotton industry at present known.

The simple reference to a fibre or textile, under such names as kâr̲paśi, katân, tinon, carbaby or Gossypion may be of no historic value whatever. It has to be shown that the word had the same significance then as to-day. Many illustrations might, in fact, be given of the confusion that prevailed regarding the separate recognition of the chief textiles of the world, down even to the 17th century. In Manchester, for example, a particular texture of goods, woven of wool, was in 1590 sold under the name of "Manchester Cottons." In 1664 the dispute between Sir Martin Noel and the East India Company as to whether "Calico was linen or no" became acute, and that controversy shows how very reluctantly the name "cotton" was in England accepted as indicative of a distinct fibre.
GOSSYPIUM
History

Arab Authors.

There is, however, every reason for believing that the Arabs knew of cotton and wore cotton garments before the present era. Unhappily no writer can be discovered who effectually bridges over the gap between the period of the Periplus and that of the physicians who wrote in the 7th to the 10th centuries. Serapion, an Arab medical writer (who lived about 850 A.D.), quotes several earlier Arab authors, among whom Ibn Hanifa, he says (speaking of Kelbe), described the cotton as growing there on trees which lived for twenty years but attained their best bearing condition about the ninth year. Renaudot gives a translation of the journal of an Arab (Sulaiman) who visited China and India in the 9th century. The original Arabic MS. bears the date 1173, and was translated in 1718 by Renaudot, and again in 1845 by Reinaud into French; but there is an English edition dated 1733. Speaking of the town of Calicut, he says that "garments are made in so extraordinary a manner that nowhere else are the like to be seen. They are for the most part round and woven to that degree of fineness that they may be drawn through a ring of middling size." Sulaiman also makes special mention of the fact that the Chinese, rich and poor, were seen to be dressed in silk, but he says nothing of cotton in China. It is one of the many surprises met with everywhere in the study of the world's production and trade in cotton, that the plant was not cultivated in China for its fibre until the 13th century. In the 6th century we read of the Emperor Ou-ti having possessed a robe of cotton that he held in much esteem. Towards the end of the 7th century cotton was an ornamental shrub in Chinese gardens. Mayer says that it was not until about 1000 A.D. that the plant was fully introduced into China, and this view is accepted by Bretschneider. There was apparently in China (as in Europe) much opposition to the introduction of cotton as a textile.

Indian Perennial Cottons.

Marco Polo (who travelled through a large portion of Asia in 1290 A.D.) refers to the production and manufacture of cotton in Persia, Kashgar, Yarkand, Khotan, Gujarat, Cambay, Telingana, Malabar, Bengal, etc., but is absolutely silent on these subjects in connection with China. Speaking of Gujarhat, he says the cotton trees are of great size and attain an age of twenty years, but he adds, when of that age the cotton is only used to quilt or stuff beds. Referring doubtless to Masulipatam, he says it produces specially fine "buckrams" (muslins) and chintzes. The Rev. E. Terry, Chaplain to Sir Thomas Roe's Embassy to India in 1615, speaks of the cotton plants near Surat as growing for three or four years before being uprooted. The cotton plant seen by Rheede in Malabar, during 1686, he describes as a shrub 10 to 12 feet in height, found growing in sandy places—he does not say cultivated.

Cotton in Egypt.

Turning now and very briefly to Egypt. Pliny, in his account of Ethiopia, speaks of the portion that borders on Egypt having cotton plants that afford a more copious yield than is customary in any large pods. Yates (Text. Antig., 1843, 334-54), commenting on that passage, observes that the plant referred to may have been G. arboreum. He further says that cotton was not grown in Egypt proper during ancient times. In support of that view he affirms that the MS. copies of both Pliny and Julius Pollux (a century later than Pliny), that have been cited as upholding an ancient cultivation, have had that interpretation put upon them as parts taken from the original text. He accordingly maintains that cotton was first cultivated in Egypt about the 13th and 14th centuries, and in support of that opinion mentions the fact that the Arab physician Abdullatif, who visited Egypt in 1200 A.D., and published a list of the plants he saw, makes no mention of cotton. Further, Yates points out that the ancient paintings and sculptures of Egypt, while they show flax cultivation and purification of the fibre, give not the slightest indication of cotton. And this view is confirmed by Prosper Alpinus (De Pl. Aegypti, 1592, 29), who makes the significant observation that the Egyptians in 1592 imported cotton for their own use from Syria and Cyprus, and only cultivated in their gardens, as a curious and ornamental plant, the Gossypium which he figured and described, viz. G. arboreum. He adds, however, that the Arabs make webs of that cotton which they call sesa. Forskal (Fl. Eg. Arab., 1775, 125) indicates two forms of cotton met with by him: G. rubrum, which he says was known to the Arabs as oth, hadie, or odjas (from the description given, the plant indicated was very likely to have been G. arboreum, Linn.); while his second species (which he calls G. arboreum) answers fairly closely to G. herbaceum. [Ofj. Adler and Caseanowitz, Biblical Antig., in Ann. Rept. Smithsonian Inst., 1896, 1005.]

It is thus very remarkable that the accounts given by the earlier authors
regarding Indian and Egyptian cottons almost all point to perennial, not annual plants, and so persistently as to suggest that the annual stock may have been a subsequent discovery obtained very possibly from Arabia.

In the 9th century Sicily was taken by the Saracens, and according to Abu Zacaria Ebn el Awam (Banqueri, transl., ii., ch. 22, 103) they at once introduced the cultivation of cotton. From the account given of the methods of cultivation the plant must have been the annual stock, now known as *Gossypium herbaceum*. In the 10th century the Muhammadans carried the self-same cotton plant (as I take it) across the Mediterranean to Spain, and for three centuries thereafter Barcelona had a flourishing cotton industry. There would thus seem no doubt the plant disseminated by the Muhammadans was *G. herbaceum*, the species presently cultivated in the regions indicated. Where they obtained that plant may be a matter of uncertainty, but to-day the centre of its area of cultivation might almost be given as the northern tracts of Arabia and Mesopotamia, where it stands every chance of being indigenous. There is no doubt, however, that the Levantine (not the Indian) plant was closely associated with the early Saracens; their religion, their cotton and their sugar might be spoken of as the triple agents of their civilisation.

As a cultivated plant, that cotton was carried by them to Constantinople, and very possibly through Turkey, Asia Minor, Armenia, Kurdistan and Mesopotamia to Persia, if not even to the frontier of India. So also they in time may have conveyed it to Egypt, in connection with their Baghdad trade, which on the conquest of Spain went via Alexandria. But before passing away from this subject it may be added that there would seem no doubt a limited cultivation of cotton had been established in Crimea and South Italy some short time prior to the European conquests of the Saracens, so that it is just possible it may have existed, if it was not indigenous in some of the islands of the Mediterranean, prior to the knowledge of its utilisation as a textile, just as the tea plant existed in Assam prior to its being brought from China by Gordon and Fortune. It is not surprising, therefore, that Dioscorides should make no mention of cotton. The cultivation of *G. herbaceum* in time, however, was diffused throughout the countries bordering both shores of the Mediterranean, and a cotton trade was established which held sway for several centuries.

It may perhaps suffice for the purpose of this work to indicate very briefly the chief historic facts in the rise and present position of the cotton production and trade of the New World and of the cotton manufacturing enterprise of Great Britain. The earliest mention of the English cotton trade appears to occur in a little poetic work entitled *The Politie of Keeping the Sea*. This is given by Hakluyt in his *Voyages*, etc. (i., 213), and was apparently originally published in 1430. The merchants of Genoa are spoken of as carrying silk, pepper, woad and cotton to England, and as taking back woollen goods. It is thus probable that at an even earlier date than indicated England procured cotton from the Levant, since the fibre is spoken of as an ordinary commodity. In 1492 Columbus discovered the West Indies and America. The Spaniards on their arrival in the New World found cotton being cultivated and manufactured, from the West Indies to Peru and from Mexico to Brazil. In 1498 Vasco da Gama sailed for India round the Cape of Good Hope. The success of that expedition gave to Western Europe a direct route to India, and struck a severe blow at the commercial supremacy of Venice and Genoa. "Thus previous to the discovery of America and the West Indies and for some time afterwards, England, and probably all Europe, were supplied with cotton from the Levant." (Milburn, *Or. Comm.*, 1813, ii., 279-82). Down to the close of the 16th century England obtained her cotton (a small demand) from the Levant, and her supplies of Indian cotton goods via the Mediterranean ports. As late as 1641 we read that "the town of Manchester buys cotton-wool in London, that comes first from Cyprus and Smyrna." The supply, if any, from the West Indies must accordingly have been very insignificant. The early historians of Brazil affirm that a cotton plant was found indigenous there, and that the Natives made use of it to supply the cotton of their simple needs. In Bahia it must have been cultivated, however, since De Souza speaks of it (1570-87) as cleaned with the hoe, two or three times a year. Pizarro in 1522 found cotton in Peru, and it has since been recognised in the ancient tombs of that country. De Vaca is reported to have discovered, in 1536, a wild cotton in Texas and Louisiana. Thus then, when first made known to Europe, the American continent, as also the West Indies, possessed not only a cotton industry but both wild and cultivated cottons, independent of those of the Old World. But we know nothing for certain of

ANNUAL AND PERENNIAL PLANTS

United States.
the species of American cottons until approximately two centuries after their original discovery.

The first attempt to grow cotton in the United States was in Virginia. It was not, however, until the second decade of the 17th century that systematic cultivation was organised, and then from seed obtained both from the Levant and from the West Indies. It took nearly a hundred years from that date before the plantations became of national importance, but the seat of the industry gradually shifted south and west. England began to manufacture cotton about 1635, and continued to draw on the Levant for her supplies of the raw fibre. An outcry against the imports of Indian cotton goods began to be raised in England. Marcgraf (who died in 1644) speaks of the cotton seen by him in Brazil as having the seeds united together—the condition we now call kidney-cotton. According to Samuel Wilson, Smyrna and Cyprus seed, by the close of the 17th century, had been successfully acclimatised in Carolina.

The 18th century opened with repressive legislation passed by the British Parliament against Indian calicoes, but witnessed the imports by England and Scotland of raw cotton amounting to 1,000,000 lb. Cotton was raised in Georgia from seed supplied from Chelsea by Philip Miller (the original stock of the green-seeded plant now known as G. hiostatum). In 1782 muslins were first made in England, and in that year South American or Brazilian cotton began to be regularly received. Two years later a ship which brought eight bags of cotton from America to Liverpool was seized on the ground that so much cotton could not have been produced in the United States. In 1786 the green-seeded cotton was in the States the most largely grown of all kinds, but in that year the black-seeded or Sea Island cotton was introduced from the Bahama.

Through Patrick Walsh, Pernambuco cotton was successfully introduced into the United States in 1789. Dr. Hove was sent to India to study the Indian cotton trade and Indian cotton plants, but his mission was resented by the East India Company, and his report was not published for sixty years after his return to England. Shortly after the date of his visit the East India Company commenced, however, a series of experiments with a view to improve the quality and increase the quantity of cotton produced in India. Up to this point England obtained her supplies of raw cotton from the Levant, India, the West Indies and South America, the finest qualities being spoken of as coming from Surinam and Cayenne. The century closed with the exports from the United States to England at 9,532,263 lb. and from India at 729,643 lb.

The 19th century opened with the cotton crop of the United States being returned as 48,000,000 lb., contributed as follows:—South Carolina, 20 million; Georgia, 10 million; Virginia, 5 million; North Carolina, 4 million; and Tennessee, 7 million pounds. The exports from that crop to Great Britain were 28,000,000 lb. Total consumption of raw cotton in Great Britain came to 64 million pounds. The Indian supply from India was 64 million pounds, or just one-third of the quantity drawn from the new area—the United States of America. The first Indian cotton mill was built near Calcutta in 1818, and the first of the Bombay series in 1851. Improvements in bleaching, dyeing and cylinder printing soon placed British calicoes in a position to hold their own against similar goods from any other part of the world. Resist printing was introduced by Sir Robert Peel. The Sea Island cotton raised at Hilton Head, South Carolina, fetched the highest price then known. Mexican cotton-seed was introduced into Mississippi by Walter Burling, and by crossing with the existing plant was supposed to have improved the quality of the cotton very greatly. Mention, so far as I can discover, has never been made of any of the indigenous cottons of the States (if such existed) having been grown by the colonists. They grew first Levant cotton, then Miller's green-seeded cotton, and finally Sea Island cotton. Which of these was crossed with Mexican has not been stated, but presumably the green-seed, and this hint should be of value.

Cotton cultivation was systematically prosecuted in Egypt about 1821, and rapidly obtained a position in quality of staple second only to that of the States, but there is very little information as to the original stock or of the subsequent stages in the production of the better races now met with in that country. The year 1825 witnessed ruinous speculation in cotton. From 1829 to 1841 the East India Company made strenuous efforts to improve the Indian staple. Large sums were spent in the form of awards, and ten experienced cotton-growers were procured from the Southern States of America with a view to establish the cultivation of New Orleans cotton. Excepting in Dharwar, failure was the
INDIAN AND ARABIAN WILD COTTON

GOSSEPIUM HERBAEUM
Levant Cotton

only result, and the subject was allowed to drop from public attention. In 1841 cotton yarns were in Manchester spun up to No. 460's, and the United States rapidly obtained a monopoly of the market in raw cotton. In 1850 the imports into Great Britain were 664 million pounds of raw cotton, and her exports of manufactured cotton goods were valued at £28,000,000. About this time a scheme was formulated in England to raise a sum of £20,000,000 to be expended in India during five years, in measures calculated to forward India as a cotton-producing country. The outbreak of the Mutiny put an end, however, to these negotiations. Commenting on the effect of the American Civil War and the Great Cotton Famine of 1862-6, Dabney (The Cotton Plant, U.S. Dept. Agri. Bull., 1896, No. 33, 14) very truly observes, "Probably no equally great industry was ever more completely paralysed or had its future placed in greater jeopardy than cotton-growing in the United States during the war of 1861-5." In 1863 a Cotton Commissioner was appointed for Bombay, and the year following for Berar and the Central Provinces. Cotton farms were established under these Commissioners. The Bombay Cotton Frauds Act IX. of 1863 became law, but it is generally believed it did more harm than good and was shortly after repealed. For the ten years ending 1859 Great Britain imported an average of 2,318,575 bales of cotton (each 400 lb.), and of that amount India supplied 405,291 bales. But the ten years ending 1869, which included the troublous times of the American war, Great Britain imported an average of 2,736,601 bales, of which India supplied 1,282,172 bales—the record year being 1866, when India furnished 1,847,759 bales. Thirty years later (1899) Great Britain took 4,065,617 bales, of which India furnished only 77,297 bales; but in 1903 the Indian portion slightly improved, Great Britain having taken 208,550 bales of Indian cotton.

The immediate response made by India during the cotton famine shows her capabilities, but as in the United States, so in India, the demands of her own mills had become a controlling factor in the amount available for export. But the 19th century closed with India, instead of exporting cotton goods, having become the largest single market for English manufactured cottons—its demands for British cotton goods having been just under £20,000,000.

The 20th century may be spoken of as characterised by a new feature, namely, the rise of Continental, American and Indian cotton-manufacturing enterprise seriously threatening the supremacy of England in the cotton markets of the world. The Tariff Commission's Report of June 6, 1905, may be said to have been written with a view to establish this new phase. From that publication the following may be abstracted:—In 1876-80 the annual consumption of cotton in the United Kingdom exceeded that of the Continent by 2,030,000 cwt., and that of the United States by 5,070,000 cwt.; in the period 1901-4 the annual consumption in the United Kingdom was 8,020,000 cwt. less than on the Continent, and 2,930,000 cwt. less than in the United States.

II. THE CULTIVATED AND WILD COTTONS OF INDIA.

(A) FUZZY-SEEDED COTTONS OF THE OLD WORLD.

G. Stocksii, Mast., Fl. Br. Ind., 1874, i., 346; Watt, Wild and Cult. Cotton Pl. of the World, 1907, 73-7, t. 6; hiraguni kápás. This very interesting wild species is found near Karachi, India, and across the Persian Gulf, on the Dhofar Mountains of South-East Arabia.

There would seem little doubt that the writers who have supposed this to be the wild condition of G. herbaeum, Linn., are in error, but not more so than those who have taken it for a naturalised and degenerate state of some American species. Moreover, no one would appear to have demonstrated by actual experiment the forms, if any, that have resulted from using G. Stocksii in hybridisation with other species, hence its influence on the Indian cultivated cottons must be accepted, for the present, as purely imaginary.

GOSSYPIUM
ARBOREUM
Deo Kapas

Habitat.—Probably indigenous to North Arabia and Asia Minor. Not known to exist as a wild species anywhere. It occurs in the Mediterranean regions (Sicily, Malta, Greece, Crete, Cyprus, Algiers, Turkey), in Syria, Mesopotamia, Armenia, Persia, Afghanistan, Baluchistan, in the North-West Frontier Province of India, and in the northern portions of the cotton area of the United States of America. It may, in fact, be described as a warm-temperate species, and is at least one of the plants that yields, or formerly yielded, the so-called “Short-staple American Cotton” of commerce. There is every reason for believing that it was the species first cultivated by Europeans. It was the bushy, cultivated, annual Gossypium or Xylon first mentioned by botanical writers. Moreover (as already fully shown), the field plant of the Levant was the first commercial cotton of Europe, which, at an early date, was carried to the United States and there largely cultivated some time before the discovery of the other special races that ultimately drove it into a position of secondary importance. It was that discovery, in fact, that gave the States their supremacy and caused the area of production to move to the south and west.

From the practical standpoint it is essential, therefore, that a clear conception of the plant which in all probability was the species that first attracted the attention of European manufacturers. Dr. Roxburgh—one of the most accurate of botanists—described and prepared an MS. drawing of an Indian plant which he accepted as being G. herbaceum Linn., but in that opinion he was in error. If, in the two forms, it is found that one is a distinct, G. herbaceum, Roxb., and G. herbaceum Linn., are so. As understood by Roxburgh, the Indian plant embraced Dacca Cotton (G. neglectum, Tod.), also the Berar and China Cottons (G. Nanking, Meyen). It was apparently with the object of primarily separating the Indian country cottons from the Levant plant that Todaro formed his G. Wightianum. That species was founded on but one form (Oss. Sp. di Cot., 1863, No. 12, 47), but subsequently Todaro fell into the error of grouping several Indian plants with it.

Cultivated Forms.—The forms of G. herbaceum, Linn., that are deemed of greatest value are (a) those suited to cold countries, and (b) those in the United States that are so much hybridised with G. hirsutum that they are often accepted as grades of that plant. The large-leaved hairy states of this species require a much warmer climate than the sub-glabrous (and therefore more) typical conditions. Some of the recent writers, such as Cook (U.S. Dept. Agri. Bul., 1906, No. 88, 9), would appear, however, to go to an unnecessary extreme when they affirm, as Cook does, that “the Upland type of cotton was recognised as a distinct species by Linnæus under the name G. hirsutum, but many subsequent writers have erroneously confused the Old World species G. herbaceum, which is not cultivated in the United States, though often so reported.” It certainly was very largely cultivated prior to 1732, and for many years thereafter, as the Upland Cotton, and I believe still survives, though mostly in a state of hybridisation with G. hirsutum.

Habitat.—A small tree or large shrub which has often been claimed as originally an African species, but few botanists have discovered it anywhere in what could be regarded as an indigenous habitat. It has been reported as wild in Upper Guinea, Abyssinia, and Upper Egypt. [Cf. De Candolle, Orig. Cult. Plants, 405.] Certainly so far as botanical publications are concerned it was figured and described by Alinus as an Egyptian plant a hundred years before Plukenet wrote of it, “Gossypium herbaceum maderaspense.” It is said to be met with in gardens (especially near temples) in Egypt, Africa, Arabia, India, but though much less abundant has also been found in China, Japan, Java and the Malaya. Lamarck (quoting Sonnerat, Hist. Voy., x., 460), speaks of it as growing plentifully in the plains of Macassar. So far as presently known, the arboreous

576
form (which may be called the typical condition) can hardly be said to be cultivated as a source of fibre to-day, though according to Indian tradition it is the cotton that should be selected in preparing the Brahmanical string, and has often been affirmed was also the cotton specially used by the Egyptian priests in the construction of their robes. Many of the Arab writers speak of its fibre as spun and woven. The classic records of a "tree-cotton" carry us many centuries beyond the first mention of a herbaceous field crop, and what is even more curious still, most of the early writers on Indian cottons, such as Rheece, Terry, Rumplius, etc., describe and figure "tree-cottons" (from admitted personal knowledge), but say absolutely nothing about herbaceous field crops of cottons.

Cultivated Forms.—I regard this species as embracing several fairly distinct forms, some of which have been assigned independent positions by certain authors. But while in these a natural assemblage of characteristics is preserved, hardly any one feature is constant. Thus, for example, the flowers may be yellow, the leaves may be very considerably hairy, and the seeds of the seeds may be grey or brown. The more arborescent form occurs chiefly (so far as India is concerned) as an ornamental garden plant. When grown as a field crop G. arboreum may be either an annual or perennial, and in the latter case is generally sown in rows, being thus employed to shade more delicate annual cottons or other plants. Moreover, the agricultural forms are so much modified, very possibly by hybridisation, that they cannot be regarded as constituting varieties—in fact, many of them are but climatic sports that lose their properties on being carried from one region to another. It may be accepted, accordingly, that in India at least the cultivation of G. arboreum is quite as ancient, if not more ancient, than that of any other cotton. Some of the Indian races referable to this species (primarily) may be regarded as having derived from G. arboreum the soft silky character of their flosses, while the length and strength of their staples have come from the other ancestral elements. In others a strain from G. arboreum would seem to have been sought on account of the strength thus imparted to withstand seasonal climatic changes—the plant for the most part becoming a hardy perennial.

There are many cultivated states of this species found all over India, Egypt and Africa. As already explained, these manifest a constant tendency to throw back towards the arborescent condition with dark purple flowers, whenever they are allowed to become perennial or to be naturalised. The following are some of the more remarkable varis or cultivated races of this species:—

Var. sanguinea, Watt, l.c. 91-5, t. 9; G. sanguineum, Hassk., Cat. Hort. Bog., 200; Todaro, Relaz. Cult. dei Cot., 1877-8, 179, t. 1. This form is rarely met with in India, though frequent in Africa. A red-flowered herbaceous field cotton was, however, at one time common in India, and is occasionally still met with in Oldh. Buchanan-Hamilton, who gave special attention to the subject of the Indian cottons, did not apparently preserve a specimen of G. arboreum proper in his herbarium. Sets of his plants are to be seen in the Kew, the British Museum, the Wallichian and more especially in the Edinburgh herbaria, and among these may be discovered admirable samples of a red-flowered herbaceous plant which botanically is derived almost immediately from G. arboreum, with possibly a strain of G. Nunking. Of that plant Buchanan-Hamilton has recorded the following observation:—"No. 1549, G. nigrum, vide Comment. meum in Hort. Mal. p. primam. var. (a) rubicundum; G. indicum, Willd., Sp. Pl., iii., 803? Colum ubique in India vulgarissima." Now if the plant shown by that specimen was cultivated everywhere in India and very common in 1808, it must, I fear, be spoken of as a nearly unknown to-day and its place taken by a multitude of forms of yellow-flowered plants considerably more remote from G. arboreum, Unn. Of these may be mentioned:—

Habitat.—A large pyramidal bush, chiefly grown as a field crop. Cultivated
throughout Bengal, Assam and the United Provinces, less abundant in South India and Burma, distributed by cultivation to Africa, the West Indies and China. The names given to this plant, and the traditions of the people of India regarding it, suggest its having originated in the drier tracts of the Gangetic basin. Recently it has been carried to all the regions where the perennial cottons (presumably of *G. Nuancing* origin) formerly prevailed, and the craving for a short cheap staple has even seen its attempted cultivation in Gujarat and Kathiawar—the home of what may be characterised as the long-staple cottons of India.

In point of historic sequence, the earliest botanic reference to this plant would appear to be that in the *Hortus Malabaricus* (1680), thus associating it with India, the headquarters of its present-day cultivation. Rheede speaks of it as a shrub 10 to 12 feet in height, found growing in sandy places. But as it to remove the possibility of its being supposed to be *G. arboreum*, he carefully describes the long, narrow segments of its smooth, soft leaves, and then adds that the flowers are pale yellow with purple claws and the seeds have a white to grey fuzz. Buchanan-Hamilton, who wrote a commentary on Rheede’s great work in 1822, and had himself visited Malabar, observed that so far as he had seen in that district, cotton was raised (as Rheede had described it) by the Natives in the form of small trees planted in corners of gardens and not in fields, nor was the cotton for sale. But Buchanan-Hamilton, unfortunately, had come to the conclusion that all the cultivated cottons of India were mere races that differ from each other vastly less than do the varieties of the cabbage. He thus did not allow himself to realise that even accepting so restricted a botanical view, they might still be of great agricultural and commercial value, and therefore worthy of separate recognition. Accordingly, he omitted to add that the cotton of Malabar might be described as a perennial state of the self-same plant to which he had at one time assigned the name *G. viridescens*. On the other hand, Roxburgh, commenting on Rheede’s *Cudu pariri*, observed that he could not bring himself to believe that it was *G. arboreum*. The fact that it was a small tree and thus a perennial precluded him apparently from assigning it its true position along with the "Bengal and Dacca Cottons," to which he most unfortunately gave the name *G. herbaceum*.

The cultivated races of this plant known to exist in India are very numerous and much diversified as to yield and merit of staple. Perhaps the most significant feature of the story of this variety is that while to-day it affords the most inferior grades of Asiatic cottons, at one time it seems to have yielded several superior staples. Of these may be mentioned the much-talked-of Dacca cotton.

This very remarkable cotton might fairly well be described as an extreme form of *var. neglecta*. It is raised as an annual crop by the people of the Garo hills, who use it in the fabrication of a peculiar kind of blanket, which is formed by rows of tufts of the wool placed by hand across the fabric and bound in that position by the weft being forced home on each such row. Whether this peculiar textile suggested the selection that has resulted in the production of the Garo hills long-boll cotton, it is difficult to say. Certain it is that when carried to other parts of India the plant throws off most of the characteristic features above indicated and becomes a large form of *var. neglecta*, or perhaps rather of *var. rosea*.

**Var. rosea**, Watt, l.c. 112–4, t. 14; *G. roseum*, Tod., *Relat. Cult. dei Cot.*, 164–8, t. 2; Nurdki Cotton, Middleton, l.c. 11; *G. roseum*, Gammie, *Ind. Cot.*, 1905. The *varadi*, *katil belati*, *nimari*, *bangai* (Sylhet), and *nurdki* (Bengal).

This is in reality but an extreme form of *G. arboreum*, *Linna.* var. *neglecta*. When shown a typical example of this plant by itself (such as Wight’s No. 213 from Coimbatore) there is little difficulty in admitting it to a varietal position. But when the study is extended to the cotton fields it is found that the transition into the ordinary form of *var. neglecta* is so gradual and continuous that it is impossible to separate the two. In fact, the so-called acclimatised Garo hills cotton of Nagpur might even more accurately be described as the present plant. The cultivators of India, being familiar with the normal condition, had brought to this this robust and hardy plant with its small pink-coloured flowers and large bolls, and they at once gave it distinctive names, such as those mentioned above. It is the most inferior of all Indian cottons, though the most prolific yielder.

578
CHINESE AND JAPANESE COTTONS

The advance of the varadi cotton across India might be said to have been some few years ago regularly chronicled from district to district and hailed as a treasure by the advocates of low-grade cottons, while viewed as a calamity by others. Middleton says: "White-flowered cotton is a dangerous rival to the finer varieties. By nature it is made to supplant. When brought to a new district, instead of pining as most exiled cottons do, it develops all its best properties, grows robust, matures early, is prolific and so wins the favour of the cultivators; once established, it begins to degenerate, joins company with the worst of the native varieties, and forms the mixed growths that constitute the bulk of the 'Bengals' of commerce."

It is most curious that the name vilayati, often given to this as also to other robust races of G. arboreum, var. neglecta, should have begun to be used in Khandesh and Berar about the very time that the record exists of Major Trevor Clarke having supplied seed of a cross he had effected between the Garo hills cotton and Hinganghat. It is thus fairly certain that one of the first serious efforts to improve the Indian stock gave to the cotton growers of that country their most prolific though most inferior staple-yielding plant.

Habitat.—An annual or perennial bush with delicately formed and often purple-coloured twigs; cultivated in China, Japan, the Malayas, Siam, Burma, India, the North-West Himalaya, Persia, Central Asia, Celebes, Upper Egypt and Africa (doubtfully in Madagascar and Arabia). No person has recorded the discovery of the wild state of this protean species, and yet its specific characteristics are so constant with many of the cottons, within a large part of the areas indicated, that the separation of the assemblage, from G. herbaceum, G. arboreum, and G. oblatofollum, not only meets a commercial necessity but coincides with many historic facts of importance.

Trigault (1615) says that cotton grows in great abundance but is not indigenous to China, in fact was introduced (? from Egypt) about four hundred years before his time. Dampier (Voyages, 1691) speaks of having seen a small cotton plant on an island near Formosa. One of the most interesting of the early writers on Chinese Cotton may be said to be Barrow (Travels in China, 1806 (2nd ed.), 550–7, 560). He tells us that the beautiful coloured cotton, known in commerce by the name of the chief city Nanking, was exported, the Chinese purchasing in exchange the cheaper white cottons of Bengal and Bombay. It was, he remarks, planted in rows and grew for three years, thereafter being uprooted and the fields prepared for other crops. Fortune (Three Years' Wanderings in China, 1847, 264) explains that the kakhi or Nanking cotton was a mere sport from the common white cotton of China.

Economically G. Nanking is, at the present day, doubtless much more valuable than var. sanguiina or any of the other G. arboreum forms. Moreover, some of the G. Nanking series display characters of far greater interest than the mere length of the corolla (which Todaro lays stress on), and they might, in fact, be broken up into several varieties or distinctive races. Thus, for example, Bretschneider's specimen has the seeds black and almost devoid of an under-velvet—a character which brings to mind the naked black-seeded so-called indigenous cottons of South India (see below), but it is highly probable that both these may have to be regarded as indicating hybridisation with one of the naked-seeded forms. So again, some of the Indian examples of this species have purple flowers, others yellow with purple blotches, and in still others the flowers are pale yellow with a purple tinge on the extremities of the petals. A range of variability such as that can be best accounted for on the assumption that the assemblage embraces many cultivated races, of which each very possibly owes its peculiarities largely to hybridisation.

Cultivated Forms.—It would be rash to affirm (in the present state of know-

579
GOSSYPIUM
VAR. NADAM
Coonada

ledge) that the special cultivated states to which G. Nanking may be referred constitute definite varieties that can readily and invariably be separated from each other. The point of importance is that within certain fairly well defined areas there are commercially and agriculturally distinctive cottons that would appear to be states or races of G. Nanking. A detailed acquaintance with the cultivated cottons of Egypt, China, Japan, Siam, the Malay, etc., will in the future doubtless suggest varietal or racial groups, in amplification of the Indian series here dealt with:

Var. rubicunda, Watt, l.c. 126–8, tt. 17, 18; G. rubicunda, Roxb. MS.; G. obtusifolium, Burk. (in part), Mem. Dept. Agri. Ind., i., No. 4. This was formerly a much more important plant than it is to-day. It occurs occasionally here and there over the hotter parts of India. Hove, who studied the Indian cottons in the field during 1787, wrote of Cambay, on November 6, that the cottons were then in full bloom with scarlet flowers and quite another species from the yellow-flowered bush grown at Dioll in Broach. "On my journey," he continues, "to Kerwan in Cambay, for the space of sixteen miles, wherever I cast my eye, I could see nothing else but cotton plantations. Where the soil consisted of a heavy clay those districts were planted with the yellow sort, and those which consisted of sand, or were situated higher from the adjacent ground, were planted with the red sort." He then gives particulars of the method of propagation, more especially the pruning of the perennial plants. Pruning as a system of improving staple is alluded to by many of the early travellers. At Desberah in Broach, Hove was told, the red cotton was known as dyva norma capaes. One of the most remarkable features of Hove's account of the Bombay cotton cultivation, one hundred and twenty years ago, is the stress he lays upon the necessity for free irrigation with yellow-flowered cotton, which in this respect differs, he adds, materially from the red.

It is significant that all the best examples of var. rubicunda in the Kew, British Museum and Edinburgh herbaria appear to have been obtained from South and West or North-West India. It might be described as a hybrid from G. Nanking or G. obtusifolium. Its place seems to have been taken in Madras and the Deccan, to a very large extent, and possibly quite recently, by the yellow-flowered bani and nadam cottons.

Var. himalayana, Watt, l.c. 124–6, t. 16. A herbaceous annual or biennial yellow-flowered cultivated cotton. This is one of the chief forms grown along the Himalaya, and on some of the lower hills of India proper. It is generally called bagar or watni cotton. It seems probable that the Chinese and Japanese plant yields a superior staple to any of its Indian representatives; on this account, and because the true G. Nanking has repeatedly been introduced into India (cf. Roxburgh), it seems desirable to separate the Indian from the Chinese plant. In the Indian form, the leaves are large and broad, the lobes triangular acuminate, and the base very often almost cordate, while the whole plant is frequently very hairy, a departure from the type that possibly denotes hybridisation with G. obtusifolium.

Var. Nadam, Watt, l.c. 128–31; Capas, Rumphius, Herb. Amb., iv., 33–7, t. 12; Middleton, Agri. Ledg., 1895, No. 89, 8; G. indicum, Gammie, Ind. Cott., 1905, 6, pl. ix. In trade the cotton of this assemblage is often designated "Coonada," and besides nadam there are several other vernacular names that denote the series, such as yerra (red) also paiia, burada, etc. They are usually perennial, bushy plants, with dark-green foliage and deep-red coloured stems. The chief staple of Burma, the wa-gale, is an annual; the wa-ni, according to Burkil, is a kakhi-coloured wa-gale; lastly, the wa-gyi is a perennial—they are all three states of this variety.

I adopt the name nadam (or yerra) because it is that, ascribed by the Natives of India to one of the most extensively cultivated representatives of the present series of cottons—the nadam (or paiia or burada) cottons of South India. Middleton speaks of it as the roji of Madras, but he might also have added, or the bani of Central and Northern India. There is, however, a considerable range within even the nadams. Generally speaking they are the inferior cottons of the Madras Presidency; have often flowers pink in bud and turning reddish purple with age (hence called yerra cottons); they are sown either during the north-east monsoon (September to November) or during the south-west monsoon (from April to June), and occupy the land from three to five or more years. They begin to bear in about nine months after sowing, and yield two harvests in their second year, viz. the one in September and the other in January.
OOMRAS AND HINGANGHATS

are mostly grown on red sandy or stony soils, very rarely on black soils. They are for the most part perennials, and as such attain a height of 6 to 8 feet; they are accordingly largely cultivated as mixed crops, being grown in rows through the fields or as hedges to protect other crops.

Var. Bani, Watt, l.c. 131-4; Middleton, l.c. pl. iii; G. herbaceum, var. Jetti, Gammie, l.c. 4, pl. iv. This affords the finest and most silky qualities of the cottons known in trade as the Oomras (Amracti), the Hinganghats, the Nagpurs and Bihars. Under each of these there are usually two grades, viz. the bani and the jari. The former grows on the higher and drier soils, especially of the southern districts; gives a fine silky fibre but low yield. The latter is raised on the lower black soils of the northern districts; gives an inferior staple of a woolly character but does so very profusely. Jari seems originally to have been simply a lower quality of bani, and produced possibly by crossing it with var. neglecta; nowadays it is pure neglecta. To the circumstance of bani being one of the races of the Chinese cotton plant is due its silky staple. The description of the shape of the leaves and colour of the flowers of this special form is almost precisely that given for Nadam, except that the leaves in the finest grades of bani are much larger, thinner in texture, more undulated and much more hairy. The bracteoles are usually very large purple entire, or with few long pointed teeth.

It is met with over a wide area, bears numerous distinctive names, and manifests a considerable range in quality of staple. It mingles with the Nadam cottons of the south and east, with the Roji of the west, and with the bhimlayana cottons of the north. It is known in Bihar as jetti or desi (deshika); in Bengal proper it is bhogila; in Berar it has numerous synonyms such as sidki, jadi; in Hyderabad one of the best forms is that produced at Bhanais; in Southern Kathiawar it seems also to be known by the names of mathio, tiffinla, gangri, etc. It occurs in Berar, the Central Provinces, Bihar and the drier tracts of Bengal. It is essentially the best cotton met with on all the dry soils that have to be classed as second best in cotton-production.

Var. Roji, Watt, l.c. 134-7. A perennial, bushy, yellow-flowered, cultivated cotton that might be described as specially prevalent in Baroda and Khaibar. It is a tall much-branched shrub, often climbing in hedges 6 to 8 feet with straight ascending branches. When left to grow in the hedgerows roji becomes subdecandent, the wool shortens and turns rufous-coloured, and the fuzz lengthens and becomes also red-coloured. If allowed to remain in the fields for more than three or four seasons the wool degenerates in quality and, as stated by the early authors, is then fit for upholstery purposes only. But Middleton observes, “Roji is markedly different from the annual cottons and does not seem to hybridise with them.”

One of the earliest and perhaps the most interesting direct allusions to this cotton is that given by the Rev. E. Terry, who accompanied Sir Thomas Roe’s Embassy to India (Voy. E. Ind., 1615, 368). Speaking of the neighbourhood of Surat, he says: “For their Cotton-wooll, they sow seed, and very large quantities of Ground in East-Indies are thus seeded. It grows up like small Rose-bushes and then puts forth many yellow blossoms. Amongst that Wool they find seeds to sow again as they have occasion; but those shrubs bear that Wool three or four years ere they supplant them. Of this Cotton-wooll they make divers sorts of white Cloth.” This recalls at once the description of Indian cotton given by Theophrastus (see p. 571).

There is only one perennial cotton with yellow blossoms in Gujarat, and accordingly it seems safe to assume it was the plant to which Terry referred. Here is another indication that the perennial cottons were once upon a time more largely cultivated than they are to-day, if we are not justified in believing that the perennial cottons were the early condition, the annual plant a later product of greater skill in cultivation. Howe (170 years after Terry’s time) repeatedly alludes to perennial cotton seen by him—both red and yellow flowered—but he also gives a full account of the cultivation of the annual plant, and devotes special attention to what he calls a new method recently introduced. This may possibly point to the extended cultivation of the annual crop. But by the date of Howe’s visit the roji cotton had been assigned the secondary position which it has since held. Howe’s actual specimens are in the British Museum, and it has to be admitted that they could not be separated botanically from any corresponding set of more recent date. But he has no sample of what

THE COTTON PLANT

could be called a high-grade kahnami, his nearest approach to that being a specimen that might be described as the agria cotton of to-day.

To conclude this account of the forms of G. Nanking, it may have been observed that I have not attempted to describe the races that might be mentioned as examples of each of the great groups, Nadam, Bauta, Raja and himalayan. But it is next to impossible to furnish descriptions that would be intelligible to persons who have not a personal acquaintance with the living plants. To the cultivators of India they are, however, often of considerable value. Into one or other of the varieties of G. Nanking have to be placed all the yellow-flowered perennial cottons with thick leathery, broad, five-lobed, imperfectly cordate leaves, having three glands and large ovate acute, thick-toothed bracteoles.

A shrubby very ramous plant with small leaves, having three, more rarely five, obtuse entire lobes, stipules falcate; bracteoles entire; capsule ovate, cells 3-seeded; seeds free, clothed with firmly adhering short greenish-grey down, under a small portion of ash-coloured wool. A native of Ceylon, but not cultivated. Flowered during the rains and cold season in the Botanic Gardens at Calcutta, where it was cultivated from seed obtained from Ceylon of a plant reported to be there wild.

The above, very slightly abbreviated, is Roxburgh's original account of this species. The additional information available may be said to consist of a manuscript coloured drawing made under Roxburgh's supervision and named by him, the original of which is in the Calcutta Herbarium, and an exact copy in the Royal Herbarium, Kew. It is, however, the plant called G. herbaceum by most writers who have described the cottons of India and Africa, and is the G. hirsutum, Linn. Herb., but not of Linn., Sp. Pl. Roxburgh was apparently not aware that it was a wild plant in Khandesh and Gujarat, nor that it was the type of the most important cottons of India. Under the name G. herbaceum he described the plant now accepted as G. arboreum, var. neglecta, and linked that with G. Nanking (China and Berar Cottons), but kept all three distinct from G. obtusifolium. [No plant that could be supposed to correspond with G. obtusifolium is, however, mentioned in Linn., Sp. Pl.; in Fl. Zeyl.; in Burmann, Thes. Zeyl.; in Rheede, Hort. Mal.; nor in Rumphius, Herb. Amb., etc., etc.] Lastly, Trimen says there is no indigenous cotton in Ceylon.

Habitat.—A distinctly Oriental species, the various manifestations of which are met with in India, Ceylon, Malay Archipelago, Philippine Islands, Africa and Upper Egypt. I have in India repeatedly collected a Gossypium in a wild or self-sown condition, and was, I believe, the first person definitely to suggest its identity with G. obtusifolium. It occurs, for example, here and there all over Kathiawar. It is fairly common in the hedges of Gujarat, and was found by me in Khandesh and in the Deccan. If in all these instances it has to be regarded as but a survival of former cultivation, there would seem every likelihood that in some of its known habitats it has existed in the feral condition for a great many years, perhaps centuries. Further, the plant is perfectly easily recognised from all the other Indian cottons, though certain states of G. Nanking come very near to it indeed, if such instances are not hybrids between the two species. But the plant does not seem to be confined to India and Africa. Vidal collected it in the Island of Timor, Philippine, and the label attached to his specimen describes it as "wild." So also Dr. A. B. Meyer found it in the Malay Archipelago.

Cultivated Forms.—To distinguish the cultivated forms collectively, of this species, from those of Africa and other parts of the world, it may be useful to group them as embraced under a special Indian variety as follows:—

One of the most remarkable features of this plant is the circumstance that while it is the most valuable of all Indian cottons to-day, it is the one least understood and last of all to have been described by botanists. It is a cultivated
GUJARAT FINE COTTONS

annual cotton, with seeds much smaller, more definitely and compactly formed than in the wild plant, and fuzz very short, usually ashy-grey in colour. The change in the shape and size of the seed is a direct result of selection intended to lower percentage weight of seed to floss (lint). Varthema (Travels (ed. Hakl. Soc.), 1510, 107) speaks of the cotton of Cambay being much exported; he also says Bengal cotton is sent to Mecca, and in a footnote mentions the cotton of Burma. Mandelslo (Travels, in Olearius, Hist. Muscovy, etc., 1638-40, many passages) makes frequent mention of the cotton of Gujarat and Agra, but not in such a way as to allow of any opinions being formed regarding the plant that was then grown. In Milburn's Oriental Commerce (1813, i., 260) special mention is made of the Ahmood being at that time the finest grade of Gujarat cotton.

Habitat.—This is cultivated in a belt of country that fringes the west coast of India from the Rann of Kach through Katiawar and Gujarat, to the southern Maráthá country and Southashtra.

Soils.—The cultivated states of G. obtusifolium are exceedingly difficult to classify, since they blend almost imperceptibly from one type to another, in direct adaptation to smaller and less conspicuous climatic and soil variations than is experienced in the other cotton areas. There are in India three main classes of cotton soils with three corresponding main groups of cotton plants:—

(a) Rich black loamy soils, such as those of Kathiawar, Gujarat, Khandesh or the Karnátak. These are collectively often spoken of as the “Black Cotton Soils.”
(b) Mixed red and black stony soils, such as those of the Deccan, Berar, the Central Provinces, etc.
(c) Alluvial sandy soils such as those in the Ganges and Indus basins. Within (a) the forms of G. obtusifolium are mainly grown; within (b) of G. Nanking; and of G. arboreum. But in each one of these great cotton areas there may be local modifications both in climate, soil, exposure, etc., so that a limited cultivation of all three plants may exist or be possible in any one province. Speaking generally, however, G. Nanking, when met with on the black cotton soils, is of a superior quality to that seen anywhere else and G. arboreum is there very nearly unknown. These soils are too valuable to be used for the inferior grades, and consequently it is within G. obtusifolium itself, as a rule, that the adaptations of plant to environment have taken place. On the red and black stony soils G. obtusifolium rapidly degenerates or becomes hybridised with G. Nanking. In the areas of sandy dry soils G. obtusifolium becomes unknown, and the higher grades there met with are some of the stocks or hybrids of G. Nanking. It is not to be wondered at, therefore, that in regions so eminently suited for cotton as those possessed of black cotton soils, every little variation in soil, climate, altitude, marine influence, etc., should have resulted in the production of special forms adapted, district by district, if not field by field. The most favoured conditions, and the localities accordingly of the finest Indian staples, are Surat, Broach, Ahmedabad and Kathiawar. But within even these four districts there are well-marked minor areas that have apparently directly originated some of the special forms of G. obtusifolium that have presently to be indicated. In 1891, and again in 1894, I had the pleasure of studying the cottons of Gujarat practically on the last occasion in company with Prof. Middleton, now of the Board of Agriculture, who was at that time in the service of His Highness the Maharajah of Baroda. We marched over the greater part of the province as well as Kathiawar (when the cottons were in flower), and Middleton's great personal knowledge of the country enabled him not only to point out to me the kaleidoscopic blendings of the plants, but the immediate relationship of these to the variations in soil. [Cf. Ann. Rept. Ind. Mus. Calc., 1893-4, 2-5.] The rich, deep black soil of Broach and Násvári is known as the kahnam, and this was observed to yield the finest of all Indian cottons, accordingly known as the kahnam or Broach deshi (= country). The districts south-east of Baroda were seen to produce a considerably lower grade of kahnam cotton. So also both sides of the Dhadar river (between Baroda and Broach) were noted to change into a sterileous loam with the appearance of a distinctive plant known as the gogharti. That particular cotton, thus occupies an intermediate zone between the plants of the deep black kahnam soil proper and the lighter or shallower soils known as goradu to the north and west. On these lighter loamy soils are to be found the karni cottons of Bhavnagar, Palitana, Dhola, Amrolí and Junagardh, the ambli (of Dholera), and the wagria of Wadliwan, Virangam, Morvi, North Kathiawar and Kach.

A similar classification doubtless prevails in the southern Maráthá country.
The *kumpta* (coompta) cottons of Dharwar and Belgaum are the southern equivalents of the *kahnami* cottons of Gujarat. Still farther to the South (in the Madras Presidency), the *uppams* of Tinnevelly, Coimbatore, etc. referable commonly with the *gohhari* cottons, while the *tellapatti* or *jowari-hatti* (hybrid) cottons of Bellary and Karnal, in some respects answer to the *wagra* of North Gujarat.

**Races.**

The following may be given as the chief cultivated races of this species:—

(A) **Pure Races.**

(a) *Kahnami* : the *deshi* cottons of Broach, Surat, Navsari, Baroda, etc.

(b) *Gohhari*: one of the inferior but profitable cottons of Baroda and Broach.

(c) *Lalio*: the *deshi* cotton of Ahmedabad and Kathiawar—the *Dolliren* Cottons.

(d) *Kumpta*: the characteristic cotton of the southern Marathá country and known in trade as "Coomptas."

(e) *Uppam*: the long-staple cotton of South India, found mainly in Tinnevelly and Coimbatore.

(B) **Hybridised Races.**

(f) *Kanvi*: a recently introduced stock that often bears the name of *khan-puri* and is probably a hybrid with *G. arboretum*, var. *neglecta*.

(g) *Wagra*: the Common Cotton of North Gujarat, Kathiawar and Kach; is probably a hybrid with *G. *sanzing*—hence the breadth of leaf.

(h) *Tellapatti*: the black-seeded cotton of South India that is often called *jowari-hatti*. There seem to little doubt that this is a naturally produced hybrid between the *uppam* and Bourbon cottons.

**Exotic Species.**

For the purpose of this work it is hardly necessary to deal with every species and variety simply on the ground that at some time or other it may have been grown in India, or may even exist as an acclimatised (wild) plant. It is desirable to confine attention to the forms that can be said to be regularly cultivated, and which, therefore, participate in the supply of cotton that finds its way to market, or which have contributed (by hybridisation) to the production of some of the special races now grown in India. Suffice it to say that every cultivated cotton of any note in the world has at some time or other been experimentally grown in India. In all but two cases these have ultimately, however, come to be regarded as less valuable than the Asiatic stocks; hence certain forms, being neglected, have escaped into the neighbouring hedgerows or jungles and thus survived to this day, under conditions that have occasioned their being mistaken for indigenous (wild) plants. It may, therefore, serve the present purpose if the exotic cottons of India be discussed under two great groups:—

- *Fuzzy-seeded* and *Naked-seeded*—As already observed, a classification exclusively based on any one structural peculiarity would of necessity be misleading; more especially if the selected character could be shown, as in the present instance, to be very largely a special adaptable condition. The grouping suggested is of value, however, when viewed carefully in conjunction with the assemblage of other characteristics that may be said to demarcate the species. It is, moreover, a simple and convenient method of recognising the more important New World cottons.

It may be recollected that the seeds of most wild cottons contain a more or less complete coating of hairs, formed, it is believed, with a view to protection from insect enemies. Certain developments of that feature may, therefore, be regarded as brought into existence primarily as a consequence of definite adaptations, but by human selection these have been fostered or changed in accordance with an altogether new purpose, namely the supply of fibre of a particular length, strength or colour. In some instances, a proportion only of the coating has been elongated, either naturally or as a direct consequence of cultivation. Hence it has come about that the coating of hairs may be referable to two layers—an under coating of short hairs (the fuzz), and an outer coating (the floss). But, on the other hand, the whole of the coating may elongate into floss, the seeds in such cases being described as "naked," that is to say, not possessed of a fuzz. Lastly, the elongation of the floss may not be constant or uniform; a certain proportion may be shorter than the rest. Want of uniformity in the length of the staple is a serious defect, hence in selection of stock this aspect has to be carefully considered. But now comes a curious circumstance, and one of great practical interest: seeds possessed of a fuzz have, as a rule,
their floss more securely and firmly bound to the seed-coat than is the case with naked seeds. This has led to two classes of gins, namely saw-gins and roller-gins, the former being regarded as necessary to tear the firmly bound fibre from the seed-coat, and the latter sufficient for the naked-seeded cottons. The tearing of the staple is a significant feature that lowers very materially the value of the floss, apart altogether from other considerations. A naked-seeded readily separable floss is, therefore, a high qualification, and one that marks great progression in cotton cultivation.

**Fuzzy-seeded Cottons of the New World.**—The species that fall into this position are:-

A botanical specimen contributed by Philip Miller is preserved in the British Museum and is, therefore, very possibly the actual type of the species. Another specimen of the same plant will be found in the Badminton Garden herbarium (also preserved in the British Museum), which was very probably the source from whence Miller obtained seed. And it is just possible the Badminton stock came from Guadeloupe Island, having been contributed by the brothers Lignon, mentioned by Tournefort as having sent seeds of West Indian plants, more especially from Guadeloupe, to Paris. It is interesting, therefore, to be able to add that the record exists of seed having been grown in Georgia in 1754, from a supply furnished by Miller from the Chelsea Physic Garden. There is thus little doubt that the introduction of the actual stock of the New Orleans, Georgian, and many other short-staple American cottons, dates very possibly from the supply sent out by Miller. But to this same plant has to be attributed the Egyptian (Delta lands) cotton—a plant that existed very possibly in Upper Egypt long anterior to the modern traffic, the stock of which we know came very largely from the United States of America. So also the so-called saw-ginned Dharwar cottons of recent Indian commerce were obtained from the States, though later supplies were procured from Egypt, from belief that they represented a special and peculiar plant known in trade as "Egyptian Cotton."

Some years previous to this historic introduction of the Dharwar stock, Roxburgh spoke of the plant having been only of late brought into India. He does not tell us where it came from, but his description occasions no doubt as to its determination, and he was the first botanist to affirm that the seeds were free from each other. Interest was being taken in the plant the world over, however, since towards the close of the 18th century Murray furnished an admirable picture and description of it, under the name G. latifolium. During the past fifty years, however, the proportion of this cotton in India has gradually concentrated in the Deccan. It is, of course, also met with in other parts of India, but success has chiefly attended its acclimatisation in Dharwar and the neighbouring districts, hence its being known in trade as Saw-ginned Dharwar.

In 1894 I made a tour on foot through certain districts of the Central Provinces and Berar, in order to study in the field the cottons there cultivated. In many parts of Nagpur, Wardha, Ellichpur, Amraoti and Akola I found the present plant very largely mixed in all the fields of the so-called higher grade "Oomras." In many cases it would not have been an over-estimate to say that they contained from 20 to 30 per cent. of G. hirsutum, the balance being G. Sanking, var. Bani, of an inferior stock for the most part. The latter was a much larger and more prolific yielder, and the former was grown, so the cultivators told me, entirely because the mixture was believed to raise the grade of the staple. Except, therefore, in Dharwar, where it is grown as a pure crop, the condition mentioned as discovered in the Central Provinces is characteristic of the occurrence of the present plant in India as a whole. It has, however, greatly degenerated, and is often not more than a foot or a foot and a half in height; is a coarse, stunted, much-branched, erect, greenish-red, dust-coated bush, the last-mentioned peculiarity being a consequence of the abundance, length and strength of the hairs with which the shoots, leaf-stalks and veins are coated. The seeds are always large, ovate, truncated on one extremity and have a strong dense fuzz, which may be grey or green in colour. The floss
adheres very firmly, hence necessitating the use of saw-gins, but it is fairly long and silky.

As met with in India, the plant has degenerated very greatly from the standard preserved in the United States and in Egypt—has, in fact, approached in many directions to the specific conditions of *G. punctatum*, although I am not aware of its ever having been recorded as met with as an escape from cultivation. Had systematic selection of stock been pursued in India, there is little doubt that a higher standard than exists might have been maintained, if not a progression secured. Of this there can be no doubt, that the Upland Cottons of America have advanced until the plant that now affords them is no longer *G. hirsutum*, but a greatly improved stock that botanically might be described as a hybrid between *G. hirsutum* and *G. mexicanum*.

This somewhat remarkable plant is mentioned here mainly in order to allow of its separation from *G. brasiliense* (which by Parlato and others has been incorrectly called *G. religiosum*). It is not of much importance commercially as its separation from *G. hirsutum* is a matter of great difficulty, and, moreover, the plant does not appear to be very extensively cultivated. It is best distinguished from the normal condition of saw-ginned Dharwar cotton by its trailing habit and more softly hairy condition. The lateral shoots are much elongated and slender and the internodes are long, straight and profusely tomentose. It is not uncommon to find popular writers in India affirming that the name *religiosum* was given to denote a cotton cultivated by mendicants or one met with near temples. The name was first used by Linnaeus, and there is no proof whatever that his specimen came from India. Moreover, the plant that in India might deserve the name *religiosum* would be the *deo kāpas* or *ram-kāpas*, which is *G. arboreum*. Roxburgh was the first botanist who critically studied the plant, and he came to the very correct conclusion that it could "scarcely be more than a variety of *hirsutum*.”

A remarkable plant met with now and again throughout the cotton areas, more especially in Africa, though the type was described from a plant raised (so Todaro says) from seed procured from Mexico. Its leaves are even more deeply palmated—the lobes being almost linear—than is the case with *G. brasiliense*, but they are in addition plicate-tomentose, while the seeds are semi-conglomerated and partially coated with a velvet. One of the most striking peculiarities of this plant is the immense size of the calyx. By most writers this has been confused with kidney cotton (*G. brasiliense*), but others call it the true Pernambuco cotton of commerce, which they hold to be thus distinct from the kidney cotton. By still others it is the original stock of the ashmouni cotton of Egypt, an opinion which I do not accept. Perhaps its best popular name is Red Peruvian.

*G. peruvianum*, Cav. Diss., 1785–90, 313, t. 168; *G. vitifolium*, Roxb., Fl. Ind., iii., 186; *G. religiosum*, Parl. (in part, but non Linn.); *G. hirsutum*, Cook, Weevil Resist. Adapt. of Cot. Pl.; Watt, l.c. 213–26, tt. 37, 38. *U.S. Dept. Agri. Pl. Indust. Bull.*, 1906, No. 83, 8. Possibly indigenous to Central and South America; is the so-called Peruvian Cotton now met with in most cotton-growing countries, especially West Africa, where it received numerous distinctive local names, such as *owu* of Abbeokuta and *ukoko* of the Congo; and most of the races of ordinary or short-staple Egyptians, such as the Ashmouni, *Mit Afi, Zafiri* and *Abassi*.

This somewhat obscure species links together *G. mexicanum* and *G. brasiliense*. It has the palmatised foliage of the latter with the blistering habit of twigs and fuzz-coated seeds of the former. It is somewhat significant that
UPLAND AND GEORGIAN COTTONS

all the American and African cultivated cottons that possess seeds more or less coated with a velvet or fuzz (e.g. *G. hirsutum*, *G. mexicanum* and *G. peruviana*) have the leaves more or less pilose, while the forms with sub-glabrous leaves (e.g. *G. purpurascens*, *G. vitifolium* and *G. brasilense*) have the seeds practically naked; that is to say, they do not possess a fuzz.

*G. mexicanum*, Tod., *Relaz. Cult. dei Cot.*, 193, tt. vi., xii., f. 32; Watt, *l.c.* 226-44, tt. 39-42. This hybrid species is often very difficult to separate from *G. purpurascens* when in foliage. The leaves are broad, smooth, glabrescent with five to seven radiating veins and lobes; peduncles prolonged, pedicels short and flowers small, pale-coloured, nodding; seeds large, with thin ashy fuzz, and copious woolly floss. Apparently originally procured from Mexico, but so far as known is met with under cultivation only.

Roxburgh tells us that this was introduced into India by W. Hamilton in 1804, but subsequently he seems to have confused it with Bourbon Cotton (*G. purpurascens*), and gave both plants the botanical name of *G. barbadense*, *Wilt.*, since both his MS. drawings (so named) are in reality *G. mexicanum*. He further apparently alludes to this plant under *G. hirsutum* as being grey-seeded. Wight, Spry and many other Indian writers refer to Mexican Cotton in the Journals of the Agri.-Horticultural Society. However, it has been admitted that some uncertainty exists as to the plant Todaro actually meant by the name *G. mexicanum*. If his coloured illustration be accepted arbitrarily as the type, then it has to be confessed that it is not very plentiful in herbaria. As in all the samples seen by me that approach most closely to that type, the plants either came from Mexico or were raised from seed procured from that country, as Todaro affirmed was the case with the plant figured and described by him. But in all the best tracts of America, from which the finest Upland and Georgian Cottons are procured, the plant there grown is almost exactly intermediate between the type of *G. hirsutum* and that of *G. mexicanum*. The leaves are large and broad in fully-formed conditions, 5-, sometimes even 7-lobed or only angled. In texture they are smooth, thick, leathery and either very hairy (in forms that approach to *G. hirsutum*) or almost quite glabrous (in those with a closer approximation to *G. mexicanum*). In the United States fresh stock has again and again been imported from Mexico, and the admission made that the previously existing stocks had been thereby much improved. There would thus seem little doubt that the improvement that has been consistently reported as taking place has run parallel with an undoubted advancement from the older type of *G. hirsutum* towards that which more appropriately should (from the botanical standpoint) be designated *G. mexicanum*. But they are one and all hybrids, and the suggestion may be offered that they have been derived from *G. hirsutum* as the one stock, and either *G. purpurascens* or *G. vitifolium* (*G. barbadense*) the other—the result being the presumed hybrid condition here designated *G. mexicanum*. Of the more famed cottons of this assemblage, the following may be specially mentioned as (a) hairy (e.g. *aff. G. hirsutum*) forms:—

- "Welborn's Pet," "Willet's Red Leaf," "Parker," "Layton's Improved," "Toale," "Shine," "Simms," "Berry's Big Bell," "Culpepper," "Cummins," "Triumph," "Gibson," "Myers" and "Texas Wool." Reversions are also recorded, one example of which may be here specially mentioned, namely "King's Improved," which comes closer to *G. punctatum* than to the bulk of the modern *G. mexicanum* cottons that to-day are called by the old, but now hardly accurate name of *G. hirsutum*. Another illustration is the tendency for green-seeded stock (G. hirsutum type proper) to produce brown or grey-seeded forms (*G. mexicanum*) according as the degree of cultivation or neglect tends to develop and establish the one or other ancestor of the present-day much hybridised stock of Upland cottons.

*Naked-seeded Cottons of the New World.*—The following, among other species, may be specially mentioned in this position:

Upland and Georgian.

Introduction into India.

Mexican Cotton.

Hybrids.

Special Races.

King's Improved.

Bourbon Cotton.
there are several distinctive races, derived very possibly from *G. taitense*, *Parl.*, and which constitute the Bourbon and Porto Rico Cottons of commerce.

The seeds are not only what is called naked, but the leaves are almost glabrous. They are perennial plants with strongly angled purplish shoots and leaves ovate entire or with three lobes on the apex, the laterals arching outwards and the petioles almost thorny through the growth of glandular warts. They are all essentially insular plants, hence the greater success attained with them in South as compared with North India. They seem to be readily hybridised, and in consequence it is not uncommon for completely fuzzy seeds to appear among plants raised from the normal condition, viz. the seeds naked, except for a tuft of rust-coloured fuzz around the beak.

The Vine-leaved Cotton was probably originally a native of Central and South America, to the Amazon basin and the Lesser Antilles, but early found under cultivation throughout the cotton area of the world. It is the Egyptian long staple, Antilles, Piura, Surinam and Cayenne, St. Domingo, Guadeloupe, Barbados and other cottons. In the early literature of this genus the greatest possible obscurity prevails regarding *G. barbadense*. It might, in fact, without fear of contradiction, be affirmed that there was little or no distinction between that species and the present plant. As time advanced the form known as Sea Island Cotton appeared, and to it became restricted, by most authors, the name *G. barbadense*, leaving *G. vitifolium* to be accepted as denoting the slightly lower-grade cottons of South America and Egypt that are classed as "Long Staples." It is, in other words, highly likely that this plant may have been one of the ancestral stocks of *G. barbadense*, var. *maritima*—a plant which is perhaps the most recent addition to the prized races of cotton met with in the world. No one seems to know what was meant originally by *G. barbadense*. It nowhere exists in a wild state, and is apparently never cultivated except in the form nowadays called Sea Island, but which could hardly be accepted as *G. barbadense*, Linn. The present plant, on the other hand, exists in numerous forms. It is the vine-leaved cotton of most of the early authors, who repeatedly speak of it as met with wild or completely acclimatised. The leaves are sub-cordate with mostly only three ascending lobes, the texture often pilose-tomentose below. The bracteoles are very large, ovate-rounded, deeply succulent, slightly united below and often possessed of the bractlets described by Cook as weevil-resisting adaptations (*U.S. Dept. Agri. Bureau Pl. Industr.*, 1906, No. 88.) *Seeds* black, naked and quite free from each other.

This embraces all the higher-grade long-staple cottons. A shrubby perennial known only in a state of cultivation, and raised usually as an annual. It is glabrous or nearly so, except on the leaf-stalks and veins and the under-surfaces of young leaves.

As already suggested, there seems every probability that the early authors who accepted the name *G. barbadense* did not realise that it meant one and the same plant as that designated *G. vitifolium*. By cultivation and crossing, however, a highly specialised race, known as "Sea Island," was produced, to which by recent authors the Linnaean name *G. barbadense* became in time restricted, though Todaro, and following him some other botanists, preferred to give the new stock the name of *G. maritimum*, thus leaving *G. barbadense*
SEA ISLAND AND BRAZILIAN

GOSSYPIUM

BRASILIENSE

Brazilian

as a name for a species presumed by many to exist, but known for certain to no botanical writer. The species founded by Linnaeus may be said to turn on a specimen still preserved in the British Museum, and that specimen certainly agrees more closely with *G. vitifolium*, Lam., than with the modern Sea Island Cotton of America.

Although repeatedly introduced into India, Sea Island Cotton has, in no locality, proved a success. It is possible, however, that it might be raised profitably in the Andaman and Nicobar Islands and in some parts of Tenasserim.

The Chain, Kidney, Brazilian, Bahia, Pernambuco and Costa Rica Cottons of most popular writers, and in Burma it is *thembamua* (ship’s cotton). It was first definitely alluded to by John Lories, who lived in Brazil in 1557, and wrote a history of that country. Sir Walter Elliot, speaking of the plant as known to him in South India, calls it *paedi* (gold) *patti* and *pamidi patti* (the wealth-giving), names that denote the high expectations that were at one time entertained regarding this plant. It was apparently the first of the long-staple silky cottons of the New World to attract attention. Seeds were conveyed by Marcgraf and others, and the chain condition so well figured by Zanoni seems to have been accepted as a peculiarity of all cottons, hence Lobel (1780) thought he improved on the pictures of *G. herbaceum*, given thirty years previously by Fuchsius and Matthiolus, by adding a kidneyed mass of seven seeds.

All the nations of the world seem for a time to have vied with each other in the attempt to acclimatise the Brazilian Cotton, and in each new country to which it was conveyed the name of the region from whence immediately conveyed; accordingly in Burma, and also in the Antilles, it is called “Siam Cotton,” and in India “Ava Cotton,” etc. Roxburgh tells us in the MS. edition of his *Flora Indica* (preserved in Kew) that he became acquainted with it through seeds sent him from Farukhabad. Mr. H. St. George Tucker (Member of the Court of Directors of the East India Company) observes that Lady Hastings grew it at Fattoghar, and Roger Hunt, in 1808, addressed the East India Company on the causes of deterioration of Pernambuco and Surinam Cottons. Thus we know that prior to Roxburgh’s knowledge of it this plant had been experimentally tried in many parts of India.

It is, therefore, perhaps not to be wondered at that this cotton has got considerably more widely distributed and is moreover more frequently met with in states of acclimatisation than is the case with any of the other New World cottons. Its large capsule, compact mass of seeds and the copious coating of those naturally conveyed the impression of great value, and false expectations were raised, only to be rudely dispelled by comparisons of yield to acre. Gradually, however, all interest (or nearly so) in this particular Brazilian Cotton died out with the appearance first of the Upland Georgian Cottons, then the Mexican Cottons, and finally the Sea Island Cottons, all races that could be raised as annuals and occupy the soil for short periods. The present species in most countries accordingly fell into a state of complete neglect and either disappeared or survived as an escape from cultivation and became “the wild tree cotton” of most popular writers, the properties of which have been the will-o’-the-wisp of nearly each decade for the past century in the world’s cotton areas.

If I am correct in believing that this plant, however, represents an important stage in the development of the fine long staples of the West Indies and the Sea Islands of America, it is not by any means devoid of interest to persons interested in the production of new and improved races. But as met with in India to-day it is of no value whatever, and the expectations recently advanced regarding it would accordingly seem almost for certain doomed to disappointment, since opposed to all past experience with the plant. It may be said to have attained commercial importance within very restricted areas. In South America—its indigenous habitat—it is regarded as of special value because of its resistance of the diseases that prove disastrous to other cottons. In Guatemala, for example, it is believed to be immune from weevil.

589
I. ADULTERATION AND DETERIORATION.—Milburn (Or. Comm., 1813, 279–80) urged that it was impossible to be too attentive to the shipping of perfectly clean cotton. The adulteration and deterioration of Indian cotton has thus engaged attention for fully a century. St. George Tucker (to whom reference has been made above) wrote in 1830 a report on the Supply of Cotton from British India (cf. Reports on Cotton, Silk, and Indigo published by the Company in 1836, 152–75) in order to account for its depression in price and deterioration in quality. He gives ten reasons. Royle (Cult. and Comm. of Cotton in Ind., 1851, 551) deals frequently and effectively with this question. "When the cotton," he says, which the Native grows, "is intended for sale, the ryots have little enough encouragement to bestow more care, either in growing or in picking their cotton, for they usually get no better price for a good and clean, than they do for an indifferent article." So again, "Indian cotton is, however, from the shortness of staple, not well suited for all the purposes of the English manufacturer; but it is much more depreciated than it need be from the dirty and adulterated state in which it is sent to market." Mention has been made that (about the time of the great cotton famine, 1861–5) notice was forcibly directed to India as a future country of supply for England. An outcry was shortly after made against the adulteration and mixing of inferior with superior grade staples. This led to the passing of the Cotton Frauds Act (IX. of 1863, and the Amendment of 1878, Act VII.).

W. B. Wishart (Secretary of the Chamber of Commerce of Upper India) published in 1891 a Note on the Adulteration of Cotton in which he shows that the subject had agitated the minds of the cotton merchants of India for many years. He points out that a report issued in 1845, for example, gave details of the deterioration and decrease in outturn even then observed. Wishart then remarks: "There is now no bona fide market for our inferior cotton. Native hand-weavers cannot work it; the Chinese found out, some years ago, that it did not pay them to use it, and now our Continental customers can and do buy an article that suits them equally well at a proportionately lower price. There is, therefore, no outlet for such cottons, and Native growers and buyers have naturally taken to assisting each other by bulkling the inferior and better stuff produced in each district, the mixture constituting a quality just a little below that which spinners want."

In August 1891 a conference was held in the office of the Director of Land Records and Agriculture, Poona, at which proposals were made with a view to preserve and improve the quality of Indian cotton. In the same year Sir E. M. James (at that time Commissioner in Sind) drew up a Memorandum on Cotton. This was widely circulated by the Bombay Government, and elicited many valuable opinions and reports. The Chamber of Commerce of Bombay, for example, issued a very powerful reply, dated November 11, which fully expressed the opinion ultimately upheld by the Government, namely that while there was much need for effort at improving the stock, penal legislation was undesirable. Ten years later (Feb. 1901) the Hon. Mr. Bomanjee Petit (himself a prominent mill owner) pressed on the attention, both of the Bombay Government and the Mill Owners' Association, the serious consequences of the deterioration of the Indian cotton staple. It has now actually come about that both China and Japan have begun to produce coarse yarns of their own, and
IMPROVEMENT OF STOCK

GOSSYPIUM

IMPROVEMENT
OF STOCK

have thus commenced to close two of the most important outlets for Indian exports. In consequence the necessity to advance has been borne home on the minds of the Indian mill owners. Instead of spinning as their finest yarns 20's, they have begun to think of 80's, but for this purpose they require to import raw cotton from Egypt, if not even from America. India no longer possesses a cotton suited for that purpose, and the adulteration and mixing of the staple have thus very nearly paralysed the industry.

In consequence the outcry for legislation has once more been raised: it has been urged that a law requiring the locality of production to be stamped on all bales of cotton would have a highly beneficial result. Others look to the expectations of Sind, irrigated by a system of canals that may allow of the production of the high-grade Egyptian cottons, as the most hopeful indication of the future.

Thus history repeats itself, in no commodity of commerce with greater regularity than in the theories and practices of cotton growing and cotton trading. One lesson alone seems to stand out through the past decades of the steam-power cotton industry of India as unwavering, viz. the conviction that when the time comes for India to assume once more the rôle of a producing and even exporting country in the finer cotton goods, it must either have improved its staple or discovered a country capable of meeting its necessities in suitable raw fibre. A low-grade staple such as the bulk of that grown in India to-day is utterly unsuited for the higher class machine-made goods, even were it put down at the mills pure and clean at a price below that procurable by any other power mills in the world. Thus it has been shown that cheap production is not necessarily economic production. Expensive labour means higher intelligence, with compen-

sation in quality and price. O. P. Austin (Cotton Trade of the United States, 1900, 2608) points out, and with much force, that the low wages of the Indian cultivator are no real economy, since they prevent cotton cultivation on a large scale directed by intelligent supervision. Retrograde agriculture, such as has characterised the Indian cotton trade for a century past, must in the end fall behind in the race for commercial supremacy.

II. IMPROVEMENT OF STOCK.—The cultivated cottons of the world have been referred to three great areas—(a) Asia, (b) Africa, and (c) America. But it has sometimes been affirmed that the first two can be taken together and spoken of as the fuzzy-seeded Asiatic and the others as the naked-seeded American cottons. But it is not the case that all the fuzzy-seeded species are Asiatic, any more than that all the naked-seeded are American. Moreover, the seeds of wild cottons have either a firmly adhering coating of wool or a readily separable floss. But there are both wild and cultivated cottons that possess both a fuzz and a floss. As already mentioned, Cook (U.S. Dept. Agri. Bull., 1906, No. 88) thinks the wool may be a necessity in the protection of the seed from the enemies of the plant. Certainly in most wild forms, such as G. Stocksii, and still more so G. Davidsonii, the wool is so firmly and intricately crumpled up around the seed as to prove a veritable proboscis-proof protection, thus causing such seeds to be described as naked, the compacted fuzz having escaped detection. But of purely wild species the following among others possess a short velvety coating around the seed:—G. Harknessii (a native of California); G. Palmerii (of Mexico); G. Sturtii (of Australia), and G. tomentosum (of the Hawaiian Islands). On the other hand, the following have naked seeds :—G. Kirkii (of East Tropical
GOSSYPIUM
IMPROVEMENT

Specific Influences.

Hybridisation.

Number of Species.

American Hybrids.

THE COTTON PLANT

Africa), and G. taitense (of the Polynesian Islands). In passing it may be here added that no Asiatic indigenous cotton has a naked seed, and further that with the fuzzy-seeded Asiatic forms the bracteoles are united below, whereas with the American fuzzy-seeded cottons the bracteoles are free. The appearance, therefore, of these peculiarities in certain cultivated or long acclimatised plants may safely be regarded as denoting definite influences and not accidental sports or climatic adaptations.

It has sometimes been upheld, but with little justification, that the crossing of fuzzy-seeded and naked-seeded cottons (or of Asiatic and American cottons) was impossible. But there is perhaps no subject on which greater diversity of opinion exists than in the value or even possibility of hybridisation of the species of Gossypium. One set of writers affirms that it is difficult, if not impossible, to prevent hybridisation, while another stoutly upholds the belief that hybridisation is of no practical value, if they do not indeed go so far as to deny the possibility of its accomplishment in nature. A parallel to this diversity (and perhaps a consequent one) is the degree of acceptance of the species as established by botanists. Some writers, such as Todaro, think there may be as many as 54 species, while others, such as Parlatore, reduce them to 7, and Aliotta to 5 species, with numerous varieties and cultivated races or hybrids under each. Buchanan-Hamilton went further and reduced all to 2 (or perhaps 3) species, viz. the black (naked) seeded and the white (fuzzy) seeded, with as a third the red (kakhi) seeded cottons. In fact the controversy regarding the number of species dates even from before the formation botanically of the genus Gossypium, but I venture to think it could never have existed and cannot exist to-day, when the undoubted wild forms are made the basis of classification.

The confliction as to hybrids may be exemplified by the writings of two of the most recent authors. Aliotta (Riv. Crit. Gen. Goss. 1903) gives an elaborate statement of the races of cultivated cottons which he thinks have been produced through the cross-breeding of his five species—G. barbadense, G. religiosum, G. arboreum, G. herbaceum, and G. hirsutum. On the other hand, G. A. Gammie, Professor of Botany at Poona, Bombay, in his recent report (The Indian Cottons, 1905) reduces all the Indian cultivated forms to G. obtusifolium. He would, moreover, not appear to regard hybridisation as of any practical value whatever. He observes that the so-called species and hybrids are merely cultivated races evolved by time and environment from one prototype, but he nevertheless adds somewhat paradoxically that they are capable of being crossed with facility and that their descendants are fertile.

After many years of careful study of the Indian cottons, both in the field and the herbarium, I am constrained to join issue with Aliotta and writers of his school in thinking hybridisation has played an important role, though I am not of course prepared to reduce the ancestral stocks to five forms. Still I am satisfied that many of the more highly prized cultivated cottons are not species botanically (though it may be convenient to retain for them specific names), but are races and natural hybrids (some of the more recent artificial) adapted by selection to man’s requirements and to environment. I am at one, in fact, with the army of workers in America who not only say they have produced endless forms by crossing, but who regard that agency as of the greatest possible importance. Tracey (Dabney, The Cotton Plant, 1896, 197–224), in dealing with the cultivated varieties, remarks, “Although the plants from a single line of crosses, as fertilising Peterkin with Allen, will vary widely, still it is a general
rule that the character and habit of the future plant will be more like those of the female parent, while the fruit, the boll and its contents, will be more like those of the male parent." So again, "The tendency of the plant to vary from the typical form of any variety will be back towards its original form rather than in any other direction." From these and such-like considerations is doubtless due the affirmation that, from one or two plants specially cultivated and as a consequence of careful selection of sports, it might be possible to produce all the chief types of cultivated cottons. Hence it may be said that with few other cultivated plants is a more rigid selection of seed necessary than with cotton. Moreover, there seems little doubt that historically it can be shown that G. hirsutum, G. mediumum, G. villosum and G. barbadense, as known to us to-day, are themselves to a large extent hybrid stocks. It does not follow, however, that all hybrids may be fertile, still less that they can be invariably again further hybridised with fresh ancestral influences, according to the fancy of the operator. To the neglect of this consideration may be due much of past failure in hybridisation.

One of the most valuable and interesting papers on this subject is that written by Austin Cannon, entitled "Spermatogenesis of Hybrid Cotton" (in Bull. Torrey Bot. Club, 1903, xxx., 133-72.) The cotton hybrid experimented on was produced (so we are told) between Sea Island Cotton (Constellation brand) and Upland Cotton (Klondike brand) — G. barbadense x G. herbaceum and the hybrids were found fertile. It is, however, just possible that the plant spoken of as G. herbaceum should have been called G. hirsutum or G. mediumum, for until about 1896 Uplands were by American authors mostly spoken of under the botanical name that more properly belongs to the Mediterranean stock. All fuzzy-seeded cottons were often, in fact, regarded as one and the same species. It follows that to secure uniformity and precision in the laboratory and in the experimental farm, the foremost consideration must be the ascertainment of the species botanically that it is intended to investigate. Until such knowledge has been obtained it would be preferable to adopt some arbitrary nomenclature such as a numerical system, e.g. the "K2" of geographers, rather than to employ a misleading jargon of botanical names.

As a historic fact in Indian hybridisation it may be mentioned that in 1844 Mr. Alex. Burns of Broach crossed G. obtusifolium, var. Wightiana, with G. arboreum. He obtained a plant that had all the good points of both parents. The leaves were those of arboreum, only larger and more hairy, and the flowers were red with a yellow ring in the throat. This interesting new form, an undoubted hybrid, yielded its crop within a period of two months, much as in Broach redi, and the moss was very silky. The Bombay Chamber of Commerce expressed the opinion that the cross was an exceedingly valuable one. No further information was, however, published regarding it, and the plant seems to have died out. The circumstance is mentioned to show that crosses are possible.

Under the orders of the Government of India much has been recently done to discover the soils suited for cotton generally, and many valuable experiments have been conducted with exotic forms. What would appear the foremost consideration has, however, until very recently been almost entirely neglected, namely the attempt to improve the indigenous or long acclimatised stocks. Royle, for example, repudiated with some warmth the opinion attributed to him, that the greatest attention should be given to the cotton of the country ("Cult. and Comm. of Cotton in India", 1851, 544-5). For a good few years past I have uniformly urged, and I repeat that recommendation, namely, to make real progress it is imperative that an exhaustive and scientific investigation should be conducted—a sort of census taken—of the existing stocks, not only of India but of the world. The climatic and other causes which tend to preserve or destroy good or bad properties have to be thoroughly established. The influences of hybridisation have to be worked out on a scientific basis by testing the strength of strains from this species or that, best suited to environment, the tendencies of cultivated forms recognised and systematic renewal of stock in each locality accepted as a solemn obligation.

A few years ago I drew attention to the establishment of steam ginning factories, all over India, as having created a new danger, namely degrading equalisation of stock. Nowadays the cultivators over a wide area carry the produce of their fields to these factories: all are mixed together, and seed returned to the cultivators that in many cases may be utterly unsuited to the fields on which it has to be grown. The specialisation of centuries of natural selection is thus being

The Cotton Plant

rapidly effaced by this new phase of commercial production. It has been found useless to urge that the cultivators should reserve their own supplies of seed. They are too poor and too ignorant to do so, and, moreover, are only too frequently in the hands of the money-lenders. (See Ginning, pp. 611-2.)

Lastly another evil has crept gradually into the cotton traffic of India. England having adapted her machinery to the steadily improving staple of the United States, soon became unable to work up the short staples of India. But in Germany, Japan and India itself, special factories were built with the object of running for the lower-class goods and working up the world's supplies of short staple. The cultivators were accordingly told that they would get no more for a long time. In every district there were both high-class and low-class staples. The former gave a lower yield, compensated for by a higher price. The new condition naturally dictated the universal substitution of the lower grades, and an agricultural degradation in consequence was carried across the country in a remarkably short space of time that may take a century to efface. An official correspondence dated July, 1903, contains a letter from one of the most influential European merchants of India, which puts the present position tersely by narrating the advantages of the belati or jari plant of the Central Provinces and Berar:— (a) It is an earlier crop, thus enabling the cultivator to get a quicker return; (b) it runs accordingly less risk of injury from early cold weather; (c) it is a harder plant, less liable to disease or to deterioration from rain; (d) it gives a larger weight of lint; (e) it comes into market cleaner than the other grades.

The feature of early ripening is most important. The annual cottons of India have often been spoken of as consisting of two kinds—those that take eight months to ripen, and those that reach maturity in about five months from sowing. The cottons found on a deep, moisture-retaining, black, loamy soil are of the first class. They are usually grown as pure crops, and the particular race meet with is often remarkably uniform. The cottons of the second class occur on light soils; they are produced normally as mixed crops and manifest the greatest possible variability. The influence of rainfall, both quantity and season, is of vital importance. The vicinity of Bombay town and south of the Konkan, since it possesses double the rainfall of Broach, grows next to no cotton, even although the soil may be highly suitable. Localities, like much of South India, that have two rainy seasons possess two widely different cotton crops. It is very largely in adaptation to the conditions of soil and climate that certain cottons owe their superiority or the opposite. The substitution, for example, of inferior for superior grades has been primarily the result of the demand for that staple, but the change has to many cultivators been all the more acceptable that the plant required was in their locality harder and more risk. Some twenty to thirty years ago the Central Provinces had a fair proportion of bani (superior cotton) relative to its jari (or inferior cotton). To-day the crop is mainly jari. The former could be spun into yarns of 20's and up to 40's; the latter can rarely be used for more than counts up to 10's. The bani cottons were the once famed Ghat cottons, such as the Hinganhat of commerce. The jari has a very short staple, but is exceedingly hard and prolific.

As manifesting the present position of cotton and its degeneration, as also some of the features of the programme of improvement that may be found imperatively necessary, the following jottings regarding the famed Dacca cotton may be usefully set forth:—In view of the efforts presently being made to develop the industry of cotton cultivation in Bengal, it seems desirable that the opinions of the earliest writers be briefly indicated. Mr. Bobb, Commercial Resident of Dacca, furnished a reply to an inquiry made by the East India Company, and that reply is one of the earliest accounts of Dacca (in fact of Bengal) cotton. It is dated 1788, and speaks of the staple as "the finest cotton in the world, producing cloth of astonishing beauty and fineness." The plant is said to have been an annual, and to have afforded two crops in the year, in April and again in September. The first was the most esteemed and obtained the highest price, but was liable to failure from long drought or from violent storms, though moderate showers were highly beneficial. In the volume of Reports on Cotton, Silk and Indigo published by the East India Company in 1836, there is a report written by St. George Tucker in 1829 (Supply of Cotton from British India, 159-60) in which he discusses the superior cotton of Dacca. He calls it bairati kupa—the finest variety perhaps of the Eastern cottons. It is produced only in small quantity, in the districts north-west of Dacca, and is never exported. Its favourite
FAMID DACCA COTTON

GOSSYPIUM IMPROVEMENT OF STOCK

site seems to be the high banks of the Ganges and its tributaries. The fibre of the *bairati* is extremely fine, silky and strong, but the staple is very short and the wool adheres most tenaciously to the seed. It is admirably calculated for the manufacture of the muslins and thinner fabrics. It is perhaps too costly a production to enter largely into our manufactures. Tucker then adds that the *bogha bupaz* is the ordinary cotton staple of Bengal proper.

Roxburgh, who was appointed Superintendent of the Royal Botanic Gardens of Calcutta in 1793, early gave attention to this special Dacca cotton (Royle, *Cult. and Comm. Cotton*, 245). He gives, in his *Flora Indica*, the points of difference between the ordinary Bengal and the special Dacca cotton. The plant, he says, is more erect, has fewer branches, and the lobes of the leaves more pointed. The whole plant is tinged with red, even the petioles and nerves of the leaves, and it is less pubescent. The peduncles of the flowers are longer and the exterior margins of the petals are tinged with red. The staple is longer, much finer, and softer. Roxburgh's MS. plate of the plant thus distinguished is in the herbarium of the Royal Botanic Gardens, Calcutta (a copy of which is in Kew, and has been reproduced by me in the *Wild and Cultivated Cotton Plants of the World*, pl. 12).

It manifests all the special peculiarities mentioned, and thus doubtless faithfully represents the plant; but Roxburgh adds that the people of Dacca think the great difference lies in the spinning and allow little for the influence of the soil.

(See remarks on *Hand-loom*, p. 616.)

It has recently been affirmed that the cotton formerly used by the Dacca manufacturers, of the far-famed exceedingly fine muslins of that city, was derived from tree cottons. Further, that the loss of these special crops caused the decadence of the muslin industry. Taylor's account (*Topog. and Stat. Dacca*, 1840) would seem to give a complete refutation of that statement. Moreover, the question may be asked, "Is it or is it not a fact that with an exceedingly short staple the Dacca manufacturers are still producing (or until very recently were producing) muslins, which if not up to the old standards, are certainly far finer than could be manufactured from these staples by any process or machine known to Europe or America to-day?" Taylor says, "The material of which the fine Dacca muslins are made, is entirely the produce of the district. The plant is an annual one, and attains a height of about five feet. It is described by Roxburgh as a variety of the *G. herbaceum*, and is said to differ from the common cotton plant of Bengal in the following particulars: (1) The branches are more erect and fewer, and the lobes of the leaves more pointed. (2) The whole of the plant is tinged of a reddish colour, even the petioles and nerves of the leaves are less pubescent. (3) The peduncles, which support the flowers, are longer and the exterior margins of the petals are tinged with red. (4) The staple of the cotton is longer, much finer and softer." This is the desí or indigenous cotton of the district, which has been cultivated in the northern division from time immemorial.

"Formerly, when this article was more extensively cultivated than at present, there were different shades of quality observable in the staple, which either cannot now be distinguished or have degenerated into one of an inferior degree. They were known by the names of *Phootee*, *Nurmah* and *Bairati*. The cotton of the present day, it is affirmed by the Natives, is inferior to what it formerly was. The crops are less abundant; it is said that the fibres, though apparently equally fine and soft, are shorter and more firmly adherent to the seed, than the produce of former years. The Dacca cotton, however, notwithstanding the deterioration imputed to it, still ranks as an article of finer quality than the produce of other parts of Bengal or of the western provinces," . . . "The seeds, which are used for sowing, are carefully picked, and after having been dried in the sun are preserved in an earthen pot in which oil or *ghi* has been kept, and the vessel with its mouth stopped up, so as to exclude the external air, is hung up to the roof of the hut, and over the spot where the fire is usually kindled. The high lands are selected for this crop and are ploughed from eight to twelve times up to September and October when the seeds are sown. This is done in parallel rows, distant about a cubit from each other, and before the seeds are dropped into the ground they are moistened with water. The cotton plant is liable to injury from hailstorms, heavy rain and caterpillars." . . . "Formerly the ground for cotton was allowed to lie fallow every fourth year, and it appeared to be owing to the neglect of this circumstance in the present day, that the produce is now inferior in quality to that of former times."

"The cotton of the northern division is said to swell less than the produce
THE COTTON PLANT

of other parts of the country. This tendency of the fibre to swell in bleaching is the criterion by which the weavers judge of its quality, but whether it depends on any adherent property in the cotton itself, or on the water used in the bleaching is not known, though there is reason to believe that it is principally owing to the latter. The thread manufactured at Dumroy, which was reported by Mr. Bebb, the Commercial Resident, to swell the most, is found by the weavers at present to be equal to the thread of the best aurungs or to swell the least if bleached in Dacca, but the reverse, as Mr. Bebb describes it, if the water of Dumroy be used in the process."

Lastly, Sen (Rept. Agri. Stat. Dacca, 1889, 52) also says: "The cultivation is not now done half so carefully as was the case at the time of Dr. Taylor. The field is prepared by two to four ploughings and as many harrowings. Furrows are then drawn a cubit apart, and in these furrows cotton seeds previously moistened with dung-water are dropped in thickly. When the plants come out they are thinned to a distance of a foot from one another." (See Cultivation in Bengal, p. 607.)

Improvement, when seriously contemplated, will have to be undertaken, not at a great central farm for all India, but district by district. The establishment of seed farms for the supply of specially improved indigenous stock—a subject I had the pleasure of recommending to the consideration of the Scientific Board of Advice at their first meeting—is at present earnestly engaging the attention of the agricultural experts of the Government of India. It may, therefore, suffice by way of concluding this brief sketch of the present position and knowledge regarding the possible methods and results of improvement of cotton stock, to recapitulate the main ideas. Improvement is possible by (a) Selection of seed, in adaptation to environment and trade requirements; (b) Hybridisation, an additional agency to attain these objects; (c) Acclimatisation of prized foreign stocks. All three methods are in India receiving consideration at present. For many of the cotton districts, selection from existing stocks seems the most hopeful method. It may be said, however, that in the discovery of absolutely new stocks, hybridisation is often of special value.

The Government of India have recently appointed an expert in charge of cotton experiments. The results so far attained in selection and crossing are admittedly of a tentative nature, but Gammie's first report (Note on the Class. Ind. Cottons and Cross-breeding Exper., Poona Farm, 1901–2) manifests a useful start as accomplished. The endeavours of the Bombay Government to bring the vast tracts of Sind under Egyptian cotton through the supply of cheap canal water, would seem to have given much promise, and in the public press repeated mention has recently been made of the high prices realised for the cotton already produced. It may thus be confidently affirmed that there does not appear to be any sufficient reason for doubting the success likely to be attained in India than in other countries with the production of superior cottons. The only untoward anticipations centre around the willingness or ability of the Native cultivator to advance with the times. [Cf. R. J. Redding, Essential Steps in Securing an Early Crop of Cotton, in U.S. Dept. Agri. Farmer's Bull., 1905, No. 217; Testing Cotton Seed, in Agri. Journ. Ind., 1906, i., pt. ii., 174; also Sly, Fumigation American Cotton Seed, etc., 1907, ii., pt. ii., 212.]

III. CULTIVATION IN INDIA.

1. BOMBAY AND SIND.—Watt, l.c. 134–7, 139–54.

Area and Production.—According to the official Agricultural Statistics, the total area under cotton for 1904–5 in the British districts was 3,605,985 acres. The most important localities were Khan-
BOMBAY SUPPLY

GOSSYPIUM

CULTIVATION

Bombay

desh, 1,201,673 acres; Dharwar, 581,950; Bijapur, 455,864; Ahmedabad, 340,602; Broach, 274,699; Sind, 218,050; Belgaum, 183,207; Ahmednagar, 79,626. The area of cotton in the Native States of the Bombay Presidency is an important factor in the Indian cotton supply. This came in 1904-5 to 2,570,985 acres. Kathiawar has usually one to two million acres, and Baroda half a million acres under the crop. The Native States and British districts together thus show the Bombay Presidency with a cotton area of 6,176,970 acres in 1904-5. The yield for the same year was 893,000 bales of 400 lb., or 3,189,285 cwt. The estimated area and yield for the following year were 6,108,900 acres, yielding 1,117,000 bales, in Bombay (including Native States); and 265,000 acres, yielding 79,000 bales, in Sind (including Native States), giving totals of 6,373,900 acres and 1,196,000 bales. The Final Memorandum for the year 1906-7 gives a total of 3,995,499 acres for the British districts, including Sind, and of 3,462,854 acres for the Native States, a grand total of 7,458,353 acres. This estimate is said to be 49.9 per cent. in excess of the average of the preceding ten years. The estimated yield during the same year is 824,052 bales in the British districts (including Sind), 1,071,243 bales in the Native States. The total is thus 1,895,295 bales, an increase of 132.9 per cent. on the yield of the preceding ten years.

Traffic.—In order to arrive at some tangible conception of the local and foreign interests in the cotton of this Presidency, it may be useful to analyse production and supply in the light of the official returns of trade by rail and river and by sea coastwise, from and into town and Presidency. The most interesting features are the supplies drawn by the town from Kathiawar, from the Presidency of Bombay itself, from Berar and from the Central Provinces. The adjustment arrived at shows the Presidency in 1905-6 to make a net export of 2,765,696 cwt., and assuming this to be drawn exclusively from local production (viz. in 1905-6, 1,117,000 bales or 3,989,285 cwt.), a balance of 1,223,589 cwt. would be the net supply retained by the Presidency. It is not, of course, necessarily the case that all the actual exports of a tract of country are drawn from its own production: an error exists in all such calculations which is eliminated by dealing with the whole of India, and for a number of years, not one year. It is useful, however, to ignore such errors and to analyse the figures as they stand. Accordingly, the port town of Bombay is shown to have imported by (internal transactions) rail and by sea coastwise, 10,583,652 cwt., and to have exported by these routes 261,070 cwt., thus showing a net import of 10,322,582 cwt., and, adding the foreign imports, viz. 158,838 cwt., a total net supply of 10,481,420 cwt. The foreign exports (external transactions) came to 5,289,691 cwt., and thus there remained 5,191,729 cwt. as the supply for the Bombay town mills, or, adding the Presidency surplus (viz. 1,223,589 cwt.), 6,415,318 cwt. are shown as having been available for the Presidency and town of Bombay for the year in question. The town of Karachi imports by rail and river approximately the amount which appears in her foreign exports, viz. in 1905-6, 709,257 cwt. In 1905-6 the total imports by rail and river came to 799,721 cwt., of which the Panjáb supplied 427,485 cwt., Sind almost as much, and the balance came from Rajputana and the United Provinces.

Agricultural Operations.—A full account of the method of cultivation in Bombay is given by Mollison, of which the following may be
accepted as a summary. The soil of Broach district is deep and retentive of moisture, and over the greater part the annual rainfall exceeds 35 inches on an average. The crop is sown as soon as possible after the monsoon sets in, in June or July, but owing to the effect of the heavy rainfall, two or more sowings may be required before the seeds germinate satisfactorily. Usually the same field grows cotton every second year, and in intermediate years the ground may lie fallow or grow one of the ordinary rotation crops. Manure is rarely applied oftener than once in three years, and fifteen loads per acre is considered a full average. It should be thoroughly decayed and applied preferably before the rains.

Soils.—The crop thrives best on fairly deep black soil, with a rainfall of 30 to 40 inches, and it is grown entirely as a dry crop. The most suitable soil is the so-called "black cotton soil," which may be found in some parts to a depth of five feet or more as in Ahmedabad, Broach and Surat; but cotton also succeeds on much shallower soils.

Rotation.—Generally the crop is grown alone, but where the rainfall is heavy and the soil retentive as in Broach, rice in the same or in separate rows is often subordinate to it. Coriander, Sesamum, gram (Cicer arietinum) are sometimes sown to fill vacancies. The roj cotton of Kaira, etc., is, on sandy loam soils, always grown as a row crop with bajra (Pennisetum typhoides) or pulses. The principal rotation crop with cotton is juâr (Sorghum vulgare), but this may be modified according to district and season. Thus wheat is extensively grown as a dry rabi crop on the cotton soils of Ahmedabad, lâng (Lathyrus sativus) and a mixed crop of tuwer (Cajanus indicus) and Sesamum as rabi crops in Broach, etc.

Tillage.—Preparatory tilling begins usually in the hot weather by collecting and burning the stubble of the previous crop. Two ploughings and two more harrowings may be required before the seed is sown, but the amount of preparatory tillage necessary depends on the previous crop.

Seed.—The seeds require special preparation for sowing, as they generally cling together, owing to the lint and fuzz which may still adhere to them. This is accomplished by mixing them with a thin plaster of cowdung, mud and water, and rubbing the plastered seed on the close network of a Native bedstead. The seeds can then be passed through the seed-bowls and tubes of an ordinary country seed-drill. If sown alone the seed is drilled in rows 22 to 26 inches apart. About 15 lb. per acre is the usual seed rate. Two harrowings follow one drill to cover the seed and smooth the surface. If the seedlings are damaged before they produce true leaves, the crop should be resown, if the season has not too far advanced.

When the seedlings are about 4 inches high, the crop is ordinarily intercultured with the bullock hoe and hand-weeded. The weaklings are then thinned out and the plants left about 18 inches to 2 feet apart, if in good condition, but if backward or stunted they are left closer together. The plough is finally passed between the rows in September or October.

Crop.—Flowering begins in October–November, and may last till January if the rains are late and favourable. Picking usually commences in January and lasts till March or April. The crop is picked at short intervals, as the cultivators are afraid of their fields being robbed at night. The best time for picking is the morning, as the lint is then clean, owing to the dew on the foliage.
DIFFERENT FORMS GROWN

Yield and Cost.—According to Mollison, the average outturn of seed and cotton together in the Presidency varies from about 300 lb. per acre in the Karnátak to as high as 446 lb. in some well-cultivated fields in Broach. The proportion of clean to seed cotton is on an average about one to three. The total cost of cultivation per acre in the Surat district he estimates at Rs. 21-13 annas.

Modifications on above System.—In Surat the average rainfall is slightly heavier than in Broach, but the soil is not so deep nor so dense, and there is less risk of seedlings being destroyed by rain. The rotation crops are mostly kharif, whereas in Broach they are rabi. Juar is the principal rotation crop, always with a subordinate mixture of white tuver. Rice is never sown with cotton in Surat.

The principal variation in cultivation in the Karnátak is due to the monsoons—the south-west between June and October, and the north-east between October and December. If sowing were to take place in June, as in other districts, the Dharwar crop would ripen in the middle of the north-east monsoon and the cotton be damaged by rain. To prevent this, sowing usually takes place in the latter part of August, and may be even extended to September. The seedlings are not thinned out to the same extent as in Broach and Surat, but are left comparatively close together.

In Khandesh two forms of cotton are grown, the one on black and the other on light soil; they generally occupy the same field once in three years. The light-soil crop yields best with heavy rainfall, the black-soil crop with moderate rainfall. The seed rate is 10 to 12 lb. per acre and is sown, if possible, by June. Picking begins in October and is complete in December. In cotton-picking, care should be taken to avoid floss which is discoloured and damaged by boll-worm, as such obtains a poorer price and its presence lowers the average rate obtained.

In selecting seed for next crop, care should be taken to secure bolls from the largest, healthiest and most copiously fruiting plants. Seed should not be taken from plants on which any of the bolls are affected by boll-worm. As a further precaution against boll-worm, cotton seed should, before it is prepared for sowing, be steeped for five minutes in a \( \frac{1}{5} \) per cent. solution of copper sulphate and then dried in the sun. Disastrous effects on the cotton crop may be produced by sudden atmospheric disturbances. The most trying consequences are due to heavy rainfall, frequent changes of wind, cloudy weather and frost. An abstract from Mr. Walton’s History of Cotton in Bombay, detailing the various diseases caused by these conditions, is given in the Dictionary (iv., 70).

Exotic Cottons.—Except in the Karnátak, where an American cotton has been acclimatised, foreign cottons have failed to take any very prominent place. In this connection mention may be made of the attempts of the late Mr. Tata of Bombay to grow Egyptian cotton beyond the Ghats as a rabi crop in the eight months of dry weather that prevail between the monsoons. The result may be said to have been a failure. At Poona in 1900 two Egyptian cottons were tried. They had an unhealthy appearance from the first, many of the bolls dropped before they were ripe, and both together gave an average outturn of only 401 lb., lint and seed, per acre.

SIND.—Area and Production.—In the Final Memorandum for 1906-7
GOSSYPIUM CULTIVATION

Sind

on cotton-growing in India, issued by the Government, the total area in Sind and its Native States was 245,549 acres. The method of cultivation in Sind differs considerably from that pursued in Bombay. The rainfall is excessively small, and the greater part of the cotton is cultivated by irrigation. An unfailing supply of water can be procured from the Indus. Two methods of cultivation are employed. By the first, frequent watering is necessary after sowing, and the seed is sown on ridges in holes 18 inches apart, after the surface has been inundated. By the second, no watering after sowing is required. The only care necessary is to keep the earth about the stems loose and free from weeds.

Seasons.—In Upper Sind the crop is sown at the end of February or beginning of March, or sometimes as late as May or even June. Picking ordinarily takes place in July to August. After picking, cattle are turned on to the fields to graze, but the roots are left for a second year. Farmyard manure is used, about 12 maunds to the bigha. In other parts of Sind cotton is not cultivated till the canals fill in June, and the crop consequently is not picked till November or December.

Exotic Cottons.—Unlike Bombay, the experiments with Egyptian cottons would appear to have been successful. In a report on the experiments carried on at Dhoro Naro, dated August 30, 1904, Mr. F. Fletcher, then Deputy Director of Agriculture, said of ashmouni and abassi cottons that they yield a minimum of 1,500 lb. of seed-cotton per acre. The plants were irrigated every fifteen or twenty days, at the rate of about 380 cubic metres per acre. In his opinion the experiments so far conducted have sufficiently demonstrated that on perennially irrigated areas in Sind, the Egyptian cottons can be grown normally, and would presumably give even a large yield, but the proper time for sowing would be February or March, and not, as now practised, June to July. He further holds that over-irrigation is often practised on the Jamras. The report then concludes that if the whole of Sind were put under perennial irrigation (through a dam constructed at Bukker) the potentialities of the province for cotton-growing could not be surpassed even by the United States. Mr. Fletcher’s experience in Egypt gives an importance to his utterance on the question of cotton-growing in Sind that carries it to a higher platform than the sanguine expectations of many previous writers on Indian cotton-growing. The area under Egyptian cotton at present is 1,500 acres, but if Mr. Fletcher’s expectations are even partially realised the future may witness a greatly increased interest in this subject, much to the advantage of India. [Cf. Watt, l.c. 225–6.]

2. CENTRAL PROVINCES AND BERAR.—Watt, l.c. 131–4.—Area and Production.—On an average of the five years ending 1904–5 the tract under cotton represented 23–60 per cent. of the total cotton area in British India. In 1904–5 there were 1,492,323 acres in the Central
PRODUCTION AND YIELD

Goossypium Basim, Rotation and Nimar, Bulldna, 755,000 Nagpur, inately.

In the cotton part the list is primarily

The estimated area and yield for the year following were 1,586,000 acres and 347,000 bales in the Central Provinces; 3,197,900 acres and 483,000 bales in Berar; giving totals of 4,783,900 acres and 830,000 bales. The final forecast for 1906–7 shows the total area for both the Central Provinces and Berar at 4,852,087 acres, or an increase of 45 per cent. on the decennial average. The yield for the same year is estimated at 880,984 bales, an increase of about 8 per cent. on the previous year.

Traffic.—Since 1903–4 the figures of railborne traffic have been returned for the Central Provinces and Berar conjointly, consequently 1903–4 is the last year in which they can be discussed separately. The Berar railborne traffic in 1903–4 shows a large export and insignificant import. The net exports in 1903–4 came to 2,049,881 cwt., by far the major portion going to the town of Bombay, the balance to Bengal Provinces (practically none to Calcutta), Bombay Presidency and the Central Provinces. A fairly large amount is usually shown exported in excess of local production, indicating possibly a considerable traffic by road that escapes registration. In the Central Provinces the net export amounted in 1903–4 to only 846,957 cwt., as compared with 2,049,881 cwt. in Berar. The difference is due chiefly to the large quantity the Central Provinces export, viz. 143,822 cwt. in 1903–4, far the largest part of which comes from Berar, Rajputana and Central India. Almost the whole of the exports go to the town of Bombay, an insignificant surplus going to the Presidency of Bombay and to Bengal. In 1905–6 the net exports from the Central Provinces and Berar together amounted to 4,229,617 cwt.

Agricultural Operations.—Rotation.—In Berar, tur (Cajanus indicus), in the proportion of one-tenth, is generally associated with the cotton crop, but in the villages to the south and above the Ghats, bajra (Pennisetum typhoides) and til (Sesamum indicum) sometimes replace it. Rotation is regarded as absolutely necessary. On light soils, cotton is usually rotated with jwar only (Sorghum vulgare), but on the rich black soils of the plains, cotton, jwar and a rabi crop are rotated alternately. A plurality of crops is generally grown in the third year, separate parts of the field being devoted to wheat, gram, linsseed, or lath (Lathyrus sativus), and these in their turn are also rotated. Preparatory ploughing is not carried out every year, as it is considered to impoverish the soil, unless manure be subsequently applied. The advantages of manure are thoroughly understood by the cultivators, but there is great difficulty in Berar in obtaining a supply. Poudrette is considered best, and cowdung comes next in order. Green soiling is sometimes, but very rarely, resorted to. Ploughing generally takes place in December or January, as soon as the crop of the year is removed. The fields are always cross-ploughed. Harrowing succeeds ploughing, and in the case of unploughed fields is the only preparatory operation.

Seed.—Sowing commences with the first fall of rain, in the early part of June. The seed of the previous year's crop is always used, and

601
is prepared and sown much as in Bombay. Ten pounds of seed are considered sufficient for an acre of land. Should a period of drought occur after sowing, the seed will be destroyed; or if rainfall be excessive it may rot. In both cases the crop must be resown. From 20 to 25 inches of rain are enough provided it falls at timely intervals. Under favourable conditions the young plant will put forth four or five leaves in a fortnight, and weeding then becomes necessary. Between the rows, this is done by the bullock hoe, but on the rows, the weeds are removed by hand. Bullock hoeing is carried on at intervals of a fortnight till the pods appear.

Crop.—The bolls ripen and open in October, and the cotton is then ready for picking. The first generally takes place at the end of October or beginning of November. If the crop is a good one, three to seven pickings can be made, according to the kind of cotton grown. The total cost of cultivation has been estimated at about Rs. 13 to Rs. 15 per acre.

In the Central Provinces the method of cultivation does not differ materially from that in Berar. The soil is prepared for sowing in May to June; the seed is sown in June; picking commences in November to December, and is completed from February to March.

Having devoted so much space to the chief cotton-producing areas of India, an effort may now be made to abbreviate as far as possible the accounts that follow of the other provinces to the particulars of chief importance:

Nizam's Dominions. — Area and Production.—The authoritative figures for 1903–4, show the area to have been 2,660,713 acres and the yield 982,367 cwt., or 275,203 bales. The largest cotton area is the Aurangabad Division, which in 1903–4 grew 1,464,116 acres. Then follow Gulbarga, 374,032 acres; Bidar, 292,693 acres; and Wardangal, 75,161 acres. The forecast for 1905–6 reported an area of 2,537,000 acres and a yield of 205,000 cwt., or 759,714 cwt.

The trade returns for 1905–6 show that the net export was 801,144 cwt., or 65,430 cwt. in excess of the estimated outturn. The exports went chiefly to the town and Presidency of Bombay, and a considerable quantity to the Madras ports.

3. RAJPUTANA AND CENTRAL INDIA. — Area and Production.—The area for 1904–5 was 469,000 acres in Rajputana and 846,000 acres in Central India, a total of 1,315,000 acres. The yield for the same year was 1,150,000 cwt., or 322,000 bales. The estimated area and yield for the following year were 289,000 acres and 61,000 bales in Rajputana; 968,000 acres and 129,000 bales in Central India. The latest statistics (1906–7) estimate an area of 428,000 acres in Rajputana; 1,117,000 acres in Central India; with a yield in bales of 176,000 in Rajputana; 291,000 in Central India, giving totals of 1,545,000 acres and 467,000 bales.

The net export trade of Rajputana and Central India amounted in 1905–6 to 856,934 cwt., and as the estimated outturn in that year was 190,000 bales, or 678,571 cwt., the exports for the year were considerably in excess of the outturn. The largest share of the exports go to the town of Bombay, the United Provinces and the Presidency of Bombay. The Central Provinces, the Panjab, and the towns of Calcutta and Karachi also receive

602
considerable quantities. The imports come chiefly from Bengal, the United Provinces, the Central Provinces and Berar.

AGRICULTURAL OPERATIONS.—Rotaiton.—The soils are fertile though light. They fall under Middleton’s third class, which yields the Bengals of commerce. The plant is grown as a mixed crop, usually with til, arhar (Cajanus indicus) and san (Crotalaria juncea), etc. The ground is prepared by ploughing and manuring. The seed is then sown broadcast in the month of April or June, and the land immediately after is lightly ploughed and later on again ploughed. Picking commences in October and is completed by the end of the year. The cost of cultivation has been estimated at Rs. 25 per acre. [Cf. J. Forbes Royle, *i.e.* 309-29; Medlicott, *i.e.* 1862, 249-53; Middleton, *Rajputana Cotton, i.e.* 16.]

4. MADRAS.—Watt, *i.e.* 128-31, 151.—Area and Production.—MADRAS ordinarily grows about 14 per cent. of the cotton crop of British India, or 9-2 per cent. of the entire cotton area. In 1904-5 the total was 2,007,297 acres. The principal districts are usually the following (the figures denoting the acreages in 1904-5):—Bellary, 408,388; Karnul, 268,067; Tinnevelly, 250,521; Coimbatore, 256,948; Guntur, 210,487; Anantapur, 171,051; Cuddapah, 127,854. The yield for the same year was 132,000 bales, or 471,428 cwt. The estimated area and yield for the following year were 1,654,000 acres and 148,000 bales (528,571 cwt.). The latest available figures for the year ending December 1906 show an estimated area (raiyatwari) of 1,544,000 acres, with a yield for the same period of 151,000 bales.

Traffic.—The most noteworthy point regarding the trade of Madras in 1905-6 is the fact that the exports from the Presidency exceeded the outturn. The net export was 864,947 cwt., or 336,376 cwt. in excess of the outturn, which was drawn from beyond the Presidency. The Madras ports had a net import by rail of 932,336 cwt., and by sea coastwise of 10,195 cwt., thus giving a total import of 942,531 cwt. The foreign exports came to 800,479 cwt., and this left 142,052 cwt. as the supply of the Madras town mills.

AGRICULTURAL OPERATIONS.—Forms of Plant.—There are two forms of indigenous cotton usually grown in Madras, one depending on the south-west monsoon, the other on the north-east. The former is sown between May and July, the latter, between September and November. In Tinnevelly both are sown in the same season, October to November. In the Tamil districts these crops are known as uppam and nadam. The uppam crop is generally sown on black cotton soil, the nadam on red or gravelly soils. These produce the four commercial forms known as Tinnevellys, Westerns, Coconadas and Salen. Manure is seldom added, but cowdung or wood-ashes may sometimes be lightly scattered over the ground; and if cattle are not permitted to browse on the fields, the leaves and twigs of the previous year often remain, and thus very possibly carry disease from one crop to another. Irrigation is seldom resorted to, and the raiyat has to depend for the successful growth of his crops on the periodical rains.

Rotation.—In exceptional cases cotton is grown continuously, but the general practice is to have a rotation. The principal rotation crops are kambu (*Pennisetum typhoides*) and vardgu (*Panicum milaceum*), sometimes also chokla (*Sorghum vulgare*) and horse or Bengal gram. If the land is clean, three ploughings before sowing are ordinarily sufficient, but more may be necessary. The soil is ploughed in a drier condition than for grain crops.

Seed.—The seed, which has to be prepared as in other provinces, is generally sown broadcast, and as a rule the same stock is sown over and over again. The seed rate is about 10 lb. per acre. In some districts, however, it is drill-sown in parallel lines, alternately with pulse. The seedlings appear between the third and seventh day. When they are three weeks old the plantation is hand-weeded, and the process repeated several times during growth. The plants begin to flower about the fourth and to ripen their fruit about the sixth month of their growth. In some cases this does not take place till the eighth month. In Tinnevelly, however, the first blooms appear in the third month after sowing and the first bolls open in the fourth month.

Crop.—The pods, as a rule, are not collected as they ripen, but are allowed
Goossypium Cultivation
Mysore

Insect Pests. Cost.

Area and Production in 1906-7.

The Cotton Plant

to remain until the whole crop of the field is ready. The time of harvesting varies, according to the district and time of sowing, from January to August. The cotton crop in Madras seems to be specially liable to the attacks of numerous insects and fungal parasites. An ordinary crop of cotton (in form of seed-cotton) in Tinnevelly runs from 750 to 900 lb. per acre, while 500 lb. is stated to be a fair average when all sorts of soil are taken into consideration. The cost of cultivation varies considerably in different districts. In Anantapur it has been estimated at Rs. 2-13-2 per acre; in South Canara at Rs. 14 per acre. [Cf. Buchanan-Hamilton, Journ. through Mysore, etc., 1807, ii., 157-8, 221-3, 254, 313-4, 326-7, 450-1, 545; Royle, l.c. 464-537; Cassels, l.c. 262-3; J. Talboys Wheeler, Handbook on Cotton Cult. in Madras Pres., 1862; Gribble, Man. of Cuddapah Dist., 1875, 201-4; Nicholson, Man of Coimbatore, 1887, 232-5; Cotton in Madras Pres., Agri. Dept. Mad., Bull. 1890, No. 9; S. Iyer, Rept. on Growth of Cotton in Tinnevelly, Agri. Dept. Mad., Bull. 1891, No. 19; Middleton, l.c. 7-9; Rept. on Operations Agri. Dept. Mad., 1903-4, 5; Madras Weekly Mail, Sept. 8, 1904, 248; Nov. 24, 1904; Proc. Agri.-Hort. Soc. Mad., April-June 1905, 28-31, 36-7.]

Mysore and Coorg.—Area and Production.—The area under cotton in 1904-5 was 71,000 acres and the yield 17,857 cwt., or 5,000 bales; in 1905-6, 76,000 acres with the same yield. The principal districts are Chitaldrug, Tumkur, Mysore and Shimoga. The final estimate for 1906-7 shows a total of 89,000 acres and a yield of 10,000 bales. In 1905-6 Mysore had a net export of 40,287 cwt., or 22,430 cwt. in excess of the estimated outturn. Almost all went to Bombay Province, while small quantities found their way to the Province of Madras, the Madras ports and the town of Bombay. The imports came from the Provinces of Bombay, Madras, and the town of Bombay.

Cotton is not an important crop, and there is little of an exceptional character to be recorded regarding either the plant grown or the methods of cultivation pursued, except that after giving a crop the plants are cut down close to the ground, and in a month after the succeeding rainy season they produce a second crop about twice as large as the first. This appears to be one of the few records in modern times of the pruning of cotton. Hove records, however, that in Gujarat the red-flowered plant was regularly pruned during his time (1787). The older writers on cotton frequently allude to the practice prevailing in the West Indies. [Cf. Watt, l.c. 94, 259, 286, 309, 322.] It is curious that it should have survived in Mysore, a country closely connected with one of the once famed red-flowered cottons. [Cf. Buchanan-Hamilton, l.c. 1807, i., 40, 203, 378-9, 411; iii., 323-4, 351; Lewis Rice, Mysore Gaz., 1897, i., 125-6.]

5. Panjáb.—Area and Production.—On an average of the five years ending 1904-5 the area under cotton in the Panjáb represented about 7-3 per cent. of the total area under cotton in British India. For 1903-4 the Panjáb area, including the North-West Frontier and Native States, was 1,747,000 acres and the yield 1,492,857 cwt., or 418,000 bales. The estimated area for the following year (1905-6) was 2,017,000 acres and the yield 205,000 bales, or 732,142 cwt. The final forecast for 1906-7 gives the area as 1,408,000 acres in the Panjáb and 61,000 acres in the North-West Frontier, a total of 1,469,000 acres and yield of 370,000 bales. The most extensive areas returned for 1904-5 were:—Lyallpur, 165,849 acres; Lahore, 142,621; Hissar, 96,862; Rohtak, 95,880; Gurgaon 92,859; Karnál, 75,000; Multan, 70,342; Gujuránwála, 53,488; Sháhpur, 31,155; and Montgomery, 37,474. In the North-West Frontier, Peshawar, 19,658 acres.

Traffic.—The net exports from the Panjáb in 1905-6 amounted to
568,307 cwt. As the outturn in the same year was 732,142 cwt., it thus exceeded the net export by 163,835 cwt. The largest quantity goes to the port town of Karachi, while considerable quantities also are consigned to the towns of Bombay and Calcutta. The imports come chiefly from the United Provinces. Delhi is the most important manufacturing centre in the province.

Soils, Manures, etc.—The soil of the Panjab is generally well suited to the cultivation of cotton, if irrigated or subject to inundation. All kinds of productive soils appear equally well adapted. Manure is frequently applied, and irrigation either by canals or wells is the general rule. In some of the eastern districts cotton is raised as an unirrigated crop, but nearly always in positions where the young plants can, if necessary, be watered from a neighbouring tank. The crop is generally mixed with others, of which the commonest are til, melons and pulses. Throughout the eastern districts it is the usual practice to sow Hibiscus cannabinus in strips along the edge of the cotton fields, or in alternate rows with the crop. In the Central Panjab certain leguminous crops (species of Melilotus, Trigonella, etc.) are commonly sown with the cotton, as an after crop to be used as fodder for well-bullocks.

Seasons, Crop, etc.—The period of sowing varies in different parts of the province and is largely influenced by the rainfall and the race of plant grown, as also the altitude of locality. In Gurgaon from March to May it is sown near wells, or where there are other means of irrigation, and in June to July on rain lands as soon as the first showers break. In Shahpur and other districts sowings generally go on from the middle of February to the end of March, and in well-watered lands to April or May. The seed is sown broadcast at about the rate of 8 to 12 seeds to the acre. The crop requires to be weeded and watered several times during growth. Picking takes place about November and December. The pods do not all ripen at once, and it is necessary to go over the field several times. Picking ought to be completed before January owing to the danger of loss from frost. It is difficult to give a precise statement as to the cost of cultivation. It differs considerably in some districts, and largely depends on the method of irrigation and the use or not of manure. On land both irrigated and manured, the highest figures quoted are in Jalandhar, Rs. 37-13-4 per acre; the lowest in Jhang, Rs. 10-0-9 per acre. [Cf. Royle, Lc. 301-9; Medlicott, Lc. 218-28, 233-42; Stewart, Pb. Pl., 1869, 22; Dist. Gaz. Pb., 1890-1902; Settl. Rept. Jallandar, 1892, 123-4; Middleton, Lc. 14-5.]

Kashmir.—Lawrence (Valley of Kashmir, 1895, 340-1) gives the following account of cotton. It is found all over Kashmir up to certain elevations. Never less than three ploughings are given before sowing, and the clods are also pulverised by mallets. The seeds are soaked in water and mixed with ashes, but beyond this the plant receives no manure. Sowing takes place at the end of April and in May, and about 48 seeds of seed are sown to the acre. It is cultivated only for home consumption. The outturn is generally stated to be about two maunds (164 lb.) per acre.

6. UNITED PROVINCES.—Area and Production.—On an average of the five years ending 1904-5, the cotton crop in these Provinces represents about 6-6 per cent. of the total cotton area in British India. In 1904-5 the area, including Native States within provincial boundaries, was 1,201,000 acres. In Agra, the districts of Aligarh, 152,407 acres; Muttra, 146,981; Agra, 118,591; Bulandshahr, 109,570; Meerut, 76,866; Etawah, 61,090; Hamerpur, 52,629; Cawnpore, 52,363; and Banda, 43,591. In Oudh, the districts of Hardoi, 11,816; Una, 10,776; and Lucknow, 2,579. The yield for the same year was 1,314,285 cwt., or 368,000 bales. For 1905-6 the total area for the Provinces was 1,372,000 acres and the outturn 394,000 bales, or 1,407,142 cwt., while the final estimate for 1906-7 gives an area of 1,489,000 acres and a yield of 638,000 bales. In connection with this subject an interesting article by Moreland,
GOSSYPIUM
CULTIVATION
U. Prov.

the area sown with cotton in the United Provinces should be consulted.

Traffic.—The net export trade of the United Provinces amounted in
1905-6 to 1,497,159 cwt., or 90,012 cwt. in excess of the outturn. The
exports went chiefly to the ports of Bombay and Calcutta and to the
Panjab, small quantities also going to Bengal, Rajputana and Central
India. The imports largely came from the Panjab, Rajputana and
Central India, while smaller quantities also came from the Central
Provinces, Berar and the port of Bombay. The chief manufacturing
centre is Cawnpore.

Soils, Rotation, etc.—The best grade of cotton soils in the Provinces are rich
loams, which are either directly manured or reap some benefit from manure
applied to a previous crop. Cotton is also grown on poor soils such as the cal-
careous tracts in the neighbourhood of the great rivers. At present cotton
appears to have no definite place in the systems of cropping in vogue, which is
said to be partly due to the uncertain distribution of rainfall and the consequent
uncertain nature of the crop, partly to the low yield and the narrow margin of
profit usually secured. Subbiah (Cult. of Longer-stapled Cottons at Cawnpore
Exper. Station, 1901, 28) suggests various rotations which those interested should
consult. On the better classes of soil the crop is generally grown alone, except
where rows of arhar are sown at intervals of 5 to 7 yards, but on poor ground it
is almost invariably associated with four or five subordinate crops, of which
arhar and til are the chief. Subbiah recommends particularly in the cultivation
of longer-stapled cottons on irrigable lands, a mixture of cotton and maize in
alternate rows at a distance of 1½ to 2 feet. The seed is sown broadcast generally
about the middle of June and then ploughed in. The seed rate is about 4 to 6
seeds per acre. Irrigation is applied only to about one field in seven. Picking
commences about the beginning of October and is in progress from then till the end
of January if not cut short by frost. If the plants are allowed to remain after
January and are watered and hoed two or three times, a second gathering even
better in quality and quantity may be obtained in May and June. On the
richer classes of irrigated land Subbiah gives 140 to 230 lb. of clean fibre as an
average outturn per acre for the rainy-weather crop, and about as much for the
hot-weather crop, giving a total of 280 to 460 lb. of fibre. The cost of cultivation
per acre as estimated by Duthie and Fuller amounts to Rs. 22-9, but by
Subbiah at the Cawnpore Station from Rs. 61 to Rs. 73.

Exotic Cottons.—Subbiah’s report deals mainly with the efforts made at
the Cawnpore Experimental Farm to grow long-stapled American and Egyptian
cottons. As a rule the American cottons did better than the Egyptian, since it
was found the growing season was too short to allow the latter coming to maturity.
It is, therefore, laid down that in introducing long-stapled cottons, it is essential
that those be chosen which mature in their native habitat in about the same
time that the local country cotton does. [Cf. Royle, Cult. and Comm. Cotton
in Ind., 1851, 262-301; Medicott, Lc. 165-218, 229-32; Exper. Farm Repts.

Cotton Acclim. at Cawnpore, in Pioneer Mail, March 17, 1899, 27; Rept. Govt.
Bot. Gard. Saharanpur, 1904, 3-4.]

7. BENGAL.—Area and Production.—In the province of Bengal as now
understood, the area under cotton represents only about 0·6 per cent.
of the total area in India. In 1904-5 the estimated area and yield were
78,000 acres and 20,000 bales (71,428 cwt.); in 1905-6, 73,000 acres and
17,000 bales (60,714 cwt.); while the most recent estimate for 1906-7
forecasts the area at 76,477 acres (39,947 acres early cotton and 35,530
late) and the yield 16,030 bales (6,250 early and 9,780 late), or 57,250 cwt.
The districts with largest areas are:—Saran, 14,400 acres; Sambalpur,
11,693; Santal Parganas, 10,700; Singhbhum, 7,000; Manbhum, 5,100;
Darbhanga, 3,792; Cuttack, 3,400; Mazaffarpur, 3,000, etc.

Traffic.—The trade returns for 1905-6 show that the Province of
Bengal, exclusive of Calcutta, made a net import of 86,224 cwt. The

outturn for the same year was 60,714 cwt., so the total amount available for local purposes was 146,938 cwt. The town of Calcutta imported by rail and river and by sea (coastwise) 1,063,601 cwt. and exported 90,596, giving a net import of 973,005. By adding the foreign imports (2,331 cwt.) we get a total net import of 975,336 cwt. The foreign exports for the same year were 498,567 cwt., so that the amount available for the Calcutta mills was 474,769 cwt. Including the supply for the province (146,938 cwt.), a total of 645,505 cwt. met the local consumption.

Crops, Seasons, etc.—There are generally speaking two cotton crops in Bengal, the early, sown during the monsoon rains and harvested during the cold weather, and the late, sown at the close of the rainy season and harvested during the hot weather. Early cotton is grown chiefly in the Santal Parganas, Sambalpur, Manbhum, Singhbhum and Angul; late cotton in Saran, Muzaffapur and Darbhanga.

It is not deemed necessary to detail the methods of cultivation or other such particulars, since the crop is hardly of sufficient value. In Saran the largest cotton-growing district of Bengal, cotton is sown as a secondary crop, the seed being sown broadcasted. The so-called bhadoi cotton of Saran is sown in January and February and reaped in August; the bysakhi sown in June and July and harvested in April. Maxwell-Lefroy (Notes on Cotton in Bihar, Bull. Agri. Res. Inst., Pusa, Feb. 1904) mentions three ways by which cotton cultivation might be improved—by drainage, growing with other crops, and sowing at another time of year. He considers the failure of cotton in Bihar as due largely to its inability to withstand the wet season, and the improvements he suggests have as their main object the lessening of the effects of the wet weather. He advises sowing in August to October instead of June as the young plants would not then have to struggle through the long rainy season, and the insect pests, which are worst in June, July and August, would not affect the crop seriously. In a note drawn up at the request of the Lieutenant-Governor of Bengal, Mollison (Ind. Pl. Gaz., March 12, 1904, 345) gives an account of recent experiments in Bihar, which he considers should consult; also the efforts made by Messrs. Shaw, Wallace & Co. of Calcutta to grow tree cottons in various parts of the province. Particulars of these latter experiments have been given by Sly (Proc. Govt. Ind. Dept. Rev. and Agr., March 1905.) [Cf. Royle, Cult. and Comm. of Cotton in India, 1851, 241-62; Grant, Rural Life in Bengal, 1860, 187-8; Hunter, Stat. Acc. Beng., 1877, xvi., 105, 342-3; Sen, Rept. Agri. Stat. Dacca, 1889, 51-2; Basu, Agri. Lohardaga, 1890, pt. i., 71-3; ii., 35-7; Banerjei, Agri. Cuttack, 1893, 86-8; Middleton, l.c. 9-12; Banerjei, Monog. on Cotton Fabrics Beng., 1898; Mukerji, Handbook Ind. Agri., 1903; Natural Fert. available for Cotton in Ind., Dept. Rev. and Agri. Proc., May 1904; Ind. Pl. and Gard., Dec. 3, 1904; Feb. 18, 1905, 118-9; Capital, Jan. 14, 1904, 50.]

8. EASTERN BENGAL AND ASSAM.—Area and Production.—The area under cotton represents some 0-3 per cent. of the total under cotton in British India. In 1904-5 it was estimated at 50,000 acres and the yield 17,000 bales (60,714 cwt.); in 1905-6 at 61,000 acres with the same yield; while the latest forecast, namely for 1906-7, puts the area at 57,333 acres and the yield at 13,680 bales (48,857 cwt.). The Chittagong hill tracts are there shown to have an area of 26,636 acres; Garo hills, 23,000; Nowgong, 3,400; Sylhet, 2,060; Khasia and Jaintia hills, 1,000; while smaller areas are recorded in Cachar, Sibsagar, Goalpara, Jalpaiguri and Kamrup.

9. BURMA.—Area and Production.—Burma produces about 0-9 per cent. of the total cotton crop of British India. The area for 1904-5 was estimated at 189,000 acres and the yield 139,285 cwt., or 39,000 bales.
GOSSYPIUM CULTIVATION
Burma

The relative importance of the chief localities in Upper Burma may be expressed by the returns of the year named:—Mingyan, 65,511 acres; Sagaing, 49,575; Meiktila, 36,161; Lower Chindwin, 13,672; and in Lower Burma, Thayetmyo (Lower Burma portion), 12,275. In the following year (1905–6) the estimated area and outturn were 183,000 acres and the yield 35,000 bales (125,000 cwt.); while for 1906–7 the estimates were 186,000 acres, with the same yield.

Traffic.—The trade returns for 1905–6 show that Burma had a net export of 39,225 cwt. The outturn for the same year was 125,000 cwt., so the net supply available for local consumption was 85,775 cwt. Almost all the exports went to Calcutta, but small quantities were also sent to Bombay port and to Pondicherry.

Soils.

Crops, Seasons, etc.—The most suitable areas for cotton are found in the dry zone of Upper Burma. It is there cultivated on good and medium black cotton soil but is also found on inferior soils of a lighter colour. Burke (in a Report on Cotton in Burma dated March 25, 1904) states that cotton is grown on kain land (land periodically flooded by rivers), on taung yar (forest clearings), and on ye (high, dry land). On kain land the seed is sown in September after the floods have left the ground, but such cultivation is now rare. On forest clearings cotton is also said to be unimportant, as the land is more serviceable for other crops. The most important, therefore, is the third, viz. cotton grown on high, dry land.

Yield.

Two kinds of cotton are in general cultivation, the annual (wa-gale), which is sown in April and May and yields from October to December, and a perennial, (wa-gyi) which is sown at the same season as the annual but continues on the fields for three years and yields annually in February or March. The annual is most extensively grown. Wa-gyi is a common crop in Minbu and Thayetmyo, but rare elsewhere. Manuring is general, farmyard manure being considered best. The yield per acre of seed-cotton Burke gives as follows:—on first-class soil, 73 viss (viss = 3'65 lb.); second-class soil, 42 viss; third-class soil, 32 viss. In 1901–2 the average yield per acre of clean cotton for the whole province was only 80 lb.; according to the figures discussed in the Dictionary (taken from reports by the Deputy Commissioner of Meiktila), the yield would appear to average from 125 to 250 viss an acre of seed-cotton. (Cf. Browne, Stat. and Hist. Acc. Thayetmyo, 1873, 87–8; Rept. on Settl. Oper. Meiktila Dist., 1896–8, 7–8; Arnold, Monog. on Cotton Fabrics and Cotton Indust. Burma, 1897, 16–8; Upper Burma Gaz., 1900, ii, pt. 1, 363; Rept. on Settl. Oper. Mingyan, 1899–1901, 32, 42; Mollison, Rept. on Cotton Cult. in Burma, Aug. 18, 1904; Rangoon Times, July 3, 1903; Sly, Cotton Cult. in Burma, in Agri. Journ. Ind., 1906, i, pt. iii, 253–4.)

IV. SOILS AND MANURES.—As already mentioned, Middleton (Agri. Ledg., 1895, No. 8, 117) classifies the Indian cotton soils into three well-marked sections:—(1) rich black clay soils, such as those of Surat and Broach, which produce the finest cottons; (2) soils like those of Kathia-war, Khandesh, Berar and the Central Provinces, that produce the second-grade cottons; and (3) a very large area, too sandy or with too small a rainfall to ripen the finer cottons—the source of the Bengali commerce. Bombay Presidency has soils and climates of all three grades, but it is much more favourably placed than other provinces, by having a larger proportion of both the first and second grade soils.

In his paper on Indian soils, Leather (Agri. Ledg., 1898, No. 2) makes four main heads:—the Indo-Gangetic alluvium; black cotton or rebur; red soils lying on metamorphic formations (in Madras); and laterite soils. The first consists generally of a yellow-coloured alluvium, sometimes sandy, sometimes stiff clay. The only rocky particles larger than sand which this expanse of land contains is the nodular limestone, kankar. (For theory of formation, see p. 711.) Leather
states that in the samples he examined, the amount of phosphoric acid, though small, was more than in other Indian soils. The commonest form of red soil is a sandy clay coloured by iron peroxide. It may be derived from the rocks in situ or from the same products of decomposition washed by rain to lower levels. Laterite soils are simply original soils lying on or adjacent to laterite rocks. The composition of both these classes, according to Leather's analyses, varies considerably, but, like other soils of India, both are deficient in phosphoric acid and nitrogen.

It is on the black cotton or regur soils that Indian cottons are generally grown. Typical regur areas are well represented in the Bombay and Madras Presidencies. The condition indicated may be described as a highly argillaceous, calcareous clay, very adhesive when wet, and from its absorbent nature expanding and again contracting to a remarkable extent. In consequence, during the hot weather, such soils become fissured in every direction by huge cracks, which in depth vary greatly. In some parts, for example at Akola, they have been reported as seen from 40 to 60 feet deep. Underlying the regur is a bed of yellow-white earth consisting of clay, lime and sand intimately mixed. It has generally been supposed that the black colour is due to an admixture of organic matter, but Leather is of opinion that this cannot be the case, but that it must be due to the presence of some mineral substance. He also holds that these soils are not inordinately fertile. In the matter of phosphoric acid and nitrogen they are very poor. The fact that they do produce crops liberally, he thinks, is due to their power of retaining moisture and to their contraction, which not only forms deep and wide fissures, but causes the surface to crumble to a powder, which, getting carried into the larger fissures, thus brings about a continual inversion of the soil.

As regards the manuring of cotton crops, it has been proved by experiment that cotton responds promptly and profitably to a judicious fertilisation. The following account is taken from the results of the experiments carried out by the United States Department of Agriculture. It may be stated in the first place that a complete fertiliser is needed for cotton, i.e. one containing soluble phosphoric acid, potash and nitrogen. Neither phosphoric acid nor potash give as good results separately as when combined. The most effective constituent is phosphoric acid, but nitrogen alone has little or no effect. The best form of nitrogenous manure appears to be cotton-seed meal and nitrate of soda. The proportions of the three constituents in a complete fertiliser should accordingly be approximately, nitrogen 1 part; potash 1 part; phosphoric acid $\frac{3}{4}$ parts. The quantity used per acre varies widely with the nature and condition of the soil, but the maximum should be an amount yielding nitrogen 20 lb.; potash 20 lb.; phosphoric acid 70 lb. The profit from manuring cotton is much increased by antecedent proper preparation of the soil. Farmyard and similar bulky manures are said to be more efficient as soil-renovators than as specific fertilisers for cotton. The concentrated fertiliser should be applied in the drill, not broadcasted, at a depth of not more than 3 inches, and well mixed with the soil.

V. DISEASES AND PESTS.—While many writers make mention of a “deterioration” of the cotton plant as having taken place in India, remarkably little has been said of the actual diseases of the crop. Compared with tea or coffee, Indian cotton can hardly be said to be affected with disease further than failure of crops through unfavourable seasons. Maxwell-Lefroy, Entomologist to the Government of India, has, however, recently issued some useful and suggestive Notes on Cotton in Bihar (Bull. Agri. Res. Inst. Pusa, Feb. 1904) in which he gives brief accounts of some 14 pests met with in the cotton of that province, of which 3 are at present known in Bihar only and 11 are general to the cotton tracts of India. He groups these pests under four sections as follows:—

(a) Insects attacking the leaves and seen chiefly up to September.—Under this series he places the following:—(1) hairy caterpillar; (2) cotton-leaf caterpillar; (3) the cotton bud-worm; (4) spotted boll-worm; (5) the white weevil; and (6) the cotton leaf-hopper. (b) Insects in the stem: (7) the stem-borer and (8) the stem-eweivel. (c) Insects in the boll: (9) the spotted boll-worm and (10) the pink boll-worm; (11) the red cotton-bug; and (12) the dusky cotton-bug. (d) Miscellaneous: (13) the mealy bug; and (14) the large blister beetle.

He then concludes with a recommendation to destroy systematically all traces of the pests as they appear. In August and September a careful outlook should be kept for boll-worms, and all shoots or bolls showing signs of these should be destroyed. More recently Maxwell-Lefroy has issued a paper entitled The Insect Pests of Cotton in India (Agri. Journ. Ind., 1906, i., pt. i., 49–61; also Memoirs Dept. Agri. Ind., 1907, i., No. 2). This will be found to furnish fuller details of six of the more important of the pests, while a further note (The Pests of Introduced Cottons, 1907, i., pt. iii., 283–5) furnishes a few particulars regarding the pests to which exotic cottons are liable.

A curious disease often present to a large extent in India is known to the Natives as gosai or tulsi (the Ocimum-like). The former name (“the ascetic”) denotes the non-flowering and fruiting of badly affected plants, and the latter their colour and general appearance seen at a distance. The leaves, at first large and exceptionally vigorous, ultimately curl up and become small, very numerous, and are then seen to be coated with a woolly formation known as Erinosis—a growth at first supposed to be of fungal origin but now definitely ascertained to be caused by a mite (Phytopus gossypii). This perplexing pest is often very prevalent in Gujarat, as much as 5 to 10 per cent. of the bushes being thereby rendered more or less non-productive. It might be dealt with similarly to the treatment of Erinosis on the vine or other plants, namely by sulphur or kerosene emulsion. (Cf. G. F. Atkinson, Diseases, and L. O. Howard, Pests, in Dabney, The Cotton Plant, 1896, 279–350.)

Resistant.—O. F. Cook has written a highly interesting and most suggestive report on Weevil-resisting Adaptations of the Cotton Plant (U.S. Dept. Agri. Bull., 1906, No. 88). The form specially investigated is the kekehí cotton of Guatemala. This he describes as a dwarf annual short-season variety with numerous features which, in the absence of sufficient numbers of kelep (the so-called Guatemalan ant that kills the weevil), affords material assistance in protecting the crop against the ravages of that pest.
The plant in question matures very early and is more productive than might be expected. He classifies the protective developments into the following:—(1) those calculated to avoid the weevils by general habits of growth; (2) those which exclude the weevils or at least hinder their operations in the buds and bolls; (3) those which attract insect enemies such as the weevil-eating kelep; and (4) those which prevent the development of the weevil larvae even after the eggs have been laid.

VI. CLEANING, GINNING AND BALING, ETC.—The scientific officers who accompanied Alexander the Great and his successors to India described the cleaning, ginning, spinning and weaving of cotton in such detail that it is matter of great surprise that these operations took so much time and study to be fully accepted in Europe. There may be said to have been known in India from time immemorial two forms of gins, viz. the foot roller and the churka. The former is very little used nowadays, though specially applicable to some of the forms of hard-seeded cotton. The latter consists of two rollers of wood, or of iron made to revolve towards each other by hand labour, communicated by a crank or wheel. The seed-cotton is presented at one side against the rollers, the lint passes through, and the seed falls down in front. This is improved by modern contrivances and worked by water power or steam.

The word "gin" is an abbreviation of "engine" which began to have the meaning of machinery shortly after the discovery of steam. The use of that name in India usually denotes the employment of foreign machines for separating lint from seed. A special gin was, for example, invented by Whitney to remove the firmly adhering wool of *G. hirsutum*, and came to be known as the "saw-gin" because it consists of a series of blunt-toothed circular saws made to revolve within the interstices of an iron bed which forms the base of a large hopper. The fibre is caught by the teeth and dragged through, leaving the seed behind. This was, however, found to injure the cotton and, moreover, was not necessary with the Sea Island and other cottons, where the lint separates readily. This led to Macarthy's gin, now very extensively employed for long-stapled cottons. In this contrivance the seed-cotton is drawn in by a leather roller between a metal plate, known as the "doctor," which is fixed tangentially to the roller. A blade called the "beater" is so adjusted as to strike the cotton repeatedly and thus cause the seed to fall out.

It may be said, however, that no modern machine injures the lint and seed less than the Native churka—its one defect is its slowness, and therefore inaptitude for dealing with large quantities. To this fact is due a modern feature, and one of no small importance to the Indian
THE COTTON PLANT

cotton trade, namely the establishment all over the country of large public ginning and pressing mills, each situate in a convenient position to drain the produce of a tract of country within which it often has a monopoly. Naturally this has not proved an unalloyed blessing, though it has had some beneficial results. The cultivators hardly anywhere nowadays gin their own cotton, but carry the produce of their fields to the steam ginning mills. It has already been pointed out that widely different lint contents are in consequence inseparably mixed and ginned together, and moreover the cultivators are given, or purchase, mixed seed. This, it is believed, has rapidly equalised and lowered the Indian staple, thus rendering it imperative for the Government to organise some system of seed culture by which the special evolutions of centuries of cotton-growing may not be irretrievably lost, before the cultivators have learned the value of special selection and intelligent interchange of seed.

In the official statistics published by the Government of India for 1906 there is said to have been in 1904, 951 cotton ginning, cleaning and pressing mills that gave employment to 83,559 persons. Thacker's Directory for 1905 enumerates 73 pressing and 47 ginning mills as those of chief interest. These figures show the extent to which the ginning and pressing of cotton have assumed importance.

The necessity for economy in freights was one of the chief arguments that gave birth to cotton presses. But that consideration would seem to have engaged attention from the very earliest records of raw cotton being exported from India. The Rev. Philips Anderson has shown that as early as 1684 special presses were sent out from England to Surat. For many years the pressing and baling of cotton were done almost exclusively in Bombay; nowadays the pressing is done at the ginning factories.

VII. COTTON-SEED: AN ARTICLE OF CATTLE FOOD AND SOURCE OF OIL.—One of the modern aspects of the Indian traffic in oil-seeds may be said to be the sudden development of a foreign demand for cotton-seed, mainly in the United Kingdom. In 1898-9 the exports were returned at 37,000 cwt.; in 1899-1900 at 43,000 cwt.; in 1900-1 they suddenly advanced to 225,000 cwt.; in 1901-2 they increased tenfold, and became 2,036,000 cwt.; in 1902-3 they still advanced, viz. to 3,974,000 cwt.; in 1904-5 were 2,518,897 cwt.; in 1905-6, 3,891,339 cwt.; and in 1906-7, were 4,387,534 cwt. Thus, within five years, from being utterly insignificant the exports of cotton-seed sprang into the second place in quantity and the fourth in value of all the oil-seeds exported from India. This has very possibly been a consequence of the discovery of successful methods of hulling the seed, the decline of the American supply, or simply the extended use of cotton-seed oil as a material employed in the preparation of lard and margarine. But it is significant of India's consumption of oils and oil materials that even the very large exports of 1902-3 and subsequent years represent but from 10 to 20 per cent. of the amount available. Mollison (Inspector-General}
of Agriculture) in a paper on cotton oil-seed (Agri. Ledg., 1903, No. 9), pointed out that the seed of the United Provinces is best suited for the oil trade.

Oil.—After the cotton (lint) has been removed, the seeds are often subjected to a treatment calculated to remove any still adhering particles of flax. The cleaned seeds are then cut through and decorticated. It is particularly necessary
that this should be done, since the cake after expression of the oil is used as an article of cattle food, for which it is generally believed it would be unfit were the hulls attached. The quantity of oil usually present averages from 20 to 25 per cent. of the weight of seed. But the process of manufacture varies according to the purpose for which the oil is destined. The decorticated seeds are subjected to cold pressure, when from 10 to 12 per cent. of oil is obtained. This is of a fine quality, almost devoid of taste, and is accordingly largely used in cookery, being specially valued for frying purposes. It is often sold in mixture with olive oil or is employed as an adulterant for the cheaper grades of that oil, or pure cotton-seed oil is sold under the name of olive oil. It is also extensively utilised in the production of lard. The cake obtained from this cold expressed seed is next subjected to a further pressure, by the hot process, when an extra supply of oil is obtained up to 10 per cent. By other methods from 15 to 20 per cent. of oil is at once expressed by the hot process, from decorticated or undecorticated seed, and the cake allowed to carry the balance. It is, in fact, generally believed that the presence of a fair percentage of oil is essential, otherwise the cake is useless for cattle food. But it should be here added that very little cotton-seed is in India pressed for oil, though valued as a fertiliser.

The sp. gr. of refined cotton-seed oil varies from 0·922 to 0·924, its iodine absorption is from 105 to 109, and its saponification equivalent ranges from 285 to 294. It has a slight tendency to dry, and congeals at 32° to 45° F. By freezing the oil the glyceryl salts, which are solid at low temperatures, are separated and constitute cotton-seed stearin, an important ingredient of margarine. No information can be discovered regarding the extent to which cotton-seed oil is prepared in India. A note by Burkill records his having inspected in Burma a ginning factory and oil mill owned by Jamal Brothers. The cake prepared is exported and the oil refined. The husk is used as fuel.

Cake.—From fairly ancient records regarding the Indian cotton trade, mention is made of the seeds as a useful by-product, employed to fatten cattle. It is said that they do not at first like the seed but soon take to it very kindly, and may be given a daily ration of as much as 6 lb. In the Nagaexperimental Farm, 2 seers of cotton-seed are given daily to bullocks in place of oil-cake. Nevertheless in many parts of the country the seed is not valued even up to the present day; in fact in India as a whole, the seed can hardly be described as anywhere used by the Natives in the production of oil. The self-same cultivators who grow the cotton plant will raise special oil-yielding crops, the oil of which in some respects may be even inferior to that of the cotton-seed which they entirely neglect. This may proceed from the very generally accepted belief that cotton-seed cake is less wholesome than the whole seed. Mr. R. W. Bingham, who specially investigated the Indian oil-yielding plants half a century ago, said that cotton-seed was more used as an article of cattle food than as an oil-producing seed, and that the seed was considered a better food for working bullocks than even grain. He then added that he did not think it would pay to export the seed since owing to the fibre adhering to it, and perhaps other causes, it is very liable to heat and deteriorate in bulk. The fact that there is to-day a large and prosperous export trade in Indian cotton-seed shows the often unexpected turn that discovery or necessity gives to the trade commodities of the world. In fact, in the Journal of the British Board of Agriculture, Voelcker shows that recent results are distinctly in favour of Bombay undecorticated cotton cake, as compared with Egyptian, especially when its lower price is borne in mind.

Various machines and processes for removing the fuzz from cotton-seed have been patented. Some burn off the velvet, others chemically destroy it, and still others mechanically brush it off. It is no doubt much desired to obtain an effectual and cheap removal of the fuzz, but meantime it is interesting to learn that undecorticated seed-cake finds a market. The chapter on Feeding Value of Cotton-seed by W. Kilgore (in Dabney, The Cotton Plant, 1896, 383-422) will be found to give full particulars on this subject. Other publications of interest are the summary of Dr. T. Thorpe's views (given in Journ. Board Agric., 1898, 205-8).
Hulls and Waste Stems.—Recently it has been found that the hulls or entire seeds may be utilised in the manufacture of a superior grade of writing paper. The stubble, after the cattle have devoured all the edible portions of the plants left on the removal of the lint crop, may be decorticated and a useful fibre thus obtained. It is stated that 5 tons of stubble give a ton of bark, and that a ton of bark yields 1,500 lb. of clean fibre that can be even used as a jute substitute. [Cf. Dabney, i.e.; Connell and Carson, Steer-feeding, in U.S. Dept. Agri. Exp. Rec., 1897–8, ix., 269; Lindsey, Holland and Jones, Cotton-seed for Milch Cows, 1898–9, x., 675–81; Brooks, Cotton, etc., 1898, 309–54; American Cotton Seed Indus., Board of Trade Journ., 1903, 67; Mollison, Textbook Ind., Agri., 1901, i., 126–8; Murerji, Handbook Ind. Agri., 1901, 288–90; Journ. Board Agri., June 1901, viii., No. 1, 41–3; Blount and Bloxam, Chem. for Engin. and Manuf., 232; Mollison, Offic. Mem. on the Cotton Seed Oil Indus. and Estab. of Cotton Seed Oil Mills in Ind., Agri. Ledg., 1903, No. 9; Burtis, Cotton Seed Meal as Pigs' Food, U.S. Dept. Agri. Exper. VIII. THE COTTON FIBRE.—The cotton fibre is a unicellular hair arising from the fibrillar layer of the seed-coat. If taken from the seed of a ripe but unopened pod, it will be found to be a straight, flattened, hollow tube, not quite cylindrical but thickest a little below the middle, tapered abruptly below and more gradually to the apex. With growth, the cell wall thickens, becomes thinnest along the centre and thickest towards what may be called the margins. In consequence of this unequal thickening, maturity is marked by the thinnest parts shrinking most and thus causing the cell to become spirally twisted on itself. The cotton cell may hence be spoken of as a fibril from \( \frac{1}{3} \) to 2 inches in length, twisted spirally. Wiesner (\textit{Die Rohst. des Pflanzenr.}, 1903, ii., 240–1) gives a series of measurements to show that the broadest section generally falls a little below the middle. It is a noteworthy circumstance, and moreover one of practical importance, that the moss taken from a capsule always consists of fibres of various lengths. Allard (\textit{U.S. Dept. Agri. Bureau Pl. Indus. Bull.}, 1907, No. 111, 13–5) has shown that this is frequently a consequence of certain cells separating from the seeds and uniting with other cells, thus producing the apparent though not real greater length. This discovery may prove of great value. Average Indian moss does not come to three-quarters of an inch in length, while some varieties of Sea Island have a staple two inches long. 

Evan Leigh (\textit{The Science of Modern Cotton Spinning}) gives the following measurements as representative of the lengths (maximum) of cotton staples:—New Orleans, 1.16 inch; Sea Island, 1.80 inch; Brazilian, 1.31 inch; Egyptian, 1.52 inch; Indian (indigenous), 1.02 inch; Upland American grown in India, 1.21 inch; Sea Island grown in India, 1.65 inch. [Cf. Watt, i.e., 1907, 25–51.]

Structurally, the cotton fibre consists of a wall of almost pure cellulose, lined by a delicate layer of protoplasm, which disappears early in the growth of the fibre as the secondary placed deposits increase and a central core of endochrome is formed—the colouring material of the cell. The wall constitutes from one-third to two-thirds of the diameter of the cell. Recently an exceedingly interesting discovery was made by H. de Mosenthal (\textit{Journ. Soc. Chem. Indus.}, March 31, 1904), namely that the cotton cell-wall consists of two layers, termed the outer and inner, which are pierced by minute pores, leading into the lumen of the fibre. These
pores, hitherto unobserved, offer an explanation of the way moisture penetrates to the interior. Among the ripe flosses of every grade is often present a certain percentage of quite unripe hairs. These are very thin, have weak cuticles, and show no twisting; they are the cause of much depreciation, since they cannot be worked up nor dyed in the same manner as fully formed flosses. In practical work such hairs are known as “dead cotton.” According to Hanausek (Tech. Mikroskopie, 1900, 5–8; also Winton and Barber, transl., 1907, 58–68), dead cotton is commonest in coarser grades (Levantine and Indian) and rarest in Sea Island. [Cf. Flatters, The Cotton Plant, 1906, 59–92.]

The commercial value of cotton is chiefly affected by the length and uniformity of the staple. Silkiness, fineness, strength, cleanliness and colour are the other important factors. Tables showing the physical properties of the various staples of commerce are given by Hannan (Text. Fibres Comm., 1902, 94–9), while Flatters contributes micro-photographs and comparative descriptions of the flosses of the following trade samples:—Florida, Brown Egyptian, New Orleans, Peruvian Rough and Hingan-ghat. As offered for sale, cotton always contains moisture varying from 7½ to 12½ per cent. over absolute dryness. With regard to the influence of moisture on spinning, the reader should consult Dobson (Humidity in Cotton Spinning, Sept. 17, 1894).

When immersed in a solution of caustic soda, cotton fibre undergoes an important change. The cell-walls swell and acquire silky gloss. Cotton so treated is known as mercerised. The process was invented and patented in 1851 by John Mercer, a Lancashire calico-printer. The swelling of the fibre causes a shrinkage in length, it becomes more transparent, gains in strength and weight, while its capability for taking up certain dyes is vastly increased.

Chemically, the mature fibre consists of almost pure cellulose with about 3 per cent. of other substances. The most important of these are cotton wax, fatty and pectic acid, endochromic colouring matter, and albuminous substances. The fibre is insoluble in water, alcohol, ether, fixed and volatile oils or vegetable acids, but soluble in strong alkaline solutions and is decomposed by concentrated mineral acids. Cuprammonia causes a complete disorganisation of the cellulose deposits.

IX. INDIAN MANUFACTURES.

The cotton manufactures of India may be said to be referable to three groups:—1. Indian Hand-loom goods. 2. Indian Power-loom goods. 3. Foreign Power-loom goods.

These three have to be clearly borne in mind both in connection with the present chapter and that on trade. The late Sir James Westland
said of India, and with some force, that “weaving is for the most part the pursuit of the bye-time of the persons who weave.” That is doubtless the condition in many parts of the country to-day, but here and there centres of professional hand-loom weaving still exist where the village weaver holds an honoured position. He, in fact, turns out a fair portion of the dresses worn by the more conservative and orthodox members of the community. Increased prosperity of these hard-working and highly deserving craftsmen was entertained by some writers as likely to ensue when the repeal (in 1896) was announced of the tax on yarn, conjointly with the imposition of a countervailing duty on power-loom manufactures, both foreign and Indian. It was thought that all that need further be done, to restore and uphold the hand-loom industry, was to teach the Native weavers the use of the fly-shuttle and a few other such contrivances.

A century ago or more these very contrivances had in Europe been found quite useless in the contest with steam, but it was presumed conditions existed in India that raised the possibility of hand-loom improvement to a position of supreme importance. Hence it was urged, among other considerations, that “the hope of the hand-loom industry lies in the production of goods of a kind which cannot profitably be made by the power-loom, such as those compounded in an intricate fashion or made in a very complicated pattern. The fact that after a long struggle with the products of the mills, the hand-loom industry still survives, may be held to show that it has vitality to preserve it yet for many years.” It would very possibly be nearer the truth to say that the hope of the hand-loom weaver lies in the restriction of his operations to lines that are too small to tempt the competition of the power-loom worker. It may, in fact, be safely affirmed that there is nothing either too fine in texture or too complicated in pattern for the power-loom manufacturer to produce. His advent on the field is alone restricted by the possibilities of profit. The finest Dacca muslins and the most intricate Kashmir shawls can be and have been produced by machinery cheaper than by hand labour. But there are markets eminently suited to the hand-weaver, such as the production of special saris and lungis of a particular shape and size that the power-loom producer does not successfully contest.

There is this also in favour of the hand-loom weaver—he can purchase the very best English spun yarn and produce a quality of fabric admittedly superior to the very best power-loom textiles ordinarily turned out by the Indian mills. But, let it be repeated, his safety lies in the goods he manufactures being of a fancy or special nature, meeting local markets known to him, rather than in regular commercial articles intended for large markets.

**HAND-LOOM INDUSTRY.**—It would occupy much time to review, however briefly, the chief centres of hand-loom production and the class of goods turned out. The figures given within brackets, in the enumeration that follows of the cotton-weaving centres of India, denote the number of steam-power mills in 1904. The square brackets show the provincial totals and the round brackets the district totals, while districts without figures have no power-loom mills.

The districts most famed are:—**Panjāb** [8]—namely, Dera Ismail Khan, Multān, Shāhpur, Kohat, Peshawar, Lahore (2), Armitzar (1), Delhi (5), Rohtak, Sialkot, Ludhiana, Gurdaspur, and Jallandhar. Thus 13 districts of the Panjāb are noted for their cotton manufactures, and three of these possess power looms. Similarly the **United Provinces** [9]—Benares, Bulandshahr, Sikandrabad, Azamgarh, Lucknow, Cawnpore (4), Mirzapore (1), Aligarh (1), Agra (3), Fyza-

---

616
bad, Rai Bareli and Rampur. Central Provinces [7]—Nagpur (2), Umner, Bhandara, Burhanpur, Sambalpur, Chanda, Hinganghat (2), Jabalpur (1), Pulgaon (1), and Raj Nandgaon (1). Berar [2]—Badnera (1), Akola (1), and Elichpur. Rajputana and Central India [4]—Kota, Gwalior, Indore (1), Ujjain (1), Ajmir-Merwara (1), and Kishengarh (1). Hyderabad [3]—Aurangabad (1), Hyderabad town (1), and Kukuraga (1). Bengal [10]—Calcutta (7), Howrah (3), Bardwan, Birbhum, Serampore, Nadia, Murshidabad, Jessore, Dinajpur, Rangpur, Bogra, Dacca, Tippera, Faridpur, Chittagong, Patna, Shahabud, Saran, Monghyr, Bhagalpur, Cuttack. Assam—Sibsagar and Manipur. Bombay [141]—Bombay City: (84), Ahmedabad (32), Broach (4), Surat (3), Baroda (1), Verungam (2), Wadhwan (1), Naraid (1), Julgaon (1), Bhavnagar (1), Hubli (2), Sholapur (3), Belgaum (2), Darwar (1), Bijapur, Poona (2), Nasik, Thana Moru (1). Sind—Hala, Narapur and Karachi. Madras [17]—Madras town (4), Chingleput (Godavari), Nellore, Vizagapatam, Masulipatam, Salem, North Arcot (Arni), Coimbatore (1), Bellary (1), Tanjore, Madura (1), Pondicherry (5), Tinnevelly (2), Tuticcorin (1), Calicut (1), and Travancore (1). Mysore [2]—Bangalore (2) and Shimoga. Burma—A domestic industry only.

**Sites for Factories.**—The selection of sites for steam-power factories has been governed mainly by three considerations:—(1) proximity to supply of raw cotton; (2) the existence of an indigenous industry and therefore of a community of professional weavers who might be drawn upon for labour; and (3) facilities of transport to important markets. As indicated by the figures in the above enumeration, the modern power-loom industry has followed very much in the path of the ancient hand-loom craft. The fine muslins of Dacca, Arni, Chanderi, Kota, Rohtak, Benares and other localities are still being manufactured. Many writers speak of Dacca muslins as being a product of past ages. So long ago as 1820 Mr. Walter Hamilton, one of the Company's officials resident in Dacca, prophesied that with the decline and fall of the Delhi Court the loss of the fine muslins of Dacca might be expected, since the demand for these expensive fabrics very possibly would cease. But at the Delhi Durbar Exhibition of 1903 some remarkably fine muslins of Dacca were sold on behalf of the manufacturers—and these were very nearly as fine as the samples in the Calcutta Museum, which were procured in 1884 and made somewhere about that date. There is no very ancient sample of these muslins known anywhere, so that we have little by which to compare the famed ancient textiles with the modern productions. But the examples presently being turned out would measure 400's or 450's, while English power looms have been known to produce 600's. Cotton yarns are said to be counts of 20's, 30's or 400's, when not more than a like number of hanks of 840 yards go to the pound avoirdupois.

The point of interest in these Dacca muslins, however, lies in the fact that the hand spinners of Dacca are producing to-day yarns of a fineness that no machinery in the world could spin from the inferior staple which they use. Dr. Taylor wrote, in 1840, that the Dacca spinners failed to use the fine American cottons, and gave as their reason the fact that the English yarn swells on bleaching, while that of Dacca shrinks and becomes finer and stronger. It would thus appear that the European spinner, with all his beautiful machinery, may still have something to learn from the hand spinner, and that something might possibly lead to his being able to spin shorter staples than he at present considers indispensable. This hint seems worthy of careful investigation (see pp. 594-5, 607).

**Special Indian Goods.**—The artistic cottons produced in India are referable to two main heads—long cloths or damasks and muslins, plain or figured. The patterns are usually woven, not printed. When checked

617
they are in North India commonly termed kheses, to the South gabris : when striped they are susis. The usual colours are dark red for Hindus, dark blue for Muhammadans, in both cases interwoven with white. The dhoti or dholar is worn by men and is a piece of plain cloth generally having a coloured border and measuring about 5 yards in length and 1½ yards in breadth. It may be made locally or imported. The sari or woman's upper garment varies greatly according to the wealth, position, caste, etc., of the wearer as regards the material, quality or degree and nature of ornamentation. With finer materials it is usually a gauze, and is still very largely hand-loom work. The sari is, from an art point of view, perhaps the most picturesque of all Indian garments. The chadar or shawl is a sheet usually about three yards long and half as wide. It is worn by men, but by women of certain castes only. The pagri or lungi (turban) is a long narrow strip of cloth worn by men round the head or around the waist as a cummer-band (kamar-band). Mandelslo (Travels, in Olearius, Hist. Musoevy, etc., 1662, 27, 83) discusses the cotton manufactures of Broitschia (Broach) and of the "comerbants" or girdles of silk and fine cotton.

Throughout India certain localities are famed for the quality, design, etc., of their kheses, gabris, susis, dhotis, saris, chadors, pagris and lungis, etc. The merchant who may desire to open up a trade in manufacturing and supplying these special goods must ascertain the exact size and shape, the particular quality and colour in demand in each locality. The mere fact of offering a superior quality of goods is no inducement to trade. Few communities in the world are more conservative regarding their garments than are the various races and castes of India.

The figured or flowered muslins—jamdanis—are by far the most artistic of the cotton manufactures. These are literally cotton brocades, the patterns or flowers being formed by spools carrying special threads of cotton, silk, wool or gold, that are thrown by hand within the warp and thus become supplementary to the weft. The centres most famed for these artistic textiles are Dacca, Santipur, Chittagong, Tanda and Chanderi. The figured muslins of Calcutta and Lucknow are needle-embroidered (chicken) work.

**STEAM-POWER MILLS: Spinning and Weaving.**—The first cotton mill founded in India was at Fort Gloster (the Bowreah Cotton Mills Company, Ltd.), near Calcutta. This received its charter in 1818 as a cotton mill, a coffee plantation and a rum distillery. Some years later the first of the Bombay series was established, namely the Bombay Spinning and Weaving Company (1851), and ten years later there were a dozen mills and 338,000 spindles at work. In 1879 the number had increased to 58 mills and 1,500,000 spindles, giving employment to 39,537 persons; in 1886-7 there were 90 mills with 16,926 looms and 2,202,602 spindles; in 1896-7, 155 mills, 37,303 looms and 3,984,023 spindles; and in 1901-2, 194 mills, 41,815 looms and 4,992,249 spindles. Within the decade ending 1901-2 the number of looms had increased by 69 per cent., and of spindles by 52 per cent. The capital invested in the 194 mills has been published as Rs. 16,01,40,384 plus £650,000; in 1904-5 they had still further expanded, namely to 203 mills with a capital of Rs. 15,97,41,301 plus £1,067,245, and had 47,305 looms and 5,196,432 spindles. In the Moral and Material Progress of India (1905-6, 176) the following statement occurs:—"There were at the end of 1905-6 in British India and Native
States 204 cotton mills containing 52,300 looms and 5,293,800 spindles, and giving employment on an average to 212,700 persons every day. Of these, 104 were exclusively spinning mills, eight were exclusively weaving mills, and in the rest both spinning and weaving were carried on. The capital invested, including an estimate for ten companies worked by private proprietors, for which accurate returns are not available, was £10,690,000 (paid-up capital and debenture loans). The industry is located, as regards 70 per cent. of the mills, in the Bombay Presidency, while there are 19 mills in the territory of Native States and in French possessions in India. Between the years 1893 and 1900 the industry was depressed, profits being affected by the disturbances in exchange relations with the Far East which followed the closure of the Indian mints, by over-production, by plague, by poor crops, by famine and by the disturbances in China. Since 1901 there has, however, been a satisfactory improvement. The Indian mills give permanent employment to 186,271 weavers, besides occasional employment to large numbers of cultivators, carters, boatmen, etc., etc. By way of comparison, it may be stated that in 1904 there were 2,077 mills in Great Britain; 1,201 in the United States; 500 in Italy; 420 in France; 390 in Germany; 304 in Russia and Poland; 257 in Spain; 203 in India; 64 in Japan; and 22 in Canada—the grand total of the world, including all others not specified, being 6,014 cotton mills.

Wages of Indian Operatives in the Cotton Industry.—It would be impossible to furnish an average wage of all the employees in a mill that would be of any value, since the different classes of labour naturally command different wages. Still more impossible would it be to produce a figure or set of figures that could be regarded as applicable to the whole of India. The following returns taken from an actual statement given by the Government of India (in the publication known as Prices and Wages, 1906) are, however, highly instructive and indicate the average wages (piece-work and monthly wage, in Rs.) paid at the Manockjee Petit Mills of Bombay in January of each year from 1882 to 1906:—doffer, in 1882 Rs. 5, in 1906 Rs. 6.5; winder, in 1882 Rs. 5 to 7, in 1906 Rs. 6 to 9; royer, in 1882 Rs. 14 to 16, in 1906 Rs. 12 to 15; reeler, in 1882 Rs. 5 to 7, in 1906 Rs. 7-5 to 9; opener, in 1882 Rs. 15 to 17, in 1906 Rs. 12 to 20; weaver, in 1882 Rs. 14 to 20, in 1906 Rs. 12 to 30; jobber, in 1882 Rs. 35 to 45, in 1906 Rs. 30 to 50. These are only a few out of the many, but they are sufficiently representative to show the wide range of wages earned, and to indicate the immense importance of the industry to a locality like Bombay that can lay claim to 79,270 men, 28,412 women, 13,590 young persons, and 5,883 children, a total of 127,155, all earnings wages on the scale indicated (the special cases mentioned), manifesting the highest, the lowest, and the medium class earners.

TAXATION.—Cotton goods imported into India were for many years subject to a duty of 5 per cent. This tax existed, for example, before the date of the Mutiny and was continued when the East India Company ceased to exist. It was raised to 10 per cent., then in 1864 reduced to 7½ per cent., and in 1875 to 5 per cent. with lower rates for twists and yarns. But, by a Resolution of the House of Commons, 1877, it was ruled that these duties, being protective, should, as early as possible, be repealed. Accordingly, in 1882, the Indian import tariff was practically abolished and no fresh duties were levied until 1894. In March of that year import duties were charged on most articles except cotton goods. The omission of cotton was vigorously opposed by the Indian manufacturers, and a few
THE COTTON PLANT

months later the bill was accordingly amended and certain cotton imports were excised. The cotton goods and yarns imported into India are mainly of the finer qualities, whereas those manufactured in India (chiefly on account of the inferior quality of the local staple) are of the lower grades. But with the medium-class goods, the foreign supply overlapped the local production, and hence, with a view to take away the protective character of the customs duty, it was decided to impose an excise duty of 5 per cent. on the medium qualities of yarn produced in India. Technically this is expressed by saying that all Indian-produced yarns above 20's were taxed. It was soon found, however, that this endeavour to equalise the burden of taxation on the two great competing sets of cotton manufacturers (Indian and Foreign) was not a success. In 1896 a further Act was accordingly passed by which cotton yarns were freed from taxation and a uniform duty of 3½ per cent. imposed on all woven goods imported into India or manufactured by Indian power-loom mills, the village hand-loom industry being exempted. In 1902, B. J. Padshah wrote a Memorandum on the Profits of the Cotton Industry of India and the Cotton Duties, to which the editor of The Times of India contributed an Introduction: these papers will richly reward perusal. They may be accepted as setting forth present Indian commercial opinion. Padshah hinges the whole of his critical and very able review on two conceptions that he endeavours to disprove, viz. “that the average profits of the Mill Industry are high”: “that the Cotton Duties would be really paid by the consumer of cotton goods and not by the producer.” The net duty collected on the goods manufactured by the Indian mills for the four years 1901-2 to 1904-5 was, 1901-2, Rs. 17,77,965; 1902-3, Rs. 18,91,010; 1903-4, Rs. 20,95,149; and 1904-5, Rs. 24,06,976.

X. INDIAN TRADE IN RAW COTTON AND COTTON MANUFACTURES, BOTH LOCAL AND FOREIGN.

RAW COTTON.—So much has already been said regarding the Indian Cotton Trade that this account may be fittingly drawn to a close by a few short paragraphs devoted to the more important sections under which transactions are ordinarily conducted. The total area (according to the Final Memorandum of the Commercial Intelligence Department for the year 1906-7) occupied by cotton was 14,918,000 acres in 1904-5, with
a crop of 3,826,000 bales; in the following year the corresponding figures were 21,072,000 acres and 3,426,000 bales; and for 1906-7 they are estimated at 22,344,000 acres with 4,908,000 bales. These are the actual returns, as also the estimates for all India (British and Native States). In 1904-5 the yield of the British districts alone came approximately to 34 million bales, while the exports and mill consumption together came to 3,390,413 bales. In 1905-6 the Final General Memorandum estimates the yield in British districts only at about 2,244,000 bales, while the mill consumption is said to have been 2,025,733 bales and the exports approximately 2,000,000 bales. Going back to previous years, in 1903-4 the acreage was 18,042,781, the outturn 3,168,113 bales; the foreign exports were 7,931,075 cwt. (or 2,220,701 bales), thus leaving a balance (plus the produce of Native States) of 947,412 bales as available to meet local demands. But the scarcity of cotton in Europe, then prevalent, very possibly created a stronger demand for Indian cotton than can be regarded as normal. It may, therefore, be desirable to examine the returns of the year previous. In 1902-3 the crop was 16,581,046 acres, yielding 3,367,030 bales, and the exports to foreign countries 1,692,545 bales, thus leaving a balance to meet local demands of 1,674,485 bales, or exactly one-half the production. At the present day the hand-loom weavers rarely spin their own yarn, but purchase supplies either of the imported or of the Indian mill-spun yarn. It may thus be accepted that the balance of production over the demands of the Indian mills is available for the foreign markets.

Exports.—During the past seven years the following were the exports in cwt. and rupee values:—1900-1, 3,575,703 cwt. and Rs. 10,12,74,007; 1901-2, 5,700,014 cwt. and Rs. 4,42,60,933; 1902-3, 6,044,806 cwt. and Rs. 14,75,71,981; 1903-4, 7,931,075 cwt. and Rs. 24,37,61,464; 1904-5, 5,657,743 cwt. and Rs. 17,43,46,872; 1905-6, 7,399,534 cwt. and Rs. 21,34,15,195; and 1906-7, 7,400,839 cwt. and Rs. 21,94,84,609. These figures thus show an average valuation of close on fifteen crores of rupees; and if we assume an equal valuation for the share of the crop retained (well under the mark), the total value of the cotton raised in India would not be far short of thirty crores, or say £20,000,000.

Low Grade.—Reference has already been made to the degeneration that has taken place in the staple grown in India. The cultivators have allowed themselves to be driven into the production of an inferior staple or they have deliberately selected to grow that class of cotton. If the manufacturer would pay no more for a long than for a short staple, the Indian cultivators naturally sought out the plant that could give them the highest and most profitable yield. It is not surprising, therefore, that within the past thirty years or so the fine long-stapled cottons of India—the cottons that at one time were much admired and found a ready sale in Europe—have gradually disappeared, and that inferior but highly productive, early ripening and hardy races have taken their places (or are rapidly doing so). But the change that has come over the cotton industry may be spoken of as a consequence of various influences. The Indian mills having at hand an inferior staple, concentrated their attention on low-count yarns and inferior piece goods. So successful were they that in a remarkably short time they closed the Indian doors to imported goods of that class. England, on the other
hand, went in for long-staple cottons in order to produce high-grade goods. She found these in the United States, and thus gradually closed her doors against the short-staple cottons of India. But that inferior yarns might come to be refused both in India and China seems never to have been contemplated, yet it may now be affirmed that the future prosperity of the Indian cotton industry will turn very largely on whether or not the Indian cultivator can produce cotton superior and cleaner to that presently grown. With better-grade cotton it may in all fairness be said that it can be but a question of time when the Indian mills will claim a steadily increasing proportion of the supply of higher-count goods not only to India but perhaps to the world.

MANUFACTURES.—Local Trade in Yarn.—The production of yarn by the Indian mills (British and Native) has progressed steadily, but not phenomenally. The outturn (including Native States) in 1893–6 came to 432 million lb.; in 1900–1 it fell to 352 million; in 1902–3 rose to 575 million; in 1904–5 stood at 578 million; and in 1905–6 at 655 million lb., with in addition 25 million lb. produced by the mills located in the Native States. Of the amount for 1904–5, Bombay Presidency claimed as its share 422 million lb., being followed by Bengal with 38 million, Madras, 30 million, the United Provinces, 27 million, the Panjáb, 11 million, and lastly by the Native States with 2241/2 million lb. Of the total production in 1904–5 about 110 million lb. in the British districts and 4 million in the Native States were in higher counts, that is to say, qualities above 20's. This was about 10 million lb. in excess of 1903–4, and 43 million in excess of 1900–1. One of the most significant features of the modern traffic in Indian cotton manufactures is this increase of the outturn of the higher-count yarn, for which a fair amount of foreign raw cotton is being imported, and recently an increasing local production. In 1904–5, 192,544 cwt. of cotton were obtained from the United Kingdom, Germany, Egypt and the United States, etc., and in 1905–6 this supply stood at 161,476 cwt. The production of counts in 1904–5 was 51 million lb., in excess of that of 1899–1900. Attention has been drawn (in the Review of Trade) to the fact that the imports of high-count yarns have been almost in the inverse ratio to the expansion of the exports of Indian-produced yarns of that class (30's and over). By way of contrast with this prosperous Indian industry, it may be pointed out that the weight of twist and yarn imported in 1888–9 was 521/2 million lb.; in 1898–9 it stood at 451/2 million; in 1903–4 at only 28 million; though it rose again in 1905–6 to 451/2 million lb.

Exports of Indian Yarn.—With regard to the exports of Indian twists and yarns, in 1876–7 these stood at close on 8 million lb., valued at 363½ lakhs of rupees; in 1903–4, at 252½ million lb., valued at about 9 crores of rupees (£6,000,000); in 1905–6 at 297½ million lb., valued at over 12 crores (£8,000,000); and in 1906–7 at 243½ million lb., valued at 10 crores (£6,931,021). Deducting these exports from the above-mentioned total production of yarn at the Indian mills, in 1903–4 there remained 303½ million lb. plus the foreign imports of, say, 28 million lb. of yarns, etc., as the amount to be worked up by the Indian power and hand looms; and in 1905–6 about 337½ million lb. plus the foreign imports, viz. 45½ million lb.

Piece Goods.—The woven goods produced by the Indian mills came to 95 million lb. in 1899–1900; 117 million lb. in 1902–3; 131 million lb. in 1903–4; 152 million lb. in 1904–5; and 156 million lb. in 1905–6, with in addition 7 million lb. turned out by mills in Native States. The
manufactures are mainly grey unbleached; to be more exact, an average of about 83 per cent. are of that nature (126 million lb. out of the total 156 in 1905-6). The proportion of higher-class goods varies in the different provinces; in 1903-4 Madras showed 64 per cent., the Central Provinces 28 per cent., and Bombay 17 per cent. of their manufactures as white and coloured goods, hosiery, etc. It seems probable that the grey goods represent about four yards to the lb. in weight, so that in 1902-3 approximately 386 million yards of grey goods were produced by the Indian mills, 435 million in 1903-4, 524 million in 1904-5, and 540 million yards in 1905-6; while approximately 80 million yards of coloured, etc., were produced in 1902-3, 100 million in 1903-4, 108 million in 1904-5, and 112 million in 1905-6. The goods turned out at the Indian mills are grey—described as chadars, dhutis (or dhottis), drills, jacobets, madapollams, dulls, printers, shirtings, sheetings (T-cloths). Finer Goods—figured, coloured or miscellaneous goods and hosiery. Although the home market is likely for many years to be of primary importance to the Indian mills, the exports of Indian-woven cotton goods cannot be called unimportant. In 1903-4 the exports were valued at Rs. 1,63,07,648; in 1905-6 at Rs. 2,03,78,124 (= £1,358,541); and in 1906-7, Rs. 1,77,17,086 (= £1,181,139).

Foreign Trade.—Turning now to the Imports from foreign countries—chiefly Great Britain—a traffic which constitutes nearly two-fifths of the whole imports taken by India. The trade in yarns, as already indicated, has declined. The piece goods are referred to the following chief groups:—Grey or Unbleached; White or Bleached; and Coloured, Printed or Dyed. India received in 1903-4, 1,085 million; in 1904-5, 1,210 million; in 1905-6, 1,348 million; and in 1906-7, 1,298 million yards of Grey piece goods. In 1903-4, 466 million; in 1904-5, 584 million; in 1905-6, 572 million; and in 1906-7, 494 million yards of White goods. In 1903-4, 481 million; in 1904-5, 493 million; in 1905-6, 541 million; and in 1906-7, 524 million yards of Coloured and printed cotton goods. These therefore totalled in 1903-4 to 2,032 million; in 1904-5 to 2,288 million; in 1905-6 to 2,463 million; and in 1906-7, 2,318 million yards; and the re-exports from these were in 1903-4, 66 million; in 1904-5, 63 million; in 1905-6, 67 million; and in 1906-7, 61 million yards, thus leaving in 1903-4, 1,966 million yards available for India; in 1904-5, 2,225 million; in 1905-6, 2,396 million; and in 1906-7, 2,257 million yards.

Adding together the estimates of grey and coloured goods given above as the production of the Indian mills, we obtain the following:—466 million yards in 1902-3; 535 million in 1903-4; 632 million in 1904-5; and 648 million in 1905-6. Deducting from these the exports to foreign countries, viz. 69 million yards in 1902-3, 75 million in 1903-4, 87 million in 1904-5, and 91 million in 1905-6, we arrive at 397, 460, 545 and 547 million yards respectively available for India; and adding these sums to the total imports also mentioned above, the grand totals become 2,448, 2,426, 2,833, and 3,016 million yards as the net Indian supplies for the years in question. This, in a population of 300 millions, allows each person to get about eight to ten yards per annum. It would thus seem that while the Indian mills are spinning very largely for China and other foreign markets, the looms are far more concerned with the home than any foreign markets. Hence but for the exports of raw cotton and the existence of power-loom mills, the Indian area of cotton cultivation would be reduced.
GRAPHITE AND BLACKLEAD

The Future.

to about one-quarter its present extent. That is to say, one-half the total production is exported raw and one-quarter in the form of yarn, thus leaving one-quarter to meet the existing local demands. The great feature of the future may be said to be the extent to which Indian manufactures of piece goods may curtail the imports from foreign countries, just as the production of yarn has most certainly curtailed imports of yarn from foreign countries into India.

[D.E.P., vi., pt. i., 92-4.]

Plumbago.

Production.

Graphite; Ball, Man. Econ. Geol. Ind., iii., 50-6; Holland, Mem. Geol. Surv. Ind., 1900, xxviii., 126; 1901, xxx., 174; Rec. Geol. Surv. Ind., 1905, xxxii., pt. 1, 51. Graphite consists almost entirely of pure carbon with a small proportion of iron. It is known also as Blacklead and Plumbago from its appearance, though lead does not enter into its composition.

A full account of the various localities where graphite has been found in India is given in the Dictionary, but though these are fairly numerous and scattered over a wide area, it is only in the State of Travancore that any progress in graphite mining has been made. Prospecting has also been attempted in the Godavari district, Madras Presidency, and in the Ruby Mines district of Upper Burma. According to Holland, regular returns were not available before 1901, but for the period 1901-3 the following records of production in Travancore are available:—1901-2, 2,490 tons; 1902, 4,575 tons; 1903, 3,394 tons.

Graphite is used chiefly in the manufacture of pencils, crucibles, grate and iron-work polish, as a lubricator for machinery, in electrotyping, in the facings of moulds, etc., etc. In India the native mineral appears to be but occasionally utilised, and then only for polishing pottery.

Uses.

D.E.P., iv., 177-84.

GREWIA. Linn.: Fl. Br. Ind., i., 383-93; Gamble, Man. Ind. Timbs., 1902, 108-12; Duthie, Fl. Upper Gang. Plain, 1903, 109-17; Prain, Beng. Pl., i., 281-4; Tiliaceæ. A genus of plants which contains about 60 species, 12 only being trees, the rest shrubs or climbers. Of these 36 are natives of India.

Fibre.

The species of Grewia are of little economic importance apart from the fact that the inner bark of most species yields a fibre, used in the manufacture of ropes and sometimes of paper. Some have a tough and close-grained wood, recommended for purposes where elasticity and strength are required. Accordingly the chief articles manufactured of these woods are banghy-poles, bows, axe and speak handles and the like. Dr. Bidie, in an article in The Fishing Gazette, 1897 (quoted in Ind. For., 1897, xxiii., 148), remarks that the wood of three species, G. oppositifolia, G. tiltefolia and G. vestita, should make excellent material for fishing-rods. The fruits of many of the species are edible. The most important are:—

G. asiatica, Linn., the phalsa, shukri, dahmi; wild in Central and South India, cultivated elsewhere. G. cutilifera, Royse, the dhámam; indigenous and planted from Hazara and the Panjáb Salt Range to Sikkim at 3,000 to 6,000 feet. G. oppositifolia, Roxb., the bīd, pastuvanne, etc.; North-West Himalaya, from the Indus to Nepal, ascending to 6,000 feet. G. tiltefolia, Vahl., the phalsa, khesla, etc.; Sub-Himalayan tract from the Jumna to Nepal, ascending to 4,000 feet; Central and South India; Upper Burma; low country of Ceylon. G. vestita, Wall., the dhámam, sepalosra, etc. Indigenous in the Sub-Himalayan tract from Dehra Dun to Assam; accord to Gamble, common in sal and similar forests. [Cf. Pharmacog. Ind., 1890, i., 238; Dodge, Useful Fibre Pl. of the World, 1897, 187; Woodrow, Gard. in Ind., 1899, 189; Agri. Ledg., 1901, No. 9, 212; Firminger, Man. Gard. Ind., 1904, 286.]

624
GUTTA-PERCHA

GUZOTIA ABYSSINICA, Cass.; Fl. Br. Ind., iii., 308; Woodrow, Gard. in Ind., 1899, 365; Mollison, Handbook Ind. Agri., 1901, iii., 101-2; Rec. Bot. Surv. Ind., 1902, ii., 91; iii., 229; Prain, Beng. Plants, 1903, i., 614; Cooke, Fl. Pres. Bomb., 1904, ii., 66; Compositae. Niger Seed and Oil. The kalā-tīl, surgiya, rāmtīl, kernani, khurāni, ulisi, valesulī, huchchelū, gurellu, etc. A native of tropical Africa, but cultivated as an oil-seed here and there in most of the provinces of India.

It is a kharif crop, sown from June to August and harvested in November or December. Rough and rocky laterite or light sandy soil is generally chosen, and the preparation of the land is very simple. Two ploughings before sowing are sufficient, and manure is not necessary. The seed is drilled in rows 11 to 13 inches apart, and 4 to 6 lb. per acre is held to be a sufficient seed rate. It is more commonly grown alone, but is sometimes accompanied by a pulse-crop. In Bengal a considerable portion of land is under this crop, especially in Chota Nagpur Division, but unfortunately the Niger seed is returned in the Agricultural Statistics under the general heading of "Other Oil Seeds," of which there are usually 500,000 acres, with 150,000 of these in Chota Nagpur. The "Others" are over and above linseed, rape, til, so that a fair proportion must be niger. In Madras linseed and til (sesamum) are separately returned, but a much larger area than both these put together is usually devoted to "Other Oil Seeds." In 1904-5 the "Others" came to 1,018,483 acres, of which 286,509 are in South Arcot; 111,594 in Anantapur; 92,461 in Cuddapah; 84,810 in Bellary; 71,351 in Kurnul; 56,730 in Trichinopoly; 51,909 in Tanjore; and 47,215 in North Arcot, with lesser areas in the other districts. It is impossible to discover the exact proportions of these areas devoted to niger, but they must be considerable. In the United Provinces the acreage of "Other Oil Seeds" was in 1904-5, 113,731, and in the Central Provinces the corresponding figure was 314,716, of both of which a certain proportion would have been niger seed. Bombay is the only province that appears to give separate returns for the acreage of this oil seed. In 1905-6 (according to the Season and Crop Report) the total land used for it was 169,883 acres, of which Nasik had 68,940; Poona 22,843; Ahmednagar 14,784; Satara 16,026; Bijapur 7,960; and Ratnagiri 7,147 acres, etc. Rice (Mysore Gaz., 1897, i., 123) gives an account of the niger seed in the various districts of Mysore, which the reader should consult.

When the crop is ripe it is cut near the root and stacked for eight days. It is then exposed for two or three days in the sun, then the seed beaten out with a stick and separated from fragments of the plant by a fan. The greater part is sold to the oil-makers for expression of the oil, the yield of which is about 35 per cent. of the weight of the seed. But the seed dries quickly and in England yields only about 16 gallons of oil per quarter of seed, while rape seed yields 20 gallons. The oil is pale yellow or orange in colour with little odour and sweet taste, more limpish than rape oil, with a specific gravity of 0·924 to 0·928. In its drying properties it ranks between cotton and linseed oil. For making paints, lubricating and lighting, this oil is useful, and in many parts of India is employed in cookery and for anointing the body: it is also frequently used as an adulterant for more valuable oils. It is said to be useful in cases of fracture and dislocation of bones among cattle. The oil-cake is highly appreciated in some parts of the country as a cattle food. In the English market the value of the oil is about 37s. per quarter. The production of this oil-crop has suffered in recent years, like that of most other oils, through the remarkable expansion of the traffic in kerosene and other mineral oils and the by-products of these illuminants and lubricants. [Cf. Basu, Agri. Lohardaga, 1890, pt. i., 70; Pharmocog. Ind., 1891, ii., 269-71; Agri. Ledg., 1895, No. 24, 502; Hurst, Lubricat. Oils, Fats, etc., 1896, 199; Agri. Ledg., 1896, No. 28, 280; 1899, No. 12, 121, 144; 1901, 364; Sett. Rept. Betul Dist. Cent. Prov., 1901, 31; Wright and Mitchell, Oils, Fats, etc., 1903, 497; Imp. Inst. Tech. Repts., 1903, 128; Agri. Ledg., 1903, No. 7, 171; Hanousek, Micro. Tech. Prod. (Winton and Barber, transl.), 357.]

GUTTA-PERCHA.—Since Gutta-percha can hardly be characterised as an Indian product, it will be dealt with here very briefly. It is the commercial name for the inspissated milky sap of several plants of which nearly all (or at least all the important ones) belong to the natural

Uses.

Oil-cake.
order Sapotaceae. The word "gutta-percha" is of Malayan origin: it signifies the gum or gutta or getah of the tree known as percha; according to some writers percha is also the ancient name of Sumatra, so that getah-percha would denote the gutta of Sumatra. And the true gum is to-day almost exclusively a Malayan product. As it reaches the market gutta-percha is, however, largely adulterated. There are high- and low-priced qualities as well as substances that more or less resemble gutta-percha, but which are adulterants rather than grades of gutta. The present article deals with both the pure gutta-percha and its substitutes.

Gutta-percha first definitely appeared in Europe in 1845, and the discovery soon thereafter of its varied utilisations caused an immense demand. Dr. W. Montgomery read a paper on it before the Society of Arts, London, from which date it became a regular article of trade. It is extensively employed in coating telegraphic cables, owing to its being a perfect insulator, whilst it is able to withstand in a remarkable degree exposure to varying atmospheric conditions. It keeps good for ten years, if exposed to the open air: 20 years, if protected in tubes; but 20 years, when submerged, have no appreciable effect upon it. Under the action of light, heat and air it slowly oxidises, becomes converted into a brittle resin soluble in hot alcohol. Chemically gutta-percha is almost identical with india-rubber (which see, pp. 647–60). It differs physically, being tough and inelastic. Since the date gutta-percha was made known to Europe perhaps no substance has developed more rapidly, and with india-rubber its uses may be said to be so many and so important as to make these two substances perfectly indispensable to commerce.

**Trade.**—The immense demand has caused an extended inquiry all over the globe with the view of expanding the area of supply or of discovering useful substitutes. During the past seven years the imports of the United Kingdom alone have been:—1900, 126,059 cwt., £1,685,568; 1901, 88,438 cwt., £1,382,646; 1902, 83,889 cwt., £1,150,902; 1903, 46,411 cwt., £587,712; 1904, 27,288 cwt., £288,535; 1905, 45,434 cwt., £361,475; 1906, 53,271 cwt., £489,280. Of these quantities the Straits Settlements supplied from one-half to three-fourths of the total, but it would seem as if the supply from the Straits was decreasing while that from Venezuela, from British Guiana and from the Netherlands was expanding. It must not, however, be forgotten that a fairly large proportion of these imports are in gutta-percha substitutes, chiefly Balata. Burn-Murdock (Ind. For., 1905, xxxi., 309–20) has contributed useful particulars regarding the extraction, purification, properties, prices and traffic in gutta-percha, also a statement of the exports from Singapore from 1886 to 1903.

*Gutta-Percha Trade*
A feature of the gutta-percha trade in which India is much interested is the possibility of some method being discovered by which the milky juices of certain abundant plants might be transformed into useful substitutes. The following may be given as the gutta-percha-yielding plants, as also those that it would seem desirable should in future be experimented with as gutta substitutes:

Achras Sapota, Linn.; Sapotaceae. The Sapota or Sapodilla tree. Is largely cultivated in Bengal for its fruit; yields the Mexican Chicle-gum. [Cf. Journ. Agri.-Hort. Soc. Ind., 1844, iii., 147; Junelle, l.c., 1903, 521-3.]

Alstonia scholaris, R. Br. (see p. 60); Apocynaceae. The chatuan; is believed to be the source of guttapulei of Singapore. Hooper (Rept. Labor. Ind. Mus., 1903-6, 29) found the latex to contain 45.1 insol., 41.8 resin and 13.1 ash. [Cf. Manson, l.c. 82.]

Bassia Mottleyana, De Vriese; Sapotaceae. A tree of Malacca and Borneo known as the kattian. The milk of this tree is regarded as an inferior quality of gutta-percha. Hooper (l.c., 1903-6, 27) says three samples of the milk of B. latifolia from Hoshtagad showed on the average 48.9 gutta, 38.8 resin and 12.3 per cent. ash. It was light grey, plastic, but the yield per tree small. A sample from Tinnevelly of B. longifolia afforded 22.6 gutta, 62.7 resin and 14.7 per cent. ash (see pp. 116-20).

Calotropis gigantea and C. procera, R. Br. (see pp. 205-6); Asclepiadaceae. The madar or akanda, abundant bushes all over India, have often been suggested as capable of affording a limitless quantity of milky sap. Whether that could be utilised profitably has not been definitely ascertained. Over the greater part of the Upper, Western and Central Provinces of India they cover many thousand square miles of waste land, and the utilisation of that herbage would be of infinite value to the people. [Cf. Manson, l.c. 87.]

Euphorbia nerifolia, Linn.; Euphorbiaceae (see p. 530).

E. Royleana, Bolus. (see p. 531).

E. Tirucalli, Linn. (see p. 531).

E. trigona—Haworth—the katti-mandu. This shrub yields the cement kattimandu, often spoken of in connection with South India and the Deccan. It was specially recommended by Sir Walter Elliot in 1851.

Minimus Kauki, Linn.; Pl. Br. Ind., iii., 549; Sapotaceae. Is closely allied to if distinct from M. Balata, Gaertn., f.—a tree native in Guiana, Honduras and Brazil which affords a gum that is one of the best substitutes for gutta-percha (Junelle, l.c., 1903, 493-517). No effort appears to have been made to discover whether any of the Indian species might similarly be of value. Other species are M. Elengi, Linn.—the Deccan to Malay Peninsula; M. Roxburghiana, Wight—South India; and M. Hexandra, Roxb.—Deccan and Ceylon. But Gamble (l.c. 117) says that neither M. Elengi nor M. Kauki are in India known to yield gutta-percha. [Cf. Manson, l.c. 78.]

Palaquium ellipticum, Engl., Pflanzen., iv., i., 135; Bassia elliptica, Dalz.; Dichoposis elliptica, Bentham.; Pl. Br. Ind., iii., 542; Palaquium, Brandis, Ind. Trees, 424-5; Manson, l.c. 77; Junelle, l.c., 1903 437-85; Sapotaceae. This is the pauchoti, pauchonta, kat illupei, pala illupei, etc. A large tree of the Western Ghats from N. Kanara southwards. It affords an inferior grade of gutta-percha, which is collected by tapping the living trees. Gamble adds, “but although this substance can be utilised for waterproofing and cement it is not a complete substitute for the proper article.”

P. Gutta, Burch, in Ann. Jard. Brux., 1885, v., 40; Dichoposis Gutta, Bentham. & Hook., f., in Gen. Pl., ii., 638; Gamble, l.c. 113-21. A tree of the Straits Settlements and Malay Archipelago, where it is known as taban merah (in Perak), niato balaan tembaga (or obang) in Sumatra, and is the source of the finer grades of the gutta-percha of commerce. But there would appear to be many qualities of the gutta obtained from this plant, some of which are apparently the produce of distinct varieties, others the results of different methods of preparation, and
still others indicate varying degrees of adulteration. For example, the taban merah (according to Burn-Murdoch—the most recent writer) is P. oblongifolium; taban chaeir is Palatium sp.; taban puteh is P. pastulatum and taban baik is P. sp. The taban puteh is much inferior to the others. On the other hand, while P. oblongifolium, Burch, is but a variety of P. gutta, still by certain writers it is held to be a distinct species and to yield the taban sutra of Perak.

Gamble (Man. Ind. Timba., 445) says, "The method of collection, usually employed by the Natives of the Malay Peninsula, is very simple but very wasteful. The tree is felled, and either the bark is stripped off altogether or rings are cut at intervals of about a foot. The sap that oozes out is then collected, put in a pot and boiled with a little water, which prevents its hardening afterwards when exposed to the air. It is then run into moulds. The trees usually chosen are those of about thirty to thirty-five years old, and each tree gives 2 to 3 lb. of gutta. Such a system is naturally a wasteful one, and if regularly continued without any arrangements for reproduction would probably lead to the exhaustion of the supply, so that it is satisfactory that French experts are said to have discovered that the gutta-percha can be obtained from the leaves without felling the tree. However this may be, there is little doubt of the value of the product, and that if it is to be regularly produced the tree must be grown in plantation and systematically worked."

P. polyanthum, Engl., Pflanzenr., iv., i., 135; Isonandra polyantha, Kurz; Dischopsis polyantha, Benth. & Hook., Gen. Pl., ii., 638. A moderate-sized tree of Cachar, Chittagong, Arakan and Pegu. This is the tali, sill-kurja, thanbin, etc. Kurz says it yields a good quality of gutta-percha and in large quantity. [Cf. P. obovatum, King and Gamble, in Hooper, Rept. Labor. Ind. Mus., 1905-6, 27,]

13. Payena lucida, a. 0c.; Isonandra polyandra, Wight, Ic., t., 1589; Fl. Br. Ind., iii., 547; Gamble, Man. Ind. Timba., 449; SapoTaeAE. The dolu-kurta of Cachar is an evergreen tree of Assam, Tenasserim and the Straits Settlements. P. Mainyaui, Clarke, a tree of Penang and Malacca. Both these trees afford gutta-percha; the last mentioned, according to Maingay, abounds in that substance.

HEMIDESMUS INDICUS, Br.; Fl. Br. Ind., iv., 5; Prain, Beng. Plants, 1903, ii., 686; Cooke, Fl. Pres. Bomb., 1904, ii., 146; AсколькоAE. Indian (or country) Sarsarapilla; anantamul (ananteel), mograbu, sugandhi pala, navnari, upasara; sardas (Sanskr.). A climbing plant of North India, from Bande to Oudh and Sikkim, and southward to Travancore and Ceylon.

The root has long been employed in Native medicine. Garcia de Orta (1563, Coll., xliii.; also in Ball, Proc. Roy. Ir. Acad., 1890, 3rd. ser., i., 656) speaks of a thorny climber which resembles the pomegranate, from the wood, bark and root of which a drug is obtained. Ball regards that passage as possibly denoting Hemidesmus, but is it not rather Smilax? The root is supposed to possess properties allied to those of sarsarapilla, and from 1864 has been official in the British Pharmacopoeia. It is prescribed usually in the form of syrup and is demulcent, alterative and diuretic. Sometimes the whole plant is pounded and a congee made with rice, or an infusion prepared of the dried leaves. In Indian commerce anantamul is found in the form of little bundles, which consist
HIBISCUS

Musk Mallow and Rozelle

of the entire roots of one or more plants, tied up with a portion of the stem. Anantamūli costs 6 to 8 annas per lb., and in Europe appears to sell at 1s. 6d. to 2s. per lb. [Cf. Pharmacog. Ind., 1891, ii., 446-9; De Silva, Indig. Food Prod., Trop., Agrist., 1891-2, xi., 820-1; Waring, Raz. Med., 1897, 72-3; Duttt, Mat. Med. Hind., 1900, 195-6; Rept. Cent. Indig. Drugs Comm., 1901, i., 194, 153; Rec. Bot. Surv. Ind. (many passages); White and Humphrey, Pharmacog., 1901, 224.]

HIBISCUS, Medik.: Fl. Br. Ind., i., 334-44; Cooke, Fl. Pres. Bomb., 1901, ii., 104-14; Duthie, Fl. Upper Gang. Plain, 1903, 87-93; Prain, Beng. Plants, i., 262-9; Wiesner, Die Rohst. des Pflanzenr., 1903, ii., 221-2; Malvaceae. A genus of herbs, shrubs or trees, which embraces about 150 species. Some 33 are indigenous to India and several others have been introduced, and are now cultivated widely. Many are of considerable economic value, one an important vegetable, and another produces a fibre that is extensively used as a substitute both for hemp and jute.

H. fleuineus, Linn.: Rec. Bot. Surv. Ind., iii., 28, 178. The ban dhenras, *jangli bhindi, kapasāiya, dula, etc.* A prickly herbaceous annual, indigenous in the hotter parts of India, from the Panjab and Bengal to South India and Ceylon. The stem yields a long, glossy, white and strong fibre, useful for twine and light cordage. The leaves and flowers are known as GRAINS D'AMBETTE. By the Natives of Northern India they are employed medicinally. Their value varies from about 4d. to Is. per lb. [Cf. Pharmacog. Ind., 1890, i., 200-10; Agri. Ledg., 1896, No. 6, 29-31; 1898, No. 15, 505; Mukerji, Handbook Ind. Agr., 1901, 329-30; Schimmell & Co., Semi.-Ann. Rept., Oct. 1902, 9.]

H. rosa-sinensis, Linn.: Woodrow, Man. of Gard., 1899, 179; Firmerger, Man. Gard. Ind. (ed. Cameron), 651; Rec. Bot. Surv. Ind., ii., 40, 84; iii., 178. The Shoe Flower, *jāsū, juva, joba, jāsavanda, etc.* An ornamental shrub, native of China, but found in most gardens in the plains of India. The bark yields a fibre. The flowers are said to produce a purple dye, and are also used in Native medicine. The roots are employed in Mysore in certain cattle diseases (Journ. Bomb. Nat. Hist. Soc., 1892-3, vii., 512-5). The stems yield a strong, silky fibre, the Rozelle Hemp of commerce, obtained by retting the twigs when in flower. The seeds are used in medicine, and have demulcent, diuretic and tonic properties. The fruit, or rather fleshy calyx, is a valuable antiscorbutic, largely eaten in the form of jellies, chutneys and other preserves. The leaves are eaten as salad and in Native curries. [Cf. Pharmacog. Ind., i., 212; Dodge, Useful Fibre Plants of the World, 1897, 196; Imp. Inst. Tech. Repts., 1903, 96.]

H. tilacceus, Linn.; Gamble, Man. Ind. Timbs., 1902, 87; Rec. Bot. Surv. Ind., ii., 177, 245, 247, etc.; iii., 179. The bula, *banāi, bellī-pata, cheluva, thinbān, etc.* A small tree or bush of the sea-coast forests and long tidal rivers all round India, Burma and Ceylon. It yields a fibre of fair quality, which can be readily separated and does not easily rot under water. In Bengal it is used for making rough ropes, in the Sundribans for cordage, and in Ceylon for mats. Gamble remarks that it ought to be useful for paper. Manson (Ind. For., 1905, xxvi., 347-50) gives an account of experiments which have recently been made in Burma with this fibre as a jute substitute. He considers it would probably fetch about £12 per ton, if sent to market in the condition that jute usually
HIBISCUS
CANNABINUS
Deccan Hemp

appears, though fibre collected in the Toungoo district of Burma and prepared by Mr. Le Fevre is said to have realised as much as £35 per ton in England. The wood is used only for fuel, and occasionally for hut-building (see *Mata and Matting*, p. 770). [Cf. Yates, *Text. Antiq.*, 1843, 304-6; *Text. Journ.*, Oct. 1890; Dodge, *l.c.* 197.]

The cultivation, both as a crop and as a hedge plant, is largely carried on in Bombay (especially the Deccan and Karnátak), the Central Provinces and Madras. Elsewhere to a much smaller extent—Bengal, chiefly Chota Nagpur; also here and there in the United Provinces and the Panjáb. The Bombay statistical returns for 1905-6 show an area of 83,109 acres, with 16 acres in Sind, and an average of about 90,000 acres annually. Rocky and laterite soils which are not suitable for jute are well adapted for the cultivation of *ambari*. It grows best on the alluvial soils of North Gujrat, but does also very well in medium black soils. It is usually grown as a mere sprinkling among other crops, and the tillage is the same as that of the crop with which it is associated, especially *bajra* and *juar*. In October-November the plants should be uprooted. Full-grown plants which have ripened their seed furnish stronger fibre than if cut while in flower. The small bundles of stalks, when dry, are tied into large bundles and steeped in water for some ten days. If the fibre is separated in the cold weather, longer steeping is required. When removed the bark and fibre readily peel off in strips from the root upwards. The strips are then beaten with a stick and threshed in water till the clean fibre is separated. It is bright and glossy, but coarse and harsh. The length is 5 to 10 feet, and the breaking strain has been variously stated at 115 to 190 lb. Hanausek (*Micro. Tech. Prod.*, Winton and Barber, transl., 1907, 83) gives interesting particulars of the microscopic structure of this fibre.

The Deccan hemp is spoken of as similar to jute, but very much superior. In India a coarse sackcloth is made from it, though its chief utilisation is for ropes and cordage. Coarse canvas is also manufactured from it, and in Bengal it is employed for all purposes for which jute is in demand, but being more durable it is used for fishing-nets and paper manufacture. *Ambári* hemp is stated to be worth about 8 lb. per rupee, but no statistics regarding the extent of the trade are available.

A few years ago a fibre appeared on the London market under the name of Bimlipatam jute, which there seems little doubt was Deccan hemp. Still more recently a new fibre from Rio de Janeiro has been much advertised under the name of Canhamo, and this has been shown by Sprague to be obtained from an allied species, *H. radiatus*, Cav. (*Fl. Br. Ind.*, i., 335). Thus for commercial purposes both the Bimlipatam jute and the Canhamo hemp may be accepted as possessing the same properties as the fibre of *H. cannabinus*.

The demand for Bimlipatam jute is stated to be yearly increasing, and in 1903-4 the exports to London amounted in value to two lakhs of rupees. On the London market it is worth from £11 to £12 12s. 6d. per ton.
BHINDI OR LADY'S FINGERS

Dunstan's chemical investigations into the properties of this fibre, published in the Imperial Institute Technical Reports, as also the further particulars afforded in The Agricultural Ledger, will be found useful and interesting. Apparently the samples of Bimlipatam jute were found of lower value than the best Bengal jute. In the subsequent investigations into this fibre it was found to be prepared on an extensive scale in a factory at Chittavalsa in Vizagapatam, as also exported from Bengal to some extent under the name of mesta pát. Comparing a sample of true jute with an authenticated sample of Deccan hemp and a good average specimen of Bimlipatam jute, it was found that the percentage of cellulose was nearly the same in all three. The last two were superior to ordinary jute in the smaller loss in mercerising and the larger increase in weight on nitration. The reports therefore conclude that Bimlipatam jute (i.e. Deccan hemp) is deserving of attention.

The seeds yield a clear and limpid oil, and have been sent to England as an oil-seed. They are used in Poona as a cattle food, and the leaves are eaten as a vegetable.

H. esculentus, Linn.; Rec. Bot. Surv. Ind., ii., 84; iii., 28, 178. The Edible Hibiscus, Lady's Fingers; ochro or okra, of the West Indies, bhindi, dhenras (or dheras), rámturáí, bendekai, vendak-kay, youn-padi-sí, tindisa, etc. A tall herb, cultivated throughout India and naturalised in all tropical countries. De Candolle regards it as of African origin. It is largely cultivated by the Natives of India as a garden crop for the sake of its fruit. It should be sown from April to June in nurseries, and transplanted when about 3 inches high. Weeding should be done regularly all through the period of growth to keep the soil loose and open. As a field crop successful cultivation largely depends on rich manuring of the soil. Two varieties, an early and a late, are grown in Bombay, both being sown in June. The acre rate of seed varies from 5 to 10 lb. and the seed is sown at intervals of about a foot, on ridges three feet apart. The early variety bears fruits from about August to September, while the late does so from the end of September to November.

In Madras, the early crop is sown in the first week of March and gathered in the first week of July; the late crop is sown in the latter part of July and gathered in towards the end of December. The yield of fruit per acre varies from 5,000 to 6,000 lb. The cost of cultivation is said to average about Rs. 5 per acre, and the profit about Rs. 9. The bast yields a white fibre which is long, silky, strong and pliant, and composed of fine individual threads. The breaking strain is 79 pounds dry, and 95 wet. In colour and texture it resembles hemp, and is well adapted for making ropes, twine and sacking, while the residual portions might be utilised for paper-making. There are no statistics of trade in ochro fibre: it is apparently sold only as an adulterant of jute or of

631
HIDES, SKINS, LEATHER and the Manufactures therefrom.—The term "Hides" denotes commercially the raw, dressed or tanned skins of full-grown cows, bullocks, buffaloes and horses, etc., while "Skins" is applied to those of calves, sheep, goats, deer and other wild animals. The term "Fur" is used for ornamental skins, with the hair or wool attached.

It may, perhaps, be as well to dispose at once of the least important group, namely, the "Furs." In addition to the skins of Deer and Antelopes, there are returned under "Furs" (D.E.P., iii., 458) some 70 different fancy or ornamental skins that are occasionally met with in trade. The following are some of the more important (mentioned in alphabetical sequence):—Cynocephalus jubatus, the Hunting Leopard; Felis pardus, the Leopard or Panther; F. agris, the Tiger; F. uncia, the Snow Leopard; Mustela, two species, the Martens; Putorius erminea, the Ermine or Stoat; Sminthys, the Squirrels; Vulpes, the Foxes; and Vulpus, the Bears; etc. It would seem that in India some of the smaller skins, such as dog-skins, snake and lizard skins, mole-skins, frog-skins and the like are utterly neglected, a consequence very possibly of the climate and the defective methods of curing presently practised.

RAW HIDES AND SKINS.—Supply.—Under Live Stock (pp. 732-52) will be found mention of the chief wild and domestic species and races of animals, the skins of which appear under Hides and Skins. It is not necessary to enumerate these again, but it may be useful to state once more that the live stock of India cannot be far short of a grand total of 220 millions, of which perhaps 40 per cent. die or are slaughtered annually. The annual average exports to foreign countries at all events were, for the five years ending 1903-4, Hides (raw and tanned) 12½ millions; Skins (raw and tanned) 37 millions, or 23 per cent. of the estimated total stock. But these returns take no cognisance of the hides and skins used up in India nor of the animals that die or are killed, but of which the hides and skins are not preserved.

Total Transactions.—It would not be far from correct to affirm that India's local manufactures in skins and leather are as valuable as her foreign trade in these commodities (raw and manufactured). In 1876-7 the total of the declared values of the imports and exports, taken together, was Rs. 3,13,77,912 (or say £2,991,800); in 1902-3 the corresponding figure was Rs. 9,27,48,853 (or say £6,183,257); and in 1903-4 the total traffic came (less the re-exports) to Rs. 9,71,04,548 (or say £6,500,000). If the idea of the internal trade being approximately as valuable as the foreign can be accepted as fairly correct, then during 1903-4 the total turnover of the industries here dealt with (exports plus consumption) would have been close on a valuation of £13,000,000. And later figures for 1906-7 show a considerable expansion, viz. to a total

632
(imports and exports, less re-exports) of Rs. 15,94,66,392 (or £10,631,093), and thus of an estimated total traffic of over twenty-one millions sterling.

**Fluctuations.**—But there are a few aspects of importance that had better be here indicated. For example, the trade in hides and skins, as also the craft in leather manufacture, are in the hands either of Muhammadans or of low-caste Hindus. They are, therefore, participated in by a comparatively small community. So again the workers in skins, hides and leather are in Northern India collectively designated *chirmfarosh.* Then there are two main classes of hides and skins:—*hallali* (slaughtered), *nurulali* (dead). The former come from the slaughter-houses of the cities, the latter from the country. The *chumars* (the special caste of skinners) wander about all over the country, and make it their business to skin dead cattle. In seasons of scarcity and famine they reap a rich harvest, but it is often affirmed that they are unscrupulous and, when they do not obtain a sufficient supply, that they are not averse to systematically poisoning cattle. With them, in fact, cattle-poisoning is held to be a profession, and to have attained the position of a high art (see *Abrus,* p. 1). Moreover, it is believed that a large proportion of the cattle that perish in India die from preventable causes, such as neglect, drought and murain. The loss to the country of a large percentage of its cattle far outweighs the total value of the traffic in skins and hides, so that the increasing exports in these articles are only too frequently the most certain indication of widespread suffering and loss. The traffic in hides and skins is accordingly subject to great fluctuations, concomitant with the vicissitudes of the seasons. The famine in Western India, during the years of 1899–1901, caused the traffic to become abnormally high, especially in untanned hides, but, due to the war in South Africa, the prices were at the same time preserved. The exports for each of those years were nearly double the normal traffic, but the demand was, nevertheless, brisk. The difficulty to procure capital—an ever-present cause of obstruction to all manufacturing enterprise in India—is doubly true of the leather trades. Religious objection assigns it a position of degradation and neglect. It became accordingly a monopoly within a restricted community, and thus not only suffers from want of capital but from the loss of invigorating competition and popular interest and favour.

**Foreign Trade.**—The exports to foreign countries from the chief seaports of India are drawn from the provinces by rail, road and river, as also coastwise by sea. These may be analysed as follows:—

**Railborne, etc.**—Unfortunately a difficulty is at once presented, viz. the railborne and the coastwise transactions are recorded in cwt. It is thus next to impossible to obtain a factor by which to reduce these to numbers of hides as in the returns of foreign trade, since the goods vary so greatly according to species of animal, size and condition, nature of curing or tanning pursued, etc., etc. The figures as they stand are, however, relatively of value:—During 1906–7 the railways of India carried 2,517,787 cwt. of hides and skins (raw and tanned), the bulk being raw. Of that large amount 1,126,302 cwt. were conveyed to CALCUTTA and were drawn—from Bengal Province, 350,938 cwt.; from the United Provinces, 354,804 cwt.; from the Panjáb, 103,855 cwt.; from the Central Provinces and Berar, 57,056 cwt.; from Madras, 13,974 cwt.; from E. Bengal and Assam, 232,036 cwt.; from Rajputana and Central India, 7,623 cwt.; and from Bombay, 4,816 cwt. The next most important receiving centres are the MADRAS PORTS, which, in the year in question, drew 520,856 cwt., namely from the Madras Presidency, 330,512 cwt.; Mysore, 38,398 cwt.; the Nizam's Territory, 44,951 cwt.; Bombay, 56,901 cwt.; Central Provinces, 633
THE LEATHER INDUSTRIES

HIDES AND SKINS

20,705 cwt.; Panjáb, 19,289 cwt.; and from the United Provinces, 5,441 cwt. Madras Presidency is third in importance, with 217,074 cwt., derived chiefly from Mysore, 77,677 cwt.; from its own port towns, 61,434 cwt. from Bombay (5,518 cwt.); from the Nizam's Territory (29,908 cwt.) Bombay Port takes the fourth position with a supply of 149,048 cwt., derived chiefly from its own Presidency, 68,823 cwt.; Panjáb, 28,765 cwt.; United Provinces, 23,419 cwt.; Central Provinces, 13,272 cwt.; Madras, 5,462 cwt. Then comes Karachi with 139,107 cwt., derived mainly from the Panjáb, 100,404 cwt.; Sind, 37,385 cwt.; and from the United Provinces, 842 cwt. Lastly the Panjáb with a total supply of 113,973 cwt., derived chiefly from Rajputana and Central India, 32,978 cwt.; and from the United Provinces, 58,782 cwt. Looking at these figures from the point of view of Exports, the Bengal Province supplies 357,794 cwt.; the United Provinces 464,376 cwt.; Madras 368,127 cwt.; the Panjáb 296,576 cwt.; Bombay 171,746 cwt.; Mysore 117,866 cwt.; Rajputana and Central India 118,613 cwt.; Central Provinces and Berar 122,774 cwt.; the Nizam's Territory 86,183 cwt.; Sind 54,559 cwt.; and E. Bengal and Assam 234,810 cwt. Thus, so far as the foreign trade is concerned, the supplies come mainly from Bengal and the United Provinces. Cawnpore is the great emporium of leather production in India, and the supplies of hides and skins procured by the tanneries of that town must be very largely drawn from local supplies, seeing that the imports are comparatively unimportant. This fact necessarily raises the United Provinces into the position of greatest importance in the hide trade.

Coastwise.—Turning now to the coastwise transactions, it is ascertained that the total imports of raw hides do not normally exceed 25 to 30 thousand cwt., valued at 10 lakhs of rupees; of raw skins about 15 thousand cwt., valued at 7 lakhs of rupees; and of dressed and tanned hides and skins about 64 thousand cwt., valued at 6 lakhs of rupees.

Exports.—In the Review of the Trade of India for 1904–5 it is shown that, according to the declared values, the prices of hides rose steadily during the preceding four years, the average price for 1904–5 being 11.4 cent. in excess of that for the previous year. The corresponding price of skins, on the other hand, fell 13.1 cent. per cent. The number of raw hides and skins exported collectively came to 31,606,246, valued at Rs. 7,05,35,585—the shares being 8,722,520 hides and 22,883,726 skins. The value of the raw hides exported from Calcutta was 84.6 cent. of the total trade. They were consigned to the Continent mainly, Germany taking 144.3 lakhs; Italy 66 lakhs; Austria-Hungary 51.3 lakhs; and Spain 22.3 lakhs. This left 23 lakhs consigned to the United Kingdom, and 40.5 lakhs to the United States. Calcutta also contributes 75.6 per cent. of the total value of the foreign exports in dried and pickled skins. About the same percentage (in value) of the foreign exports is usually drawn from India by the United States. Of the balance, France claimed 29.4 lakhs, and the United Kingdom 25.4 lakhs. The demand in France seems to be increasing. The later Review for 1905–6 states that the price of hides continued to rise, the average value per cwt. increasing from Rs. 52.4–8 in 1904–5 to Rs. 55–7–0; while that of skins continued to fall, viz. from Rs. 91.1–6 per cwt. in 1904–5 to Rs. 90.7–1 per cwt. The number of hides and skins exported in 1906–7 collectively came to 39,806,281—the shares being 12,917,277 hides and 26,889,054 skins.

TANNED HIDES AND SKINS.—The most significant feature of the coastwise returns, abundantly confirmed by most statistical statements of the Indian trade in hides and skins, may be said to be the fact that Madras is by far the most important centre for dressed skins, and that Burma is the chief coastwise market for them. Recently, however, Bengal has begun to participate largely in this Burmese supply. After Burma, Bombay affords the next most important local outlet for Madras

634
dressed skins. And this position of importance held by the Madras Presidency in the traffic in dressed and tanned skins and hides is still further borne out by a study of the foreign trade. During 1904–5 Madras furnished 91 per cent. of the dressed hides and 73 per cent. of the dressed skins, Bombay following with a fair proportion of the balance. The United States of America have hitherto been the most important market for Madras dressed skins. But within the past few years an unhappy new manifestation has appeared, namely a decline in the demand for Indian dressed skins. The export traffic in dressed goods has recently, in fact, fallen back, and the demand for Bengal raw skins advanced considerably. This is presumed to be a direct consequence of the cheaper and more efficient methods of tanning (especially that known as the chrome process) now largely practised in the United States. It points to the urgent necessity for Indian manufacturers to advance with the times or face the total loss of their trade. The tanner who pursues crude methods and continues to employ defective appliances can no more hold his own against the cheapening process of scientific progression than the hand-loom cotton weaver can stem the tide of steam-power prosperity.

Exports.—The decline in the traffic in tanned hides and skins, established within recent years, calls pointedly for serious consideration. The so-called tanning of India, given to the hides and skins exported, was, and is at its best, so imperfect and unsatisfactory that retanning in the countries to which consigned was essential. But however crude it may be, the business is by no means an unimportant one, nor one for which an effort should not be made to save it from complete annihilation. In 1900–1 the exports of tanned hides were valued at Rs. 1,46,80,048, and of skins at Rs. 3,02,61,805, or collectively Rs. 4,49,41,853 (close on three million pounds sterling). The next year, 1901–2, the collective exports of tanned hides and skins were valued at Rs. 2,65,40,461; in 1902–3 they were Rs. 2,89,81,866; in 1903–4, Rs. 3,09,88,759; in 1904–5, Rs. 2,85,17,173, or approximately one-half the value of the traffic five years previously. Commenting on this somewhat significant state of affairs, Mr. J. E. O’Conor wrote, "This transference of the trade from tanned to untanned skins is likely to proceed in an accelerated degree, to the great loss and detriment of the trade in the Madras Presidency. But it must not hastily be concluded that in itself the contraction of this industry is a subject for regret. If the industry had been established on a sound economic basis, it would not and could not have suffered, for all the natural conditions are in its favour, including cheap and abundant supplies on the spot of skins and tanning substances and cheap labour. These advantages, however, were not effectively utilised, in consequence of the absence of capital, for tanning is essentially an industry in which the possession of large resources counts for much." The position, however, may be rectified without difficulty if capital is forthcoming; and if it is desired to prove that tanning is a profitable industry, it may be observed that where it has been undertaken in accordance with sound principle, as in the leading tanning establishments in Cawnpore and Bombay, it has been an extremely profitable and expanding business" (Anglo-Ind. Review, April 1903). The returns for 1905–6 show, however, that in the severe fluctuations to which the traffic is ever subject, the pendulum has once more begun to swing forward. The ex-
ports recorded manifest a great improvement in tanned hides, amounting to an increase of 63·7 per cent. in quantity and 87·6 per cent. in value on the figures for 1904–5. The actual value of the hides exported in 1905–6 amounted to Rs. 1,54,80,070, and of the skins to Rs. 2,11,04,250, giving a total of Rs. 3,65,84,320; and in 1906–7, hides Rs. 1,72,96,337, and skins Rs. 2,72,16,204, or Rs. 4,45,12,541.

**LEATHER AND LEATHER MANUFACTURES.—Internal Industries.**

—Although the objection to taking life is held very strongly by Buddhists and to a less extent by Hindus, it has not seriously opposed the growth of a trade in leather and leather manufactures. From the most ancient times in India, furs, skins, and leather have been used, and apparently to much greater extent than is the case to-day. Speaking of the frontier of India, Stein (Ancient Khotan, 1907, 345 et seq.) describes in great detail the ancient records, correspondence, etc., written on leather and wood, which he discovered during the exploration of the Niya site, and some of which bear the date of the 3rd century A.D. "The finish given," he says, "to the leather of these ancient documents indicates extensive practice in the preparation of the material." Leather, when once prepared, was thus not objected to by the early Buddhists of Khotan, any more than are the leather straps of the sacred books used by the orthodox Brahmans of to-day, in Kashmir and India generally. Book-binding in leather Stein regards as dating back to the Hindu period of Kashmir, and thus long anterior to the Muhammadan conquest. Many of the stucco statuary and fresco paintings of Ancient Khotan show personages riding on horses and camels, the saddles and trappings of which differ but little from those in use to-day; and the riders are often depicted wearing high boots of black leather richly embroidered in gold and silk. These circumstances may thus be accepted as indicative of an ancient knowledge in leather.

It is not contemplated to deal here in detail with the contrivances and materials of leather manufacture. The various provincial Governments of India have recently had prepared a series of publications entitled *Monographs on the Tanning and Working in Leather*. These, so far as they go, are admirable publications, and will be found to afford much useful information regarding the manufacture and utilisation of leather in India.

**Leather.**—It may very truly be said that no large industry has changed more rapidly and completely than that of leather. Every axiom of the craft and even the reputation of leather itself has changed completely, for artificial leather is now a regular commodity. But speaking figuratively, India may be said to be many years behind the times. From being an industry in which time and capital had to be locked up almost indefinitely, tanning may now be spoken of as characterised by a rapidity of production and a turnover hardly equalled by any other branch of manufacturing enterprise. From being essentially a craft for manual labour, every stage in the tanning of leather and the preparation from it of the most artistically finished boots and shoes are accomplished by complex and intricate machinery. And what is even more significant, the countries that have responded most energetically to the discoveries of science and of mechanical skill have usurped or are usurping the leather trade of the world. Instead of it being now found necessary to retain hides and skins for a protracted period, subject to the slow action of some vegetable tanning material, rapid chemical methods (by mineral salts,
MODERN TANNING

HIDES AND SKINS

or even aided by electricity) have been called into existence and accepted with avidity by the trade.

Chrome Process.—By the chrome process, for example, superior leather may be produced from the strongest buffalo hides in seven days, from cow-hide in twenty-four hours, and from sheep and goat skins in six to eight hours; and these operations formerly took thirty days, or as much even as eighteen months. There are two methods of chrome tanning, viz. by one or by two vats. After the required submersion the hides or skins are removed from the drums and piled up on a table for twenty-four hours, so as to allow the tanning liquors to drain off slowly, while completing the tanning process. After this the felts are well washed in several changes of water and are then put into a solution of borax and water to neutralise any trace of acid. The neutralisation of the acid is a point that demands careful consideration. After further washing the leather is now ready to be dyed or fat liquored, according to the purpose for which intended.

A point of great moment is the circumstance that once dried, chrome leather can never again be sufficiently wetted to allow of treatment, so that the complete preparation for its final purpose must be undertaken almost immediately the hides or skins are taken from the vats. The half process pursued by many Madras tanners it would seem may have to be abandoned if they propose in the future to adopt chrome tanning. But the new process is neither expensive nor difficult, and with such improvements accomplished it is not difficult to understand why salted hides and skins are preferred to the more expensive half-tanned goods of Indian former trade. While the discoveries here briefly indicated and others too numerous to mention have proved of supreme moment to the leather trade of the rest of the world, the Native tanners of India have stood still and seen their interests being frittered away. Protracted immersion has for many years past been admitted as impossible in India. The superiority of European leather over that of India was accordingly freely acknowledged as a direct consequence of that circumstance. But now that scientific and effectual rapid methods have been designed and freely accepted in other countries, India alone stands aloof and speculates as to the obligation of Government to aid a decaying industry. With the few European manufacturers alone have the discoveries of the past twenty years assumed the position of guiding and controlling influences in internal reform and commercial advancement.

Imports of Leather.—But in spite of general backwardness the leather produced by some of the tanneries, especially those under European management, is in certain respects fully equal to the best imported article, and for rough wear the boots turned out by the Cawnpore factories are even superior (especially when the price is taken into consideration) to the corresponding imported goods. This view would seem to be supported by the fact that the imports of unwrought leather do not appear to be advancing at a rate commensurate with those of manufactured leathern goods. Thus the imports in 1900–1 stood at Rs. 5,55,911; in 1901–2 at Rs. 4,18,348; in 1902–3 at Rs. 6,61,480; in 1903–4 at Rs. 3,81,192; in 1904–5 at Rs. 3,72,167; in 1905–6 at Rs. 4,24,596; and in 1906–7, Rs. 5,04,407. If to these figures be added the value of the imports of saddlery and other goods (except boots and shoes), the grand totals became in 1903–4, Rs. 26,19,633; in 1905–6, Rs. 30,60,820; and in 1906–7, Rs. 32,58,681.
THE LEATHER INDUSTRIES

HIDES AND SKINS

Tanners.

Indian Tanneries.—Turning now to the statistics of tanneries in India, it may be said that in 1893 there were 44 tanneries that gave employment to 3,804 persons. Steadily these would appear to have increased until in 1902-3 it was ascertained that there were 202 tanneries and 6,200 employees. Of these tanneries, however, 183 were small concerns located in the Madras Presidency and concerned chiefly in the dressing of skins. In 1903-4 and subsequent years all the smaller works (those that gave employment to less than 25 persons) were excluded from consideration, and 43 tanneries were returned giving employment to 7,907 persons. In 1904-5 35 were returned, employing 5,981 persons. Of these 32 were in Madras (excluding the small skin-curing works). The tanneries of North India are six in number located in Cawnpore; four in Calcutta; three in Bombay; and one in Rajputana. The Cawnpore tanneries are by far the most important in all India. They produce superior leather, which is conveyed across the country and worked up by the local boot and shoe makers, saddlers, etc. The Cawnpore factories also turn out very superior boots and shoes, leather trunks, saddlery, etc., for which a large and growing market exists.

Indigenous Methods.—But here and there, in every town and village of India, skins may be seen tanned by certain classes of people. It is no uncommon sight to find the skins of animals filled with tanning materials and left suspended from the boughs of trees or from the beams of the verandahs of the dwelling houses, until the desired change has been accomplished in the skin. In other instances crude vats, each containing one or two skins, may be discovered near the leather workers' houses. The provincial monographs will be found to contain highly instructive photographs, not only of such vats, but also descriptive details of many of the methods and contrivances of leather-curing practised in India. The tanned skins and hides produced in India by the indigenous tanneries are traded in all over the country and used up by the village workers. But the distinctly inferior nature of the leather so used may be illustrated by the fact that the articles produced rarely fetch much more than one-fourth the values of the corresponding articles made of imported or Cawnpore (European factory) leather. So again, Indian leather, owing to its low textile strength, is unsuited for belting purposes or any necessity where strength is essential.

Tanning Materials.—India possesses an extensive series of very excellent tanning materials such as Acacia pods and bark (see pp. 6-7); Cutch (see pp. 9-13); Indian Sumach (see p. 913); the Tanner's Cassia (see pp. 289-90); the Mangroves (see pp. 98, 293); Myrobalans (see pp. 1073-6); and many others. By these and such-like materials and by various methods and contrivances, hides and skins are extensively cured, tanned and curried and the leather worked up, in response to an immense though purely local demand. [Cf. Agri. Ledg., 1896, No. 9; Hooper, Rept. on Tanning Extracts, pub. by Inspector-General of Forests, Feb. 1898; Tanning-Producing Substances, Assist. Agri. Chemist to Govt. of India, 1901; Hooper, Ind. Tanning Materials, in Agri. Ledg., 1902, No. 1, also numerous analyses in the Annual Reports of the Indian Museum (Economic) Laboratory.]

Concluding Observations.—In technical works it is said there are three chief methods of tanning:—(1) with infusion of bark or other vegetable materials; (2) with mineral salts; (3) with tanning oils. After
being tanned the skins are subjected to further treatment and are finally spoken of as "dressed."

Hides are tanned principally for sole, belting and harness leather; calf-skins for uppers of boots (light leather) and bookbinding; sheepskins afford a variety of leathers; goat skins are glove skins, although lamb skins and deer skins afford good substitutes in glove-making. The thickest sole leathers are made from the cattle of the less cultivated countries, since artificial protection seems to tend to render the skin thinner. The cattle of the River Plate are the chief source of the heavy hides or butts. Castration gives a more uniform hide, and these are much preferred. Hides of diseased animals are nearly always inferior, and moreover dangerous, as there would seem reason for believing that anthrax may be conveyed by imperfectly cured hides. Similarly the sheep most prized and most carefully produced as fleece-yielders afford very inferior skins. Hides may be preserved by being salted on the fleshy side or by being simply passed through a solution of arsenic and dried in the shade. This is the modern practice in India, especially at the yards of the large and important shippers.

**Boot and Shoe Trade.**—The Imports of boots and shoes have for some years been increasing rapidly. In 1886–7 the supply was valued at Rs. 11,31,238; in 1903–4 at Rs. 27,03,249; in 1905–6 at Rs. 34,45,418; and 1906–7, Rs. 29,08,093. One of the most significant features of this trade is the expansion of American supply, which even in India has begun to be felt. The Indian market is thus one of growing importance, and this circumstance manifests the possibilities of the local industry, already well organised. Every village and town has its shoemakers. In the cities whole streets are often devoted to them, and one of the most surprising features of the trade is the very large number of Chinese men engaged in it. Native shoes are often elaborately embroidered and even jewelled. The places most famed for artistic shoes and leather work generally are in Bengal—Cuttaick, Patna and Saran. In the United Provinces—Rampur, Lucknow, Agra, Jhansi and Saharanpur. In the Panjab—Kohat, Rawalpindi, Peshawar, Dera Ghazi Khan and Hoshiarpur. In the Central Provinces—Chanda. In Rajputana—Jaipur and Bikanir. In Bombay—Surat, Ahmedabad, Poona, Ratnagiri and Hyderabad (Sind). In South India—Raichur, Salem, Trichinopoly, Madras and Mysore. These are the chief centres in the native trade, but, as already said, Cawnpore stands out pre-eminently as the commercial centre of the modern trade (European style) in boots, shoes, saddlery, trunks, etc. Lastly, it may be added that for the past ten years or so India has been a net exporter of leather goods. In 1898–9 this traffic was valued at Rs. 3,52,027; in 1902–3 at Rs. 10,59,052; in 1905–6 at Rs. 4,88,640; and in 1906–7, Rs. 4,68,491. These exports go from Calcutta and Bombay and are consigned mainly to Natal, Cape Colony, Mauritius and Egypt, with smaller quantities to England, Russia, etc. Indian (or, to be more correct, Cawnpore) ammunition boots are now well known in trade.

**Artistic Manufactures.**—Belts, powder-flasks, saddlery, saddle-cloths, etc., etc., are extensively produced all over the country, and in some cases the goods turned out are of superior quality and highly artistic. The "Frontier Belts" of Peshawar, Bannu, Kohat and Quetta are well known and in much demand over a large portion of India. Sambar leather is also richly embroidered, and in the form of sheets, table-cloths, etc., is extensively used. The localities best known for the production of these goods are Gorakhpur in Oudh and Chanda in the Central Provinces. In the Karnul district of Madras leather mats are quaintly painted, and in many parts of Rajputana and Bombay leather is admirably stamped and engraved in bookbinding. The most noted centres for this art are Alwar and Ahmedabad. In Gujarath an industry has long existed in carving rhinoceros-hide shields. In some cases, instead of being carved the hide is so cured as to become almost transparent and of a pale amber colour. [Cf. Ind. Art at Delhi, 1903, 199–205; Hooy, Monog. Trade and Manuf. N. Ind., 1880, 90–5; Blount and Bloxam, Chem. for Engin. and Manuf., 1900, 367–95; Perkin, Yellow Colouring Matter in Tan. Mat., Chem. Soc., 1900, 423–32; Monographs.—Grant, Leather Indust. Barley.

HORDEUM VULGARE, Linn.; Fl. Br. Ind., vii., 371-2;

Habitat.—An annual grass producing many stems from a single grain, and becoming 2 to 3 feet long. It occurs throughout the temperate and extra-tropical regions of the globe, and in India is met with from the plains to altitudes of 14,000 feet above the sea-level.

There are several well-marked varieties, of which the most important are:—var. (a) hexastichon, Aitichs.; var. (β) distichon, Linn.; and var. (γ) nudum, Ard. Hexastichon, or six-rowed barley, is that which is
most commonly cultivated in India. The only variety hitherto found wild is *distichon*, which seems to be indigenous to Western Temperate Asia.

History.—Barley is amongst the most ancient of cultivated plants, but as its forms resemble each other very closely in their properties and seem to have had, in all languages, common names, it is not easy to ascertain which variety is referred to by the early writers. Proofs in abundance exist that one or other of the forms has been cultivated since the remotest times. According to Bretschneider, barley is one of the five cereals sown by the Emperor Shen-nung of China, who reigned about 2700 B.C. Theophrastus was acquainted with several forms of barley, and it was an important article of food in the time of Solomon (n.c. 1015). The variety *hexastichon* has been found in the earliest Egyptian monuments, as also in the remains of the later dwellings of Switzerland and of Savoy. The six-rowed barley is represented on the medals of Metapontes—a town in South Italy—of date 6th century B.C. The oldest known Indian (or rather Central Asiatic) samples of barley are those collected by Stein at Kara-dong (Ancient Khotan, 1907, 448). The ruins in question had been engulfed by sand about the close of the 8th century A.D. The variety most frequently met with in India is also *hexastichon*. Indra is called "the god who ripens barley," and as still manifesting ancient knowledge it may be added that the grain is employed in the ceremonies attending the birth, marriage and death, as also certain sacrificial rites. This idea is also borne out by the antiquity of the Sanskrit name *yava* (*yavaka*), which in the earliest times was a general term for corn or grain, but which with time became restricted to what must have been at least a very important grain—barley; hence have come the modern vernaculars—*jaw*, *jau*, *Indrajaw*, *jawa*, etc. The grain is also closely associated with the Indian Muhammadans. In the *Ain-i-Akbari* the crop is said to have been one of the most important in Afghanistan and Kashmir, a large part of the revenue in these countries having been obtained from barley by exacting the usual two out of every ten *kherwars* produced.

**CULTIVATION.**—Barley is a rabi crop, sown in October or November, and reaped in March or April. In Bombay it is generally grown alone, occasionally with a sprinkling of rape or mustard, but in many parts it is often mixed with wheat, gram, peas or lentils, while rape, Indian mustard and linseed are commonly sown as borderings. The soils on which it thrives best are light and sandy, and, as a rule, not highly manured. The number of ploughings before sowing varies, but four would be a fair average. The seed-rate runs from about 80 to 120 lb. per acre. It is sown by plough-furrows, the surface of the ground being subsequently levelled and beds for irrigation formed. Irrigation, however, may not be necessary, and in districts which enjoy a tolerable certainty of rain it is but rarely resorted to. Little weeding is required, the crop being left very much to itself till March—April, when it is reaped like wheat, tied up in sheaves, and stacked near the homesteads to dry. The preparation for the market is the same as that for wheat. The total cost of growing an acre is variously stated: Mukerji puts it at only Rs. 18-8; Duthie and Fuller, Rs. 20–12; and Mollison gives for Gujarat, Rs. 51–8-0. Huskless barley from Saharanpur is described in the *Kew Bulletin* (1888, 271–3).

**Areas under the Crop.**—From the *Agricultural Statistics of British India*, it appears that in recent years far the largest quantity of this cereal is grown in the United Provinces and in Bengal. The Panjáb, North-West Frontier, Ajmer-Merwara, Bômbay, the Central Provinces, Sind and Madras follow in the order given. The total area under barley in British India for the year 1905–6 was 7,326,755 acres. Similarly, in the Native States, the area in the same year is said to have been 418,463 acres, chiefly in Jaipur, Alwar, Bharatpur and Gwalior.

**Bengal.**—The cultivation of barley is mostly restricted to the central Bengal.
and northern districts. It is more especially met with in South Bihar, where it forms one of the cheapest of foods. In North Bihar (Bhagalpur) it is of less importance. The cultivation of barley diminishes south and east, and is practically not grown in Bengal proper nor in Orissa. Though in recent years Bengal stands second as regards the total area under this crop, within the province it is comparatively unimportant, the percentage of the normal area under barley having amounted in 1904-5 to only 23.5. The total barley area in that year was 1,514,700 acres, and the yield 494,243 tons; hence if an average be assumed, these figures would show 64 cwt. per acre. In 1906-7 the area was 1,411,100 acres. The chief localities are usually Patna, Bhagalpur, and Chota Nagpur. [Cf. Mukerji, *Handbook Ind. Agri.*, 1901, 245-7; Basu, *Agri. Lohardaga*, 1890, ii., 32-3; Banerjee, *Agri. Cuttack*, 1893, 78-9; *Rept. Admin. Beng.*, 1903, 15; *Ind. Planters' Gaz.*, Sept. 19, 1903; Oct. 10, 1903.]

**U. Prov.**

*United Provinces.*—These provinces stand first in British India as regards the total area under barley and the annual output. In 1905-6 it amounted to 4,127,936 acres, of which Agra contributed 3,137,104 and Oudh 990,832. The largest areas were in the Gorakhpur, Benares, Lucknow and Allahabad Divisions. Duthie and Fuller estimated the average outturn of unmixed barley at 16 maunds per acre if irrigated, 8 to 11 maunds if unirrigated. [Cf. *Cawnpore Exper. Farm Rept. Dist. Gaz.*, *U. Prov.* (many passages).]

**C. Prov. and Berar.**

*Central Provinces and Berar.*—The total area for 1905-6 in these provinces would appear to have been 11,608 acres, and the chief districts Jabalpur, Damoh, Bilaspur and Chanda. Of Berar, 94 acres have been returned as under this crop.

**Rajputana.**

*Rajputana.*—The crop is apparently an important one, especially in Ajmer-Merwara, where, during the ten years ending 1899-1900, it is returned as having occupied 161 per cent. of the average cultivated area. [Cf. *Rajputana Gaz.*, *Ajmer-Merwara*, 1904, i., 46.] But of the whole province, in 1904-5, mention is made of a total area of 38,728 acres. In irrigated land it yields an average of about 734 cwt. per acre, but in dry crop land the average outturn is given as only 146 cwt.

**Panjab and N.W. Frontier.**

*Panjáb and North-West Frontier.*—The system of cultivation is very similar to that in Bombay and the United Provinces, but the practice of topping an over-leafy crop is said to be common; the crop is generally grown unmixed. The total area for 1905-6 was 1,205,678 acres in the Panjáb and 315,272 acres in the North-West Frontier. The most important localities are usually Ferozpúr, Hissár, Gurgón in the Panjáb; Peshawar, Hazara and Bannu in the North-West Frontier. [Cf. Montgomery, *Barley Cult. Pb.*, in *Select. Rec. Finance Comm. Office*, 1885, No. 29; *Rept. Govt. Agri.-Hort. Gard. Lahore*; *Dist. Gaz. Pb.* (many passages).]

**Kashmir.**

*Kashmir.*—According to Lawrence (*Valley of Kashmir*, 1895, 341), barley is the most important spring crop, if area alone be considered. It is not, however, of good quality, and no pains are taken in its cultivation. In the higher villages, at an elevation of 7,000 feet, there is a peculiar variety known as *grim*, or Tibet barley. The grain is naked like wheat, and it is said that if cultivated at a lower level it takes on the type of ordinary barley. It is sown in May and June, ripens in August and September. Barley gives on an average 8½ maunds per acre; *grim*, about 4 maunds. [Cf. *Assess. Repts. Baltistan* :—Kaye, *Skardu Tahsil*, 1901, 8-9; Clarke, *Kargil Tahsil*, 1901, 19, 29; also *Skardu Tahsil*, 1901, 20-3.]
HORDEUM VULGARE
Cultivation Bombay.

MILLING AND MALTING

Bombay.—Barley is not extensively grown in Bombay. In 1905-6 the total area was only 23,103 acres. In that year Ahmedabad grew 11,330 acres; Kaira 3,448; Satara 4,807; Sholapur 1,284; and Panch Mahals 463. It is generally grown alone, occasionally with a sprinkling of rape or mustard. In parts of Gujarat wheat and barley are grown mixed. As in other provinces, it is a light-soil crop, the sandy loams of Kaira and Ahmedabad district being particularly suitable. Mollison remarks that 1,500 to 1,800 lb. of grain per acre and about a ton of straw are considered a full average yield. [Cf. Mollison, *Handbook Ind. Agri.*, 1901, 44-9.]

Madras.—Barley is a very unimportant crop. For the year 1905-6 the total area in the Presidency amounted to only 3,280 acres, all in the Nilgris. In Mysore the total in 1905-6 was 1,338 acres.

**Milling or Preparing.**—The process of cleaning barley for food purposes is generally carried out by pounding in wooden mortars and winnowing, or by beating with a flat board. The grain is then ground into coarse meal from which alone, or mixed with the meal of wheat or gram, *chapattis* are made and baked; or a gruel or pasty mass is made, to which salt is added and the preparation eaten with garlic, onions or chillies. In either of these forms it is a staple article of food among the poorer classes. The grain, thus roughly cleaned and ground, is richer in albuminoids than the more carefully prepared culinary barley of Europe; but at the same time it is more difficult to digest, and is thus partly unsuited for the dietary of dyspeptics or invalids.

In various parts of India barley is now largely employed in the preparation of beer or spirituous liquor, and the use of barley in Europe for malting and brewing is well known (see Malt Liquors, p. 759; Vinegar, p. 1109). Mollison gives an account of the qualities which give barley a special value for these purposes. It is also largely used as a horse and cattle fodder. In some parts of India the crop is cut two or three times when quite young, without marked injury to the final yield of grain. The straw even of ripe barley makes a fairly good fodder when cut up as *bhisa*, but is inferior to that of wheat. The grain is a good feed both for horses and cattle, either given alone or mixed with gram.

**Properties and Uses.**—The chemical composition of ordinary husked Indian barley is given by Church as follows:—in 100 parts: water 12·5, albuminoids 11·5, starch 70·0, fat 1·3, fibre 2·6, ash 2·1. The nutrient ratio is here 1:6·3 and the nutrient value 84·5. In medicine, barley is demulcent and easily digested, and is much used in the dietary of the sick. *Malt extract* has become extremely popular both as a nutritive and demulcent, and as a means for rendering other medicines palatable.

**Trade.**—Official trade statistics show the following as the EXPORTS from British India in the six years ending March 31, 1907:—1901-2, 54,648 cwt., valued at Rs. 1,80,180; 1902-3, 63,872 cwt., valued at Rs. 2,27,937; 1903-4, 113,120 cwt., valued at Rs. 3,56,421; 1904-5, 376,548 cwt., valued at Rs. 12,26,154; 1905-6, 92,810 cwt., valued at Rs. 3,12,548; and 1906-7, 406,067 cwt., valued at Rs. 12,51,753. There was thus a steady increase till 1904-5, but a sudden decrease in 1905-6. In 1904-5 (the record year) Bombay exported the largest share, viz. 231,037 cwt. (though in the previous year it exported only 25,883 cwt.); Sind 86,070 cwt.; and Bengal 59,307. The relative shares of the exporting centres are, however, subject to great variation. During the same period the IMPORTS were:—1900-1,
HORNS AND ANTLERS

88,523 cwt., valued at Rs. 3,59,845; 1901-2, 14,495 cwt., valued at Rs. 59,757; 1902-3, 628 cwt., valued at Rs. 2,718; 1903-4, 21,792 cwt., valued at Rs. 85,505; 1904-5, 7,220 cwt., valued at Rs. 28,239; 1905-6, 25,948 cwt., valued at Rs. 92,487; 1906-7, 32,339 cwt., valued at Rs. 1,09,070.

**Prices.**—The average wholesale price per 10 maunds during 1905 varied in Bengal from Rs. 17-67 in Muzzafarpur to Rs. 19-01, in Patna; in the United Provinces from Rs. 17-6 in Meerut to Rs. 22-47 in Fyzabad; in the Panjáb from Rs. 14-53 in Amritsar to Rs. 20-37 in Delhi.

**HORNS, ANTLERS, AND HORN-WORK.**—Blanford, Fa. Br. Ind. (Mammalia) 1888-91 (respective pages of species below). Horns and Antlers are largely utilized in the manufactures of the world, and in their crude state are fairly extensively exported from India. The traffic is mainly in the hands of the dealers in Hides and Skins.

The following animals will be found fully discussed under Live Stock (pp. 732-49), and, as they are the chief sources of the horns of Indian commerce, that article should be consulted:—**Bos indicus** (l.c. 483-93), the breeds of the Ox; **B. bubalus**, the wild and domesticated Buffalo; **B. grunniens**, the Yak; **B. frontalis**, the geyal; **B. gaurus**, the Bison; and **B. sondaicus**, the Banting or Burmese Wild Bull. **Capra** (l.c. 501-8), the various breeds of Goat; **C. aegagrus**, the Baluchistan, etc., Wild Goat; **C. falconeri**, the Markhor; **C. sibirica**, the Ibex. **Ovis** (l.c. 493-501), domestic Sheep; **O. hodgsoni**, the Tibetan Great Sheep; **O. nubiana**, the bharal; **O. poli**, the Great Sheep of the Pamirs; and **O. siguel**, the kuch or Wild Sheep of the Salt Range. Lastly, a small group of transitional animals such as **Hemitragus jemlahicus** (l.c. 508-12), the tahr of the Western Himalaya; **R. hylocrius**, the Nilgiri Wild Goat. **Xerorhoccus bubalus** (l.c. 512-3), the Himalayan Goat-antelope; **X. smania-tresis**, the Burmese Goat-antelope. **Cervus goral** (l.c. 516-7), the goral of the N.W. Himalaya, or Himalayan Chamois. The **Ruselaphus tygar-sinensis** (l.c. 518-9), or nilgai or Blue Bull. **Tetracerus quadricornis** (l.c. 519-21), the Four-horned Antelope. **Antilope cervicapra** (l.c. 521-4), the Black Buck. **Gasella bennettii** (l.c. 526-8), the Indian Gazelle, etc., etc. To that list of **Bovidae**—Oxen, Sheep, Goats and Antelopes—has to be added the Deer, such as **Cervus muticus** (l.c. 532-4), the Barking Deer. **Cervus axis** (l.c. 534-51), the Spotted Deer; **C. cashmirianus**, the Kashmir Stag; **C. tauricus**, the barasingha; **C. eldi**, the Manipur Deer or thameng of Burma; **C. porcinus**, the Hog-deer; **C. unicolor**, the Sambar or Rusa Deer. And **Rhinoceros unicornis** (l.c. 472-4), the great One-horned Rhinoceros, etc., etc. Such then may be given as an enumeration of animals from which, in India and its mountainous frontiers, horns and antlers are obtained. Commercially, however, the horns might almost be said to be derived from the domesticated oxen—all the others being special or fancy articles, in which there is but a limited traffic.

**Classification.**—Horns may be grouped as follows:—

I. Those that consist of bone and which possess no true horny matter in their structure.

(a) True bone, such as antlers of deer.
HORNS AND
ANTLERS

TRADE

(b) Epiphyses or separate pieces of bone covered by skin, such as in the horns of the giraffe.

II. Horns that more or less consist of true horny matter.

(c) Bone tipped by horn, such as in the horns of the prong-horned antelope.

(d) Bone covered or sheathed by true horn, such as in the ox.

(e) True horn throughout, such as the nasal horn of the rhinoceros.

True horn matter is formed by a modification of the epidermal tissue (the superficial layers of skin) and consists of an albuminoid material called keratin, a substance identical with the chief constituent of wool.

Horns of the first group are largely exported from India to England, under the name of dear-horn. The antlers chiefly traded in are those of the spotted deer (30 inches and under) and the sambar (40 inches and under). They are extensively employed in Europe as bone handles for cutlery, umbrellas, sticks, etc. The second group are valued on account of the special properties of keratin; it is elastic, flexible and tough, and readily softens under heat and allows of the substance being moulded and welded as desired. Long, straight buffalo-horn is valued as a substitute for whalebone, and on this account fetches a higher price than curved horn. Accordingly, the tips are cut off and sold separately. The horns of sheep and goats are whiter and more transparent than those of other animals, and are, therefore, most valued for comb-making, while certain buffalo-horns are in demand for ornamental work. Perhaps one-fifth of the horns imported into England are used up in the comb trade, a small proportion being utilised for fancy work, such as shoe-horns, scoops, drinking-cups and the like. The solid tips, as also the hoofs of cattle (which consist largely of keratin), are made into buttons. The long, straight horns are cut into strips softened in a solution of bi-carbonate of soda; the strips being allowed to sweat, are then bevelled and pressed together, when they unite into the strips that are employed in place of whalebone. In Jaipur and elsewhere in India long straight horns have similarly been used from ancient times in the manufacture of bows and arrows.

Trade in Horns and Hornmeal.—The EXPORTS of horn of all kinds from India were 71,894 cwt., valued at Rs. 12,80,051, in 1876–7; a decade later the quantity had been reduced by nearly one half, but the value remained the same; a decade still later the exports were 59,804 cwt., valued at Rs. 16,73,241. The traffic is one that fluctuates extremely according to climatic conditions. In times of scarcity and famine the exports increase and the horns decline in value, while in times of plenty the quantity decreases and the value increases. During 1901–2 the exports were 62,944 cwt. and Rs. 13,35,759; in 1902–3, 71,396 cwt. and Rs. 17,05,257; in 1903–4, 48,405 cwt. and Rs. 12,05,798; 1904–5, 61,582 cwt. and Rs. 13,72,375; 1905–6, 73,521 cwt. and Rs. 17,49,944; and in 1906–7, 78,771 cwt. and Rs. 16,91,532. Usually about 50 per cent. of the trade goes from Bombay, and approximately a similar proportion of the total is consigned to the United Kingdom—the shares taken in 1899–1900 having been 45,660 cwt.; in 1903–4, 25,718 cwt.; and in 1906–7, 26,678 cwt. France is the next most important receiving country, having taken in 1899–1900, 25,590 cwt.; in 1903–4, 13,226 cwt.; and in 1906–7, 32,887 cwt. The share contributed by Calcutta is ordinarily little over half that of Bombay. The IMPORTS drawn by India from foreign
countries (by sea) are unimportant, in 1904–4 having been only 353 cwt., valued at Rs. 75,041; and in 1905–6, 316 cwt., valued at Rs. 69,318.

The examination of the returns of trade carried by rail and river reveals the fact that the chief provinces of supply are Bombay, the United Provinces, Central Provinces, the Panjáb, Bengal and Madras. Official returns of the trade of England and Continental countries distinguish as a rule the traffic in deer horns from that in buffalo, and judged from these it would appear that India is one of the chief countries from which the former are obtained. Indian trade statistics do not separate the two, so that the returns reviewed above are for all grades collectively.

**Indian Industries.**—The chief forms of horn used in the Indian craft (kangi-sdz) are buffalo and bison horn, since there are religious objections to the use of cow-horn. A cup made of rhinoceros-horn is much prized by Hindus, but it is too scarce a material to be generally used. Buffalo-horn is by far the most largely employed in India of all horns, but it is the least beautiful. It is made into cups, tumblers, combs, musical instruments, work-boxes, powder-flasks, bows and arrows, hukka mouth-pieces, scent-bottles, snuff-boxes, sword, dagger and knife handles, and many other such articles. The centres of the trade are Cuttack, Monghyr, Sátkhira (Khulna), Hughlí and Serampore in Bengal, where combs, brooches, necklaces, snake bangles and the like are made. Rajputana, Jaipur and Kota are famed for their horn works. Rajkote combs, Baroda spoons, Kathiawar knife-handles, Surat and Ahmedabad veneered boxes and Baroda animal toys of horn are all well known. In Mysore, umbrella-handles, powder-boxes and buttons are made of buffalo-horn, and often richly inlaid with ivory and copper. But it is in Vizagapatam that horn veneered work may be said to have assumed the condition of high-class ware. In Ratnagiri and Savantvadi a fair trade is done in bison-horn work. Aitken (Agri. Ledg., 1897, No. 10) wrote a most interesting account of the industry in the former locality. Perhaps the most instructive feature of that publication may be said to be the method of softening the horn. It is coated with cocoanut-oil and heated before a fire until it becomes sufficiently soft to allow of its being pulled out and moulded into the desired shape.

**HYDROCOTYLE ASIATICA, Linn.; Fl. Br. Ind., ii., 669;**

Cooke, Fl. Pres. Bomb., 1903, i., 562; Duthie, Fl. Upper Ganq. Plain, 1903, 390–1; **UMBELLIFERÆ.** The Asiatic Penny-wort, brahmi, bráhmamand-uki, tholkuri, karivana, vallarái, mandukaparni. A small herbaceous plant, found throughout India from the Himalaya to Ceylon at altitudes up to 2,000 feet.

The medicinal properties of this plant were known to Sanskrit writers of very remote times, and the early European writers on Indian Materia Medica were also acquainted with the plant. The parts generally employed are the leaves, dried by exposure to the air and ground to a powder. The powder is of a pale green colour and exhalés a slight characteristic aroma. It is an alterative, tonic and a local stimulant, said to be efficacious both as an internal and external remedy in ulcerations, eczema, leprosy and other cutaneous affections. The chemistry of the leaves was first investigated by Lepine in 1855, who found they contained oily and resinous constituents, with mucilaginous principles and

INDIA-RUBBER, CAOUTCHOUC OR GUM ELASTIC.

—Caoutchouc, like gutta-percha, is a vegetable inspissated milk or latex. In both cases the substance consists of a hydrocarbon, forming corpuscle-like bodies floating in a fluid. Gutta-percha becomes soft and plastic in hot water and may be moulded into any desired shape, which it preserves on cooling. Caoutchouc, on the other hand, is not softened by heat, is impervious to water, alcohol and most acids, etc., and retains its elasticity for a considerable period. Gutta-percha is chiefly obtained from trees that belong to the Sapotaceæ, while caoutchouc is derived from certain plants which have been placed in three widely different natural orders. These are _Funtumia_, _Hancornia_, _Landolphia_ and _Willoughbeia_ of Apocynaceæ; _Castilla_ and _Ficus_ of Urticaceæ, and _Hevea_ and _Manihot_ of Euphorbiaceæ. The plants that afford gutta-percha and india-rubber thus manifest no definite botanical affinity, except that they are mostly natives of tropical countries. In the plant tissue caoutchouc circulates within certain anastomosing vessels which are distributed throughout the middle, or more rarely the inner layer of bark. [Cf. Lecomte, Journ. d'Agri. Trop., 1903, xvii., 375.] A far larger number of plants possess milk (and even a caoutchouc-yielding latex) than those generally viewed as the sources of india-rubber. The term caoutchouc is sometimes used synonymously for india-rubber, but it more correctly denotes the pure hydrocarbon isolated from the other materials with which it forms the impure rubber of commerce. Caoutchouc is highly elastic, lighter than water, has neither taste nor smell, is fusible at about 248° F. and inflammable at higher temperatures.

Methods of Agglutination.—When the bark of plants containing rubber is cut, the milk exudes, and in time hardens on exposure to the air. This agglutination may be hastened by adding salt water, alum or acetic acid to the milk; but these, more especially salt, increase one of its defects, viz. the hygroscopic property by which it becomes moist and sticky, and in consequence they injure it commercially. A favourite but wasteful method is to allow the milk to flow into holes in the ground and to be left there till the water, etc., has drained off. Boiling the milk is the system followed in Lagos, while in the Amazon valley the smoke of a smouldering fire, combined with moderate heat, is the system almost universally pursued with Para rubber. In a few cases the milk is simply allowed to dry as it trickles down the stem. This gives the Scrap Rubber of Ceará and a good deal of that of Assam and Penang. The alum (or Penang) process was recognised as being useful for Assam, where the humid atmosphere operates against the drying of the rubber. Dr. C. O. Weber, in a series of articles contributed to The India-rubber and Gutta-percha Trades Journal in 1902, also 1904, has stated the facts regarding coagulation briefly as follows:—

1. That the so-called coagulation of rubber by acids or alkalis is
INDIA-RUBBER
Collection

Albumen.

erroneous in that it is only the albumen which is coagulated by these substances, and not the india-rubber itself.

2. That the albumen contained in latex is very harmful in many respects, and that it ought to be as far as possible eliminated from the milk before attempting to agglutinate the rubber.

3. The method he recommends for coagulation is briefly as follows:—
First mix the latex with water, at least five times its volume. In cases where the latex is thick, actual boiling water may be used with advantage. In this state it can be easily strained to remove impurities. After this, add formaldehyde in the proportion of 8 oz. to a petroleum barrel; stir well and let it stand for twenty-four hours, when the rubber will collect on the top and can be lifted out in one mass. In order to remove any traces of albumen that may be suspended, the rubber should next be cut into strips and subjected to a thorough washing upon an ordinary rubber washing-machine. [Cf. Weber, Chem. India-Rubber, 1902.]

But the use of formaldehyde does not seem to have been the success that Weber anticipated, though his recommendation for cleanliness and repeated washing has been universally accepted. Biffen (Annals of Botany, 1898, xii., 165–71) suggested the use of a centrifugal separator. The milk is mixed with 50 per cent. of water, and set revolving for a time. It is then found that the rubber floats on the top in a thick mass. The albuminoids, etc., and all the adulterants are found below. It has next to be admitted that by many recent writers the value of centrifugal force has been denied, and special machinery patented in which the merit claimed is that they do not involve centrifugal action.

Indian Planting and Gardening (March 29, 1900) published a letter from Faber that gives particulars of a method of extracting caoutchouc from dry bark, said to have been discovered by a French chemist, M. G. Deiss. This process consists in keeping slices of bark and roots soaked in dilute sulphuric acid while being heated. The woody portions become decomposed and can then be washed out, thus leaving the rubber in a pure state. For other methods of extracting india-rubber by solvents or mechanical processes the reader should consult Gerber’s article on that subject. [Cf. Journ. Soc. Chem. Indust., 1902, 414–5; Kew Bull., 1898, 177–81; Mathieu, Agri. Bull. Straits and Fed. Mal. States, 1903, ii., 18–21; 1905, iv., 223–4.]

Composition of Rubber.—India-rubber may be said to consist chemically of two substances—an elastic material, on which its merit depends, and a viscid resinous substance readily oxidizable, to which it owes its depreciation. Hence the greater the percentage of resin the less the value of the sample. The property of the elastic substance also varies, and in a marked degree, between that obtained from one genus of plants and that of another, so that every gradation exists from the non-elastic hydrocarbon known as gutta-percha (which see, pp. 625–8) to the finest gum elastic. Caoutchouc yields by dry distillation a mixture of simpler hydrocarbons, called oil of caoutchouc or caoutchoucin, which forms an excellent solvent for caoutchouc and other resins.

History.—During the second voyage of Columbus it was noticed that the inhabitants of Hispaniola (Hayti) played with balls made from the gum of a tree. In 1770 Priestly recommended the use of that substance for the purpose of erasing pencil markings, hence the name “rubber.” The article was new to Europe, and the proposed utilisation of it excited some interest. It was not, however, until 1820 that the beginning of the modern industry can be traced.
Three years later Mackintosh created the waterproofing trade by dissolving rubber in naphtha. Nelson Goodyear in 1839 vulcanised it, and this rapidly led to the production of ebonite. Rubber and its products may now be spoken of as indispensable to the domestic life and to manufacturing and engineering enterprises of the entire human race. J. G. Baker wrote in 1886 (Gard. Chron., xxv., 368) an interesting article on the production of this all-important substance. Part of the supply, he then wrote, comes from South America, shipped from Para and Carthagena, part from Sierra Leone, Mozambique and Madagascar, and the remainder from tropical Asia. After exhibiting the botanical and geographical supplies, Baker dealt with the future, and what he then urged regarding cultivation has proved the keynote to present successes. So in the same way Sir George King, while reporting the introduction of Landolphia into the Botanic Gardens of Calcutta, observed that the exotic rubbers "with the exception of teuva are either very large trees or climbers: and although it may pay well to collect rubber from them in their native forests, where they have grown to maturity without cost to the collector, it is quite a different matter when their planting and protection have to be paid for, and their coming to maturity has to be awaited for years." That opinion has since been somewhat modified, though, so far as the interests of the European planters (who are at most temporary residents in the tropics) are concerned, not materially. The plantations established by the Government of India have, however, begun to prove of considerable value, as have also some of those made by private enterprise. Indeed, the experience of the past few years would seem to show that perhaps greater success may attend private enterprise in this direction than was currently believed a few years ago.

Conditions of Success.—The whole question of rubber production seems to turn on the cultivation of quick-yielding species, on superior methods of causing and securing the flow of milk, and on the high prices prevailing for carefully prepared rubber. The production of caoutchouc by the spontaneous change of the hydrocarbon isoprene is not at present of practical importance. Many of the oxidised-oil products now being manufactured manifest not a few of the properties of rubber and seem destined to relieve the strain for supplies of the natural article, but they have all one serious defect, namely they possess no elasticity. Accordingly, the fear of over-production of natural rubber, most writers think, is at present infinitesimal. [Cf. Ind. For., 1898, xxiv., 187; Kew Bull., 1899, 27; Journ. Soc. Chem. Indust., 1902, xxii., 56; 1904, xxiii., 556.]

Modern Demand.—The growth of modern demand for rubber may be manifested by the following: the exports from the Amazon valley alone in 1864 came to close on eight million pounds, and thirty years later (1904) they came to sixty-seven million pounds, a quantity that represents the systematic tapping of twenty million trees, and which fetched over thirteen million pounds sterling (see p. 660). In India, Ceylon and the Federated Malay States rubber cultivation is being vigorously prosecuted, and the future seems destined to see a still further expansion in these countries.

Asiatic Production.—In Ceylon during 1905 there are believed to have been 40,000 acres devoted to Hevea and to a lesser extent to Castillou rubber trees. The plantations are mostly within the valleys, but some extend up to an altitude of 2,000 to 2,500 feet. It seems an accepted axiom that the higher Hevea is planted, the slower it will grow and the less the yield. Castillou ceases to be profitable in Ceylon at altitudes above 1,500 feet. It has recently been urged, regarding Ceylon, that it might pay to extend plantations of these rubbers into tracts that have to be systematically irrigated. Speaking of South India, Mr. Proudlock, Curator of the Government Gardens on the Nilgiri hills, made an interesting discovery, viz. that Castillou trees three or four years old, in the Barlitar plantation (2,400 feet), yielded a somewhat

Commercial Rubbers.—The rubbers of commerce are (a) the biscuit and bottle rubbers of South America, such as the Para (the most important) which comes from Brazil, Venezuela, and recently from Ceylon and the Straits. (b) Castilloa, such as the Central American rubbers, of which there are certain grades:—Nicaragua, West Indian, Honduras, Mexican, Guatemalan, Panamanian, and Peruvian. These appear in Blocks, Sheets or Scraps. (c) The true Ceara is a dry rubber, very elastic, and free from stickiness; it coagulates in tears forming scrap. (d) Pernambuco and Mangabeira are coagulated with salt and are accordingly "wet" rubbers. (e) Numerous trade forms of African rubber, such as Gambia, Sierra Leone, Lagos, Gold Coast, Congo (ball), Calabar, Cameroon, Batanga, Liberian, etc. (f) Mozambique (ball), Sausage (liver), Madagascar (good and fine, also black). (g) Asiatic, such as Assam, Rangoon, mostly scrap rubbers formed into cakes, slabs or loaves. (h) Javan, Bornean, New Guinea, etc., rubbers (see Guutta-percha, p. 626).

The following, in alphabetical sequence of their scientific names, may be given as a brief statement of the india-rubber yielding plants of the world in which India is presently interested:—

Castilloa elastica, Ceru.; Hemsley, l.c. 156; Urticaceae. Central American, Panamanian and Nicaragua Rubber. Torquemada was the first to mention the rubber of Mexico. He gave it the name of uá. Long years after, Cross successfully introduced the plant to the Old World. In 1876 he conveyed live plants to Kew Gardens, and from that supply the plants that first reached Ceylon and finally India were distributed by Sir William Hiselton-Dyer. Willis and Wright (Handbook Veg. Econ. Prod. Ceylon, 1901, 41-5) give many useful particulars regarding the experience gained in that country. Mr. W. S. Todd subsequently was successful in having conveyed from Mexico and San Salvador seeds which he germinated in Burma and ultimately sent supplies to Samoa, a fact of some interest, since the seeds of this species are believed to lose their vitality very rapidly. But there are two species of Castilloa that yield rubber, and comparative studies have not as yet established which is the more preferable for special cultivation. The Indian and Ceylon plant is chiefly C. elastica, the Mexican species, and C. tunu, that of British Honduras and Costa Rica. This is the tunu rubber or el hule macho (the mule-rubber), but is not the mule-rubber of Brazil.

Manson (Ind. For., 1901, xxvii., 75-96) furnishes much useful information regarding the India-rubber plants of India. Of this species he remarks that it is cultivated in Mergui under wrong conditions, namely on swampy ground. He recommends that it should be tried in Tenasserim on hillsides with a western aspect. The plant has been fairly successfully grown on the hills of South India,
as, for example, near Calicut and Malabar, as also on the Nilgiri hills (Bardlar). Speaking of experience gained in Bangalore, Cameron (Rept. Govt. Bot. Gard., 1902-3, app. ii. and iii.) says this plant is intermediate between Para and Ceara, requiring neither the tropical humidity of the former nor the open and comparatively dry conditions of the latter. It is, in fact, a tree for the coffee zone. He accordingly recommends it for the moist regions of the hills and Ceara for the plateau of Mysore. [Cf. Morris, Cantor Lect. l.c. 761-5; Cire. Roy. Bot. Gard. Ceylon, 1898, ser. i., 96-104; 1905, 125-9; Cook, Journ. Agric.-Hort. Sci. Ind., 1904, 30-43; Bull. Imp. Inst., 1903, 160-7; 1904, 32-8; Trop. Agrist., 1905, xxv., 160-5, 199-200; Board of Trade Journ., 1906, 134-5; Tschiri, l.c. 1008-9; Wright, Rubber Cult. in Brit. Empire, 1907, 20-1; Herbert Wright; Cocoa, 1907, 78-9; Rubber Exper. in Bomb., in Agri. Journ. Ind., 1907, ii, pt. i, 81; Kew Bull., 1907, 103.]

Chromemora macrophylla, G. Don: Apocynaceæ. A large climbing shrub met with in North and East Bengal and the moist tropical forests of India generally from Kumaon to Travancore. Recommended as worthy of trial as a new source of rubber, but from experience gained at Buitenzorg the subject does not seem encouraging. [Cf. Kew Bull., 1896, 186; Manson, l.c. 4; Bull. Imp. Inst., 1904, 160.]

Cryptostegia grandiflora, Br. : Asclepiadaceæ. An extensive climber, fairly common on the western and southern tracts of India, and is stated to have been repeatedly cultivated with a view to the utilisation of both its milky sap and beautiful flowers. So long ago as 1893 the rubber prepared from it was reported from England as "hardly equal to Ceara rubber from Brazil, although its general qualities are very encouraging." [Cf. R.E.P., Comm. Circ., 1898, No. 2; Ind. For., 1898, xxiv., 429; Dunstan, Offic. Repts., 1903-4; Wright, l.c. 28.]

Edysanthera mirantha, O. Dec.: Gamble, Man. Ind. Timb., 488; Apocynaceæ. A large climbing shrub common in the Darjeeling Himalaya at 3,000 to 5,000 feet, also in Assam, Sylhet, the Khasia hills and Burma. In Burma it is known as nueko.

Recently a sample of the milk of this plant was furnished by the Conservator of Forests, Tenasserim, Burma, to the Reporter on Economic Products to the Government of India, with a view to obtain particulars as to the value of the caoutchouc and suggestions for a method of coagulation to be adopted with the milk. It was ultimately examined by Dunstan, who gave the analysis as caoutchouc 84-1 per cent., resin 11-5 per cent., and insoluble matter 4-4 per cent., with ash 1-3 per cent. The rubber was pronounced of a good quality. Further analysis will be necessary, the report continues, before the above results can be accepted as representative, but if furnished in quality corresponding with the sample analysed, it would be readily salable.

Ficus elastica, Roxb.; Fl. Br. Ind., v., 508-9; King, Ann. Bot. Gard. Calc., 1888, i., pt. i., 43, v. 54; Gamble, Man. Ind. Timb., 641-3; Brandis, Ind. Trees, 603; Manson, l.c. (reprinted as Comm. Circ., 1901, No. 4, 6); Hooper, Rept. Labor. Ind. Mus. (Indust. Sec.), 1903-4, 26; Reinhorz, Agri. Legd., 1904, No. 4; Bald, Cult. of Ficus elastica, 1906; Coventry in the Forest Bull. The India-rubber Fig, Indian Caoutchouc Tree, the bor, attah bor, kajiri ranket, lesu, yok bawadi, nyauung kyot paung, etc. The Karet rubber of West Java—a name which Manson points out may have been derived from the Burmese kajet (kyet).

A gigantic tree having its leaves and shoots perfectly glabrous, and which usually sends down from its branches numerous aerial roots. It frequently germinates naturally from droppings of birds, and is consequently often at first epiphytic. When under these circumstances it chances to become attached to another tree it grows slowly for the first six to ten years, and when its roots have reached the ground it usually kills the foster plant. It then grows more rapidly and becomes an immense and very lofty tree (from 100 to 200 feet in height). It is met with on
the outer Himalaya from Nepal eastward to Assam, the Khasia hills and Burma, being especially plentiful in the Hukong valley. It usually occurs in altitudes from 1,000 up to 3,000 or sometimes as much as 5,000 feet. It is now largely cultivated both as a shade or ornamental tree and as a source of rubber. For the latter purpose plantations were established in Java as early as 1872, and in Assam in 1874.

**INDIA-RUBBER PLANTATIONS.**—From the Assam Forest Department Reports of 1897–8 it may be learned that 88 acres were planted with this fig in Kulsi during 1873–7, and that in 1898 there were 2,411 trees on that plot having an average height of 87 feet 8 inches and mean girth of central bolo of 6½ feet; further that in 1878, 13 acres were planted, and the trees were in 1898, 81 feet in height and 9 feet in girth; that 25½ acres were planted in 1883, and the trees on this extension were, when reported on, 67 feet in height and 5 feet in girth; and lastly that in 1884 there was a still further addition made of 33½ more acres, the trees of which were found in 1898 to be 55 feet high and 44 feet in girth. In the report for 1904–5 (Prog. Rept. For. Admin. Assam, 9) it is stated that “56½ acres were exploited, 4,100 trees tapped and 2,550 lb. of rubber obtained. The yield of rubber varied from 62½ lb. per acre in the plantation of 1878 to 30½ lb. per acre in Block II. of the plantation of 1883.” “The cost of tapping was Rs. 672 or annas 4, pics 3 per lb.; and of the rubber obtained, 1,488 lb. were sold for Rs. 4,020–6, or Rs. 2–11–3 per lb.; 3 lb. were kept as a sample and 1,059 lb. sent to London for sale.”

In the Charduar plantation there were in 1898, 1,700 acres under this fig. Experimental tapings were made in 1896–7 and 1897–8. These gave for 21 trees 46 and 48 lb. of rubber respectively, i.e. 2½ lbs. per tree. The rubber produced was in England valued at 2s. 3d. to 2s. 9d. per lb. In the report for 1904–5 it is said that “in the Charduar and Bamoni Hill plantations, Darrang Division, 36½ acres were worked, 7,103 trees tapped, and 9,817½ lb. of rubber obtained. The yield of rubber varied from nearly 17½ lb. per acre in compartment 1 to 17½ lb. per acre in compartment 11 of Charduar. In Bamoni Hill plantation only 5½ lb. per acre were yielded, but this is accounted for by tapping being confined to small suppressed trees.” Home (Ind. For., 1899, xxv., 70) estimates the annual yearly outturn from these Government plantations at 8,000 lb. of rubber, which at 2s. 8d. would give a gross return of Rs. 16,000 or a net return of Rs. 10,400, or say 9 per cent. on the capital cost of the plantations. But does this estimate include the cost of management, rent and interest? Plantations on a much smaller scale have been attempted in Madras and Mysore.

**PROPAGATION.**—According to Claud Bald, “the prime requirements for raising this rubber are two: high, or well-drained land, and a hot steamy climate.” Fruit is produced from March to October, but according to Bald, the best seed is obtained in the hottest months, May, June and July. When collected the fruits or figs are dried in the sun and mixed with powdered charcoal to preserve them. They are about the size of peas, and at the time of sowing are broken up, and the seed thus sown mixed with portions of the disintegrated fruit. Light, sandy loam is most suitable for seed-beds and the best time for sowing would appear to be during the rains, viz. from June to September; but in some of the Government experiments the sowings are made in January and others in October. Bald recommends sowing in seed pans or boxes covered with glass. The seed is lightly scattered over the surface of the ground, and germinates about three months later. But the drainage of the beds must be perfect, and the ground allowed to become neither very wet nor very dry, and at the same time the plants
must be shaded from the sun for some time. When 2 to 3 inches high, the seedlings should be transplanted to a properly dug nursery-bed, well raised and drained. They should then be planted in lines about one foot apart. When 1 to 2 feet high, they may be put out in their permanent positions, but it is preferable to retain them in the nursery till they are 10 to 12 feet high, so as to prevent them being eaten by animals. In artificial planting it is found that rubber grows best on mounds. In the Kulei plantation of Assam, lines are cut through the forest 20 feet wide and 50 feet apart from centre to centre. On these lines 15-foot stakes are put up 25 feet apart. Round each stake a mound is thrown up, 4 feet high, on which the rubber seedlings are planted. In the Charduar plantation the lines are 100 feet apart and the trees planted 50 feet apart, but the cleared lines of 20 feet were found insufficient and so were widened to 40 feet, thus effectually checking drip and affording the light necessary for full growth. The trees may also be propagated from cuttings, which must be from young flexible shoots obtained by pollarding several branches of an old tree and allowing them to send out shoots. The best time to take cuttings is May and June. Both in Sikkim and Assam the epiphytic tendency of the plant has been simulated by tying seedlings or cuttings growing in baskets on to trees and allowing them to become attached to and to kill the trees in the way already mentioned. Gamble gives a full account of the methods of propagation pursued in various plantations which the reader should consult, as also the pamphlets by Bald and Coventry.

**INDIAN CACOUTCHOUC.**—Most of the India-rubber procured from India has been collected from wild trees in the natural forests. It is collected by the hill tribes in tracts beyond the British frontier, and sold to the people of the plains in the form of balls that have to be carefully examined for stones or mud placed in the centre. The Government plantations have recently begun, however, to contribute a superior rubber, the proportion of which is likely to be yearly increased. The latex is collected during the dry months. Eight oblique cuts are made on the main stem, sloping downwards and at a little distance from each other. The best tool for making these incisions is said to be a carpenter’s gouge worked with a small mallet. These incisions should not be deep, as the milk is secreted just below the outer bark, and the lowest should be about 4 feet from the ground. Below the incisions pots or kalesis are tied round the tree one underneath the other, which are left attached for the day. The trees should be tapped only once in three years. If tapped yearly they are liable to die. A few spoonfuls of a watery solution of alum are usually put in each vessel of milk, after it has been purified of extraneous matter. The milk coagulates and the rubber is exposed to air on sticks and allowed to drain for a week. In a month it is ready for the market. The yield from each tree in the Assam plantations at the present day is approximately 8 oz. per annum, and the average age of the trees is about 26 years; but according to some writers, the trees may be tapped at 14 years.

E. S. Carr’s remarks (Ind. For., June 1905, xxxi., 335–7) regarding method of tapping pursued in Assam and the coagulation of the rubber should prove instructive to those interested in the subject, and an article by Mann (The Tapping of Assam Rubber, in Agri. Journ. Ind., 1907, ii., pt. iii., 277–9) should also be consulted.

**Recent Publications.**—Mann (l.c. 393) reviews in a forcible manner the opinions and conclusions arrived at by Bald, Coventry and Eardley-Wilmot (in the most recent publications mentioned above on the subject of Indian *Ficus elastica*). He writes, "The factors which will determine the practical success of Assam rubber may perhaps be set out as follows:

1. "The initial or capital cost of forming a rubber plantation and bringing it into bearing."
2. "The age at which the trees will commence to yield."
3. "The yield which may be expected per tree and per acre."
4. "The cost of working abearing plantation, collecting the rubber, and placing it on the market."
5. "The value per pound of the rubber produced."
6. "The permanency of the plantation."

Mann endeavours to obtain from the publications in his hands an answer to each and every one of these issues, or to show where and in what way available particulars are wanting. His object is, from first to last, to ascertain if experience and knowledge obtained in North-East India justify extended cultivation by private enterprise, and the form which it should assume. As he confesses, his

Assam

Disappointing. Conclusions are disappointing. He continues, "The prospects are so doubtful, and even if successful so poor as compared with the culture of Para or Castillia rubber in Ceylon, the Malay States, or even South India, that one is inclined to consider any large extension of the culture of Ficus elastica in North-East India as out of the question. And I must say that this impression has been very strongly confirmed by almost all that I have seen in these districts, if the Assam rubber is to be cultivated as a separate industry. On the present evidence the length of time which it is necessary to wait for returns, the smallness of the returns when they are obtained, the doubt as to the market fifteen or twenty years hence, would seem to make investment in Assam rubber culture, as a separate venture, a very doubtful speculation in North-East India at any rate. I do not see how, at the rate of outturn obtained now at Tezpur, more than Rs. 15 to Rs. 18 per acre profit could be obtained per annum; and even if this were multiplied by four it would hardly be attractive enough to induce an investor to wait over twenty years for the result. In fact, the only possibility of Ficus elastica culture would seem to be as a by-product to tea culture, on land now waste and unsuitable for tea. In this case, the growth of Assam rubber may afford a means of turning land to profitable account which would otherwise only remain useless to its owners. It may be that future discoveries with regard to improved methods of tapping, new methods of growth, means of tapping the plants annually without injury, or of growing a larger number of healthy heavily-yielding plants on the same area, may alter the opinion above expressed. But as it stands, and with the data before us in the two pamphlets under review, I feel that no other conclusion is possible than that Assam rubber culture can only continue as a dependent of another larger and more profitable industry, and then can only occupy the inferior land."

Chemistry.—A representative sample of 1903-4 rubber from the Charduar rubber plantation was submitted to analysis in the Scientific and Technical Department of the Imperial Institute, and gave the following results:—The rubber was of a reddish-brown colour, but showed here and there small white patches. It was highly elastic and tenacious, dry, clean and free from stickiness. It was completely soluble in chloroform, carbon disulphide and benzene, and partially in ether. The analysis was as follows:—caoutchouc 76-67 per cent., resin 19-2, albuminoid matter 1-5, dirt and insoluble matter 1-7, moisture 0-0, ash in dirt 0-5. A high percentage of resin appears characteristic of rubber from the Charduar plantation. No precise data are available to show how the composition of rubber varies with the age of the tree or locality from which produced. A specimen of Assam rubber examined by Hooper gave the following:—resin 12-65, caoutchouc 85-95, water 1-0 and mineral matter 0-40, while a sample of Andaman rubber (from this tree) gave resin 4-87, caoutchouc 67-06, water 27-57 and mineral matter 0-50 per cent. There is thus a wide diversity in composition which it seems essential should be explained.

Trade.—The imports into India across its land frontier, more especially into Assam, are considerable. During the year 1901-2 these came to 1,470 cwt., valued at Rs. 1,55,656; in 1902-3, 738 cwt., valued at Rs. 65,913; in 1903-4, 1,601 cwt., valued at Rs. 1,66,629; in 1904-5, 3,083 cwt., valued at Rs. 3,50,773; in 1905-6, 2,587 cwt., valued at Rs. 3,56,413; and in 1906-7, 2,330 cwt., valued at Rs. 3,03,194. Of these amounts a very large proportion usually comes from the Naga and Mishmi hills. Recently the Government plantations have begun to contribute to the annual supply something like 3,000 lb. The exports from India to foreign countries in caoutchouc (mostly the produce of F. elastica) were in 1903-4, 1,792 cwt., valued at Rs. 3,47,196, and in 1906-7, 4,489 cwt., valued at Rs. 11,18,487; but the traffic fluctuates very greatly, especially the supply drawn from Burma, for in 1899-1900 the foreign exports were returned at 8,169 cwt., valued at Rs. 15,80,729. These foreign exports are usually drawn from Bengal (including Assam) and Burma, and are consigned chiefly to the United Kingdom and the United States. In a report furnished by the Director of the Imperial Institute (Feb. 3, 1905) the value of the Chardaur rubber is stated to have been 3s. 8d. per lb. on the London market. For
insulating purposes, however, the value of this rubber is stated to be only 3e. 3d. per lb., owing to the large quantity of resin which it usually contains.

Funtumia elaea, Stspf.; APOCYNACEAE. This is the ire or Lagos Rubber plant, which previously was known as Kieckia elastica. It is being experimentally grown on the Nilgiri hills, etc. [Cf. Morris, Cant. Lect., i.e. 776-7; Kew Bull., 1890, 241-7; 1890, 29-35; Agri. Bull. Straits and Fed. Mal. States, 1903, ix., 136-8; Bull. Imp. Inst., 1903, 160-3; Johnson and Thisleton-Dyer, Rubber Repts. of Gold Coast and Sierra Leone Col. Repts. Misc., 1904, No. 28; Wright, Cocoa, 1907, 70; Kew Bull., 1907, 187.]

Hancornia speciosa, Gomes; APOCYNACEAE. This yields the Mangabeira or Pernambuco Rubber of commerce—exported from Brazil (Kew Mus. Guide, 1907, 148). Hevea brasiliensis, Mull. Arg.; Hemaloy, Kew Bull., 1907, 154; EUPHORBIACEAE. The PARA RUBBER TREE. This and one or two allied species occur in the forests of Central and Northern Brazil, and in the forests of Para from the mouths of the Amazons, south and west. They all yield rubber. The region indicated has a climate remarkable for its uniformity of temperature, 87° F. midday and 74° F. at night, the mean being 81° F. and the highest record 95° F. The rainfall occurs principally in January to June, the maximum being in April, when it reaches 16 inches. It is a very healthy region with a remarkably fertile and continuously moist soil. The trees grow rapidly and attain some 30 feet in three years.

By far the best rubber is obtained from the species of this genus. In fact, where Hevea can be profitably grown it will never pay to cultivate any other rubber plant. The rubber afforded is stronger and possesses a much higher breaking strain than that of any other plant, its tenacity being due, so it is thought, to the method of coagulation. Once established, Hevea requires but little care, and regular weeding will preserve it, if, however, liable to several pests, more especially caterpillars, and has to be protected from browsing animals (deer, etc.) when in the young plantation stage. The trees may be tapped when about six years old, but they come into full bearing in eight to ten years. Success is closely connected with the methods of tapping and curing pursued; absolute cleanliness is indispensable. The bark of the trees about to be tapped should be first cleaned and the V-shaped cuts on the perpendicular central channel made with decision and thoroughly cleansed before the milk begins to flow. Dust, sand and other impurities greatly lower the value of the rubber, since they can with difficulty be subsequently removed. Deliberate adulteration once proved will permanently ruin a plantation or source of supply.

**INDIAN ACCLIMATISATION.**—This rubber tree has been successfully cultivated in Mergui and Tavoy. It has also been fully acclimatised in the southwest districts of Ceylon, where so much attention has been paid to the preparation of the rubber that it has actually fetched a higher price than that from the indigenous home of the plant; but while, owing to its purity, it is valuable for waterproofing, it seems to lack the tensile strength of the rubber of Para.

**Burma.**—In the Dictionary will be found a brief review (an abstract from Thisleton-Dyer's report) of the historic facts regarding the introduction of this plant into Asia from seed germinated at Kew. The first endeavours in Burma date from a small consignment of plants sent to Mergui by Sir
INDIA-RUBBER
HEVEA BRASILIENSIS
Para

George King in 1877. A second consignment was obtained in 1879 from Ceylon. In 1884 some of the better established plants began to seed, and an acclimatized stock of seedlings was thereby obtained. Manson, in his Short History of the Mergui Rubber Plantations of that Province, has carried the record to the present date. In May 1900 sanction was accorded for the gradual formation of a plantation of 10,000 acres of Hevea trees. This was to be located, 5,000 acres in the Sandawut reserve and a similar area on King Island. The work was started in 1901 by 46 acres being planted out, 12 by 12 feet. By 1904, 1,518 acres had been planted, and the operations have since been vigorously prosecuted, annual extensions taking place according to the scheme sanctioned. The purpose in view has been to demonstrate the commercial possibilities of this rubber cultivation in Mergui. Already 929 lb. of rubber have been produced, and the nurseries, according to the last report, contained 600,000 plants, with an addition of 100,000 self-sown seedlings in the original experimental garden. In the Annual Report Forest Administration of the Tenasserim Circle (1904-5, 31-3), W. E. L. Tottenham, Conservator of Forests, gives the results of a further year's efforts. The total amount of dry rubber collected during 1904-5 was 1,450 lb., of which 54 lb. 6 oz. were collected during the rains. The cost of collection came to about 11 annas per lb. The area was intended to have been extended by 1,250 acres, but owing to an outbreak of cholera only 818-65 acres were added to the plantation. Of that expansion 736·8 acres were in Mergui, and 81·78 acres on King Island. The conservator of the Northern Circle (l.c. 52) says that Hevea has not proved a success in the Katha Division. Hooper (Rept. Labor. Ind. Mus. (Indust. Soc.), 1906-7, 6) mentions the result of examination of a sample taken from a white-ant's nest (Termes gaustrai). The rubber was of great excellence, the resin having apparently been extracted by the ants.

Thus, then, it may fairly be said that Brandis, who early foretold success for Tenasserim Para-rubber cultivation, has been abundantly confirmed, and the future seems destined to see large developments. Already private enterprise is engaged in the business, and doubtless when the possibilities in this direction of forest-profits have been fully established, Government may withdraw. (Ind. For., Sept. 1905, xxxi., 330-4). For methods of propagation and systems of tapping the trees, consult the technical publications, more especially the circulars issued by the Director of the Royal Botanic Gardens, Ceylon.

South India.—A good deal of interest has recently been taken in the possibility of Travancore and even of Mysore becoming hopeful localities for Para-rubber cultivation. It is said by planters and others that thousands of acres of heavy forest-land, below 1,000 feet in altitude, exist that possess rich soils and a liberal rainfall, eminently suited for rubber, but which at present are valueless because not put to any purpose. Some progress has, however, been made, but taking South India as a whole, Para rubber has not so far been the unqualified success anticipated. A writer in the Madras Mail (March and April, 1905) seems to take a hopeful view, however, and the subject has by no means been abandoned.

Bengal and Assam.—Considerable efforts have been made to organise Para-rubber plantations in Northern and Eastern India, but with little encouragement so far. The trees have been planted out in Kurseong, Jalpaiguri and Buxa, but the reports of the Forest Department cannot be said to be favourable. [Of. Mann, Cult. of Para Rubber in North-East Ind., in Agri. Journ. Ind., 1907, ii., pt. iii., 273-6.]

AFRICAN RUBBERS

Ceara

Landolphia Kirkll, Dyur. and L. owariensis—East and West African Rubbers; Apocynaceae. A genus of climbing plants, most with in Africa, of which several species afford rubber to Sir John Kirk is due the honour of having first directed attention to these plants. Sir George King, in the Annual Report of the Royal Botanic Gardens of Calcutta for 1880-1, reported the germination of seeds obtained through Kirk. The plants unfortunately, however, subsequently died. At the Nilambur plantation of the Nilgiri hills, further efforts were made to acclimatise this plant. About the same time thirty-four plants were reported as doing well in South Malabar. In the report of the Government Botanic Gardens, Bangalore (1897-8), it is spoken of as growing like a weed. In the Report for 1902-3, Cameron wrote: "Much nonsense has been written lately concerning a new rubber plant Landolphia Thollonii found on the French Congo."... "The latex of this little shrub, which is only half a foot high, is chiefly stored in the root." The African genus Landolphia promises to be a large one, and doubtless all the species may be found to contain latex. We have one or two species on trial which grow well. But as climbing plants they are not, in my opinion, very suitable for rubber-farming in this country."

Manson (l.c. 9) observes that the Landolphias have recently been tried in Mergui and in the Rangoon Division of Pegu Circle. [Of! Ind. For., 1882, vii., 235-7; 1897, xxiii., 61-3; 1900, xxvii., 129-34, 313-30; Annals of Botany, 1900, xiv., 203; Christy, New Comm. Pl., No. 1, 8-10, and plate; No. 6, 54-6; Kew. Bull., 1899, 35-9; Morris, Cant. Lect., l.c. 1898, 773-6, 779-82; Sadebock, Die Kulturgew. der Deut. Kolon., etc., 1899, 270-7 and plates; Rev. des Cult. Colon., Feb., 1900, 121; 1901, 218; 1902, 75; Bull. Econ. Madag., 1902, 143, 145-6, 251; Imp. Inst. Tech. Repts., 1903, 152-4; Junelle, Les Pl. à Caout. et à Gutta, 1903, 824-32; Agri. Journ. Natal, 1903, 25; Bull. Imp. Inst., 1903, 68-71, 163-9; 1904, 94-5; suppl., 95-6, 165-6, 153-6; 1905, 221-2; Bull. Imp. Inst., 1905, iii., 14-8; De Indische Mercuur, June 1904; Tschirch, l.c. ii., 1013-4.]

Manihot Glazioli, Mull. Arg.; Euphorbiaceae. Ceara Rubber, Scrap Rubber, Manicoba Rubber. Cross described the tracts in Brazil where he found this plant as possessing a dry arid climate for a considerable part of the year. The rainy season, he says, begins in November and continues till May or June, but there are occasionally almost rainless years; the temperature ranges from 92° to 90° F., and the altitude is about 200 feet above the level of the sea. Ceara is a coast town in lat. 4° S.

In the early experiments at acclimatisation of rubber trees in India (1876 and subsequently) it was ascertained that while Ceylon had better been treated as the centre of the experiments with Hevea and Castillia rubber, Calcutta might with advantage be made the depot for Ceara. Sir George King accordingly wrote, in the Annual Report of the Royal Botanic Gardens of Calcutta for 1880-1, that the Ceara rubber trees continue to grow vigorously, and a few are now beginning to yield seed. In the same year, in the Annual Report of the Botanic Gardens, Nilgiri Hills (Barlar), it is said that the Ceara trees are now completely established. Lawson, for example, wrote that Ceara trees "grow very rapidly, and to all appearance thrive well; but I have been wholly unable to extract rubber from them in anything like a paying quantity, and every one else hitherto has also failed." In the report for 1890-1 the record is made of eight trees having been tapped for rubber. In the Report of the Conservator of Forests, Madras (1891-2) it is stated that in North Malabar this rubber tree grows like a weed and some of the trees are 46 feet high. In 1895-6, 309 trees were tapped in South Malabar and gave an average of 1 oz. per tree of dry rubber, valued in England at 1s. 6d. to 1s. 9d. per pound. Mr. R. L. Proudlock, in 1898, tapped a tree eighteen years old in the Barlar garden, and by a single tapping obtained 2½ oz. of dry rubber. Ceara, he adds, is quite at home and will grow almost anywhere on the Nilgiris up to 4,000 feet in al-
INDIA-RUBBER
PARAMERIA GLANDULIFERA RUBBER-YIELDING PLANTS

Milk Creeper

titude. Mention is often made of a fairly extensive cultivation in South Coimbatore. Cameron (Superintendent of the Botanic Gardens, Bangalore) has repeatedly reported on this rubber. Experiments were commenced with it as early as 1879. After enumerating the production and distribution of seed from the gardens during the past twenty-five years, he adds that Ceona rubber is now tolerably common in many parts of the Province. In a report published in the Mysore Gazette, April 1904, he further gives useful particulars of planting, propagation and tapping of the trees. In the Forest Dept. Reports of Burma mention is made of successful acclimatisation in Mergui. In 1890 a vanguard for the rubber was obtained.

It is hardly necessary to deal with other reports since enough has already been furnished to give a fairly satisfactory conception of the efforts made and results attained in India. But it may be useful to conclude with the following as indicating the opinions held by experienced scientific authorities in Europe:—The Kew Bulletin summarises the results obtained somewhat as follows:—1. The plant is readily propagated by seed or cuttings. Seeds are abundantly produced in almost every part of the world where the plant has been introduced. Sowing in the permanent position is universally adopted in Brazil. 2. The Ceona rubber plant is very hardy, a fast grower, free from insect and fungoid attacks, requires little or no attention when once established, and thrives in poor, dry, rocky soils unsuited to almost any other crop. Large plantations only are likely to prove remunerative. 3. It produces a good class of rubber, second only to the best Para. The yield is small per tree, but a return is obtained earlier than from any other species. Under skilful treatment two crops may be obtained yearly, and last in a productive state for fifteen to twenty years. 4. In spite, therefore, of the apparent want of success in Ceylon and other countries, the increasing importance of rubber suggests a reconsideration of the merits of this interesting plant.

Both in India and Burma mention is made of the fact that the large starch-yielding tuberous roots of this tree have been discovered by the wild pigs, and considerable damage done by them in seeking out and devouring the tubers. This fact suggests the possibility of these starch-yielding tubers becoming an additional source of revenue, should an extended cultivation take place. [Cf. Cross, Ind. For., 1879, iv., 27–45; Notes Ceona Rubber in Ind. For., 1882, viii., 55–61; 1897, xxiii., 456–8; 1898, xxiv., 460–1; Proc. Madras Board Rev., Oct. 1894, No. 712; Nov. 1897, No. 914; 1899, No. 518; Aug. 1904, No. 906; Morris, Cont. Lect., l. e. 1898, 765–70; Kew Bull., 1898, 1–15; R.E.P., Comum. Circ., 1897, No. 8; 1901, No. 4; Rept. Bot. Gard. Nilgiri Hills, 1902, 8; 1902–3, 9–12; 1903–4, 5–8; Imp. Inst. Tech. Repts., 1903, 147–8; Tschirch, l.c. 1906, ii., 1006–7; Rubber Exper. in Bombay, in Agri. Journ. Ind., 1907, ii., pt. i., 80–1; Wright, Rubber Cult. in Brit. Empire, 1907, 21–2; Wright, Cocoa, 1907, 79.]

PARAMERIA GLANDULIFERA, Benth.; APOCYNACEAE. The Talaiing Milk Creeper. A large climbing evergreen shrub of the borders of tidal forests on the sea coasts of Tenasserim and the Andaman Islands. It is known as talaiingzok in Burma. It would appear to have sometimes been confused with Willoughbheia edulis. The milk is obtained by a somewhat destructive method of cutting the stem into short lengths, and allowing the milk to drain into vessels containing water at a temperature of 164° to 122° F. On agitation the milk coagulates. The plant may be propagated by cuttings with great facility. The yield seems to be remarkably high and the rubber of fair quality, perhaps equal to that of Ficus elastica. Hooper (Rept. Labor. Ind. Mus. (Indiat. Sec.), 1906–7, 6) gives the analyses of three samples examined. They contained 92.39, 95.1 and 96.7 per cent. of caoutchouc. A sample from the Andaman Islands he found (l.c. 1905–6, 25) contained 92.5 per cent. of caoutchouc, 6.4 per cent. resin and 1.0 per cent. ash. In spite, therefore, of all that has been said to the contrary, this source of rubber seems worthy of more careful consideration than has as yet been meted out to it, and it seems probable that some cheaper and more economical process of collection might be devised than that practised at present, while the cost may be brought within permissible commercial limits.

In this connection it may be added that the percentage of ash is an important factor in determining the values of rubbers. The following average returns may, therefore, be of interest:—Para rubber, 1 to 2.5 per cent. ash; Ceona rubber, 2 to 3 per cent. ash; Assam rubber, 4 to 6 per cent. ash; Parameria rubber,
INDIA-RUBBER

Burmese Rubber

6.4 per cent. ash in dry rubbers. [Cf. Wright, Rubber Cult. in Brit. Empire, 1907, 28.]

Rynchodendron Wallichii, Benth.; APOCYNACEAE. A lofty evergreen climber of the Sikkim Himalayas at altitudes of 2,500 feet, also met with in Assam, Sylhet and Burma. Attention has recently been directed to this plant as a new source of rubber by Mr. Hearsey of the Forest Service, Burma. A sample of the rubber was furnished in August 1903 by the Reporter on Economic Products to Prof. W. R. Dunstan for examination. The report, dated May 1904, shows the rubber to contain 89-0 per cent. caoutchouc, 6.7 per cent. resin, 4.3 per cent. dirt, and 0.51 per cent. ash (included in the dirt). It is thus of good quality, but about 1-5 per cent. of the caoutchouc was insoluble in the usual solvents. The brokers' report on the sample was to the effect that, at present prices, it would realise 3s. 6d. per lb. Dunstan then adds that if supplied of similar quality to the sample examined, it would always sell readily.

Sapindus biglandulosum, Muell.; EUPHORBIACEAE. Yields Colombian Scrap or Virgen Rubber from British Guiana and also Bolivian Rubber. [Cf. Kew Mus. Guide, 1907, 189.]

Urceola elastica, Roxb., and U. esculenta, Benth. (Chavannesia esculenta, A. D.C.); APOCYNACEAE. These climbing shrubs yield caoutchouc of good quality. The former occurs in Malaca and Penang and the latter in Burma; common all over Pegu and met with in Martaban and Tavoy. It is known as kyatpanng (Burma) and tophet (Karen).

This rubber appears to have been first described by Dr. Thomson in 1858, subsequently by Mason (1860), and in 1874 Strettell wrote a special illustrated pamphlet on the subject (The Caoutchouc obtained from Chavannesia esculenta). Sir W. T. Thiselton-Dyer, as in the case of all the other rubber-yielding plants, contributed largely towards the development of our knowledge of the present species. The Forest Administration Reports of Burma contain, almost yearly, numerous brief references to it and its rubber. In 1897-8, for example, mention is made of 2,342 plants being in the Palon and Kimpadi Plantations of Rangoon, which were started in 1874. Perkin (Circ. R.B.G. Ceylon, 1899, 102) observes that "the latex from the thin stems, such as bear the leaves or have recently shed them, forms a sticky substance when moulded between the finger and thumb. The plant resembles Contusion in this respect. The latex both from the pith and the cortex of the young stem is sticky, hence it looks as if the true caoutchouc is only formed in the secondary bast." Manson (i.e., reprinted as Comm. Circ., 1901, No. 4, 12) gives many useful particulars.

In the Proceedings of the Government of India (Forest), June 1904, No. 5, 18–9) a collection of official communications has been brought together, extending from May 1903 to January 1904, that gives the most recent experience and results in tapping the Urceola plants in the special plantations of this species. They can hardly be regarded as conclusive, though highly instructive. On March 21–5, 1900, 469 creepers were tapped, each with thirteen cuts, and the yield came to 11,454 lb., which was not weighed till April 20, 1903. This cost Rs. 29, or Rs. 2.53 per pound. The second tapping took place on December 14–24, 1900, of 508 creepers, each receiving 30 cuts and yielding 9,853 lb. of rubber, which was weighed on January 23, 1901, and estimated to have cost Rs. 51-4 or Rs. 5-20 per lb. The writer of the report accordingly comes to the "conclusion that the cost of collection of the rubber of Chavannesia is prohibitive, and that no profitable industry can ever be developed in connection with it." But as if to show that the experiments conducted and the conclusions drawn from these cannot be regarded as final, he adds that in the Mon Valley in Minbu district the monopoly of collecting rubber from Chavannesia is sold annually by auction for Rs. 250. It is thus clear that better results can be and are obtained than in the special plantation of this plant near Rangoon. Subsequent experiments seem to show that the tappings mentioned are not necessarily conclusive of what can be done at the plantation.

Dunstan, reporting in May 1903 on samples of this rubber, furnished to him for that purpose, observes that this plant yields "a rubber which promises to be of some commercial importance, especially if it can be forwarded in large consignments of the quality represented by the sample now reported on." The analysis showed caoutchouc 81-8 per cent., resin 7.5 per cent., dirt 10.7 per cent., and ash (included in dirt) 1-8 per cent., calculated on dry rubber. The commercial experts consulted compared the rubber with

INDIGOFERA
Indigo.

TRADE IN RUBBER

Tonquin, and gave its valuation at 2s. to 2s. 1d. per lb. Dunstan then adds, "This material is evidently deserving of further attention." The Agricultural 
Ledger (1903, No. 10) gives the results of additional chemical investigations 
conducted by Leather, as also a note by Mr. S. Carr, Deputy Conservator of 
Forests, in which the methods of collection of the latex are described.

Subsequent samples were forwarded to the Imperial Institute for examination.
It was reported that three contained so high a percentage of resin as to throw 
doubts on their being correctly determined botanically. The others showed a 
high percentage of good caoutchouc, and were valued in 1904 at from 3s. 
to 4s. a lb. [Cf. Morris, Cont. Lect., I.e., 1898, 792; Bull. Imp. Inst., Sept. 
29, 1904, 156-9; Wright, Rubber Cult. in Brit. Empire, 1907, 28-9.]

Willoughbeia edulis, Roxb.: Apocynaceae. The thi-chank-nueh, possibly also 
tulasingho of Burma, and the lati-am of Bengal, is an immense climber met 
with in the forests of Assam, Sylhet, Cachar, Chittagong, Pegu, and Martaban.
It yields a large edible fruit, which from a general resemblance to the mango 
has suggested the name "climbing mango." At one time high expectations 
were entertained regarding Willoughbeia rubber. It has since transpired that 
much of the rubber in question will have to be transferred to other genera, 
and that so far as the Indian species is concerned (W. edulis), it must be no 
longer considered as a caoutchouc-yielding plant. Recent investigations 
conducted by Dunstan have shown, for example, that the very high percentage 
of resin (in some samples 84-6 per cent, with only 10-8 per cent. caoutchouc) 
necessarily exclude it from consideration as a rubber. [Cf. Wright, I.e. 29.]

Trade in India-rubber and Caoutchouc Manufactures.—Such 
p particulars (p. 654) as can be procured regarding the production of 
caoutchouc in India have been given. It remains to exhibit very 
briefly the traffic in rubber manufactures. There are no local (Indian) 
manufactures, so that the supplies of goods are drawn exclusively 
from foreign countries. In 1870-7 the imports of raw caoutchouc and 
of india-rubber manufactures collectively were valued at Rs. 1,27,759; 
twenty-five years later (1900-1) they came to Rs. 6,05,594; in 1903-4 to 
Rs. 7,03,003; in 1905-6 to Rs. 7,78,905; and in 1906-7, Rs. 10,04,782.

It may be here added that the imports into Great Britain during 1902 
came to 419,375 cwt., valued at £5,180,262, and in 1906, 607,077 cwt., 
valued at £9,966,629. Of the last-mentioned amount Brazil alone con-
tributed 253,918 cwt., and the total from British Possessions was 90,453 
cwt. The exports equal about one-half the supply (330,252 cwt. in 1906)— 
the country which takes the largest amount being the United States 
(126,969 cwt. in 1906).

INDIGOFORM. (INDIGO), the Dye-yielding Species.—A 
genus of Leguminose which comprises some 300 species, distributed 
throughout the tropical and warm temperate regions of the globe—India 
having about 40. Western India may be described as the headquarters 
of the species, so far as India is concerned, 25 (thus fully half) being peculiar 
to that Presidency. On the other hand, on the eastern side of India (the 
provinces of Bengal, Assam and Burma) there is a marked decrease in 
the number of species but a visible increase in the prevalence of those that 
are met with. It is possible, moreover, that many more species afford 
indigo than those specially cultivated for the dye. Accordingly, culti-
vation of richer dye-yielding stocks has been urged as one of the most 
of Ind., Madras, 1899, 4.] This is of supreme moment in the crisis that 
has overtaken the industry. Prain and Baker (Notes on Indigofera, 
Journ. Bot., 1902, xl, 60-7, 136-44) have furnished a very instructive 
paper, which has already proved of the greatest practical value. So also
INDIGO-YIELDING FORMS

Leake (The Localization of the Indigo-producing Substance in Indigo-yielding Plants, Journ. Roy. Hort. Soc., 1905, xxix., pts. 1–3; Annals of Botany, 1905, xix., 297–310) has devoted much attention to the selection of stock, and the practical results to be attained thereby. Space cannot be afforded here to do more than review very briefly the salient features of these and other special studies. This will be attempted while following the usual rule of treatment in alphabetical sequence of scientific names:—

**Indigofera Anll, Linn. : Mant. Pl., 1771, 272; Prain and Baker, loc. cit.**

This South American species is grown in Burma, Eastern Indo-China and Southern China, but never, so far as we now understand, in India proper. Moreover, there would appear to be three very distinct varieties (or perhaps more correctly distinct species, closely allied to *I. Anll*) that have to be dealt with in this position. These are:—

(i) *I. truxillensis*, H.B.K. : *I. tinctoria*, var. *oligophylla*, DC. An American species and very common plant. It was apparently the form chiefly cultivated in the West Indies during Sloane’s time, and is the wild indigo of West Indian writers.

(ii) *I. Anll*, Linn., var. *polyphylla*, DC.: *I. suffruticosa*, Miller, Gard. Dict., 1768 (ed. viii.), No. 2. This is the cultivated plant—*Xiniquilis pitychaeos* of Hernandez (Nova. Pl. Hist., 1651, 108), the wild form of which is the *I. guatilmala*, Linn. (non Linn.).

(iii) *I. argentea*, Burm. (non Linn.), Fl. Ind., 1768, 171, an Indian plant that is quite distinct from *I. ortetica*, though often confused with it.

**I. arrecta**, Hochst. (Schmp., Herb. Abyss. Pl., n. 1925, non Benth), in Richard, Fl. Abyss., i., 184. The Natal-Java Indigo. This is the well-known *degendeg* (dek indig) of Abyssinia and the chief indigo-producing species of Africa outside the area occupied by *I. ortetica*. It is now largely cultivated in Java under the name of Natal Indigo. Of Java, Prain (in a letter to Barber) says, "In the beginning only *I. tinctoria*, probably introduced from India or Ceylon, was grown. This, however, towards the end of the seventeenth century, was replaced by *I. sonnativa*, which held its ground for a considerable time. In the West Indies and Brazil the cultivation began with *I. sonnativa*, which was imported as 'Brazil Indigo.' Later on, however, this plant was displaced by a native species *I. truxillensis*, which soon was supplanted by another and better native species, *I. Anll*. This species, *I. Anll*, has spread all over the world and is even now the most widely grown of the dye-yielding indigos; when it reached Java it displaced *I. sonnativa*. In the West Indies *I. Anll* finally met with a formidable rival in *I. guatilmala* and in course of time the latter, being recognised as a superior kind, was adopted in Java to the exclusion of *I. Anll*. More recently in Java *I. guatilmala* has been found to be less valuable than *I. arrecta*, and the latter has practically taken its place. The historical aspect of the subject therefore indicates the advisability of at least giving a trial to *I. arrecta* in Madras. It does not, of course, follow that the plant will thrive, but if it does, it seems clear that it is the best species to grow. In Bihar, where it has been carefully tried, there are objections to the plant which it is hoped may be overcome; but in Lower Bengal it thrives much better than *I. sonnativa*.

The advantages of the plant are twofold. 'It gives much more leaf, being a much larger plant, and it is stated by those interested in the preparation of indigo to give a higher percentage of dye from the same weight of leaf.'

The objections to which Prain refers have been ably dealt with by Leake. The plant was found to germinate so imperfectly as to render its cultivation unprofitable. It has the same defect as slower, namely, the seed-coat is very hard (Bloxam and Leake, Acc. Research Work in Indigo, 1905, 33). What is, therefore, required is a machine that will scratch the seed-coat and thus facilitate germination. Recently in the public press of India it has become customary to read of "Natal-Java seed scarificated and ready for sowing" (see p. 671). Bergtheil (Ann. Rept. Imp. Dept. Agr., app., 1904–5) observes that the Java plant contains more potential colouring matter than do any of the plants ordinarily cultivated in Bihar. Mr. H. A. Bailey, who visited Java in 1899 on behalf of the Indigo Improvements Syndicate, was apparently the first person who pointedly directed the attention of Indian planters to this stock. F. M. Coventry furnishes returns which would seem to justify the opinion that the Java plant shows an increase of 35 per cent. in the amount of green plant cut per acre and of 45 per cent. increase in vat produce, over the ordinary plant of the United Provinces.
**INDIGO-YIELDING FORMS**

**TINCTORIA**

**Egyptian.**

*I. articulata*, Gouan, Illust., 1773, 49. This is *I. argentea*, Linn., Mant. Pl., ii., 273, non Burm.; *I. spicata*, Forsk.; *I. corulea*, Roxb. Is the plant which yields most of the indigo of Arabia and Egypt, still sometimes met with in Western India and as far to the east as Bhatkal in May, and the Kistna highlands.

Was formerly the species most largely grown in the Bombay Presidency, but nowdays is only occasionally seen under cultivation in Rajputana and Sind. Prain says that in the time of Roxburgh and Hamilton (1803-14) the Egyptian indigo still survived as an Indian species (probably escaped from cultivation) in Bihar, but now it seems to have quite disappeared from that region.

*I. longeracemosae*, Baillon, Herb.; *Baillon, in Bull. Soc. Linn. Paris*, 1883, pt. i., 399; Prain and Baker, l.c. 144. In the letter by Prain, to which reference has already been made, there occurs the following passage—"In Madagascar and Zanzibar there is a species—*I. longeracemosae*, very distinct both from *I. tinctoria* and from *I. sumatrana*—that is valued by the people of these islands beyond all the other species they grow, and they grow the following:—(a) and chiefly *I. Audt.* (b) less often *I. tinctoria*, (c) occasionally *I. sumatrana*, and (d), in the highlands of Madagascar, *I. arveta.*" Prain then adds that as long ago as 1875-6, Col. Beddome found this very species both in Travancore and Tinnevelly, and subsequently it was found by Lawson in Travancore.

**Forms of Tinctoria.**

**I. tinctoria**, Linn., Sp. Pl., 1753, 751. Prain and Baker establish two chief varieties of this species with several very distinct cultivated states under those, some of which may have to be viewed as worthy of distinct specific positions. The following abstract may be regarded as setting forth the salient points:

(a) var. *macaropara*, DC. The special forms of this are:

**The Wild Plant**, apparently unknown to Linnaeus or De Candolle. It was found in Nubia by Kotschya in 1841, and specimens which agree with it in every essential have also been found in Central India. Regarded as a distinct species its name would be *I. bergii*, var. [Cf. Duthie, Pl. Upper Gang. Plain, i., 256.]

**The Southern or Malabar and Mysore and Western India.** This is the plant dealt with by Linnaeus in his Flora Zeylanica, and by Burrmann in his Flora Indica. This particular form would thus appear to have been early cultivated in Southern India, though recently it has very possibly been completely displaced by *I. sumatrana*. "It was and still is the *I. tinctoria* of the cultivators in the Dutch Indies, where, however, the species is not now much in favour. Specimens of this form, evidently feral after escape, have been communicated from many places both within and beyond the limits of the area where it now is, or formerly has been in cultivation." Prain and Baker, from whom the above has been derived, add that they have seen specimens of this particular plant from the Philippine Islands; from North Queensland; from the Laccadives, where it is described as forming thickets that cover a great portion of Kadamum Island; finally from Merwaras in Rajputana, where it is not, and probably never has been cultivated. It is a wild plant in Merwara, growing by the sides of ravines, and bears the vernacular name of *sarjon*.

**The Northern Cultivated Form.**—This is largely in use in Northern India from Bihar and Tirhut westward by north to the Panjáb, where its area meets that in which some form of *I. argentea* is grown, and southward to the Circars, where *I. tinctoria* occurs. This, throughout the area specified, is the plant known as *nil*, and is the form to which the name *I. tinctoria* is applied. "It is not exactly what Linnaeus meant by *I. tinctoria*: it is, however, precisely what Gaertner intended by *I. sumatrana*, and what Lanarck has figured as *I. indica*, but not the same thing as the old *I. indica* of Miller, which is *I. hirsuta*, L." (Prain and Baker, l.c. 65). In the Annual Report of the Royal Botanic Gardens, Calcutta, for 1901-2, it is observed that while the Dutch held possession of Malabar this indigo plant, "apparently derived from the Eastern Malay, came into use there." Prain (in the letter above mentioned) observes: "About the time, 1868, there was cultivated in Malabar a different plant, *I. sumatrana*, which seems to have been introduced a little later (whether from Malabar or directly from the Malaya cannot be traced) into Bengal, where prior to its introduction, indigo was not grown at all. This plant, which generally passes under the name of *I. tinctoria*, although it is not precisely the same as the true plant of that name, has now spread gradually westward and has driven out almost completely the cultivation of the Egyptian indigo." "But what has happened in Northern India has also happened more recently in Madras." "This is all the more remarkable, because in all the older collections, such as those of..."
THE DYE OF MODERN COMMERCE

INDIGOHERA

Other Indigoes

Wight, Stocks, Law and G. Thomson, *I. samatrina* was reported only from Malabar and the Konkan, the Coromandel plant being always *I. tinctoria proper*.

It is also the form of *I. tinctoria* that was introduced from the East into the West Indies, and is the *I. tinctoria* of Linn. If, therefore, it be deemed necessary to give this plant a separate name and to remove it from being one of the cultivated states of *I. tinctoria*, then it will have to be called *I. samatrina*, Gaertn. In addition to India it also occurs in tropical Africa and Formosa. It may be distinguished from the southern form by its leaflets, which are larger and ovate-oblong or oblong, instead of obovate or suborbicular. The pods are also (in *I. samatrina*) shorter, thicker, and blunter at the apex, and are usually more numerous and straighter than in the Madras form (Duthie, *i.e.* 256). Leake has devoted much careful study to the cultivated races of this plant in relation to temperature and rainfall. His conclusions regarding the seed supply will richly repay careful personal.

(3) var. brachycarpa, DC. This form has been sent from Guatamala, Central America, Peru, etc. It is apparently not met with in India.

**Other Indigo-yielding Plants.—** The Indigo of modern commerce is thus obtained from one or other of the species of *Indigofera* discussed above. But species of *Indigofera* are distributed throughout the tropical regions of the globe (both in the Old and New Worlds) with Africa as their headquarters. And in addition to the Indigoferas several widely different plants yield the self-same substance chemically. Hence, for many ages, the dye prepared from these has borne a synonymous name in most tongues, and to such an extent has this been the case that it is impossible to say for certain whether the nilà of the classic authors of India denoted the self-same plant which yields the dye of that name in modern commerce. The word nilà simply means dark-blue colour, and is practically synonymous with kàla (black). It is often used adjectively, such as in nilgao (the blue bull), nilopala (the blue stone or lapis-lazuli), nilamani (the sapphire) and nilusaru (the blue water-lily). Nîla carries, too, the abstract "darkness," and only becomes a substantive to denote the dye-yielding species of *Indigofera* at a comparatively recent date. Anîl comes from the Arabic al-nil through the Portuguese, and should have been written annil.

The woad of the early European authors (*Isatis tinctoria*) is grown to-day in Centra Asia and has been so for ages past—a region where no species of *Indigofera* has been known to be grown (or possibly could be grown) as a source of indigo. The Sanskrit people may accordingly have first made acquaintance with the indigo of *Indigofera* in India itself, and it is just possible that their nilà may have originally been the woad, which with the ancient Britons was used, like the indigo of the American Indians, to dye the skin and hair. Complex and difficult though the art of dyeing with Indigo may be, it is thus more intimately associated with the early human race than any other known dye or pigment. And in India it would appear that a far larger number of plants are regularly resorted to as sources of this dye than is the case with almost any other country in the world. In addition to *Isatis* met with on the north-west alpine tracts and Afghanistan, mention has, for example, to be made of the *rum* of Assam and Central China (*Stroblanthus flaceliolus*, p. 1051); of the *ryom* (*Marsdenia tinctoria*, p. 774), found in the north-eastern tracts, a plant closely allied to the original indigo plant of Java; of an indigo plant (*Teprosia purpurea*) well known in Bombay and Rajputana and closely allied to one of the indigoes of the Niger and Egypt; of the *Nerium* or *pala* indigoes (*Wrightia tinctoria*,

663
INDIGOFERA
Indigo

THE INDIGO PLANT

p. 1131) of South India, the plant which would appear to have been used prior to the introduction of the species of Indigofera; of the indigoes of Burma (such as Gymnema tingens); of Cochin-China (Spilanthes tinctoria); and of North China and Siberia (Polygonum tinctorum). These and many others are plants which have been, or are being, used as sources of this particular dye in some parts of India. Is it to be wondered at, therefore, that the early records of the industry leave on the mind of the student the suspicion that the plant used in early times was, in all probability, not always the indigo of to-day? Not only has the modern industry shifted from Agra and Gujarat to Bengal, but the plant grown has been changed completely. [Cf. Joret, Les Pl. dans L’Antiq., etc., 1904, ii., 271, 345–6.]

It may serve a useful purpose to quote in some detail and in sequence of date a few of the more instructive accounts of the indigo industry of India. It is thus contemplated to concentrate attention on the Indian issues, and if possible to exemplify from past historic records and scientific experience the directions of possible economy and improvement.

Historic Records of Indigo.—Periplus of the Erythraean Sea (80 A.D.) (McCrinlde, transl., 17, 109) speaks of indigo as exported from Barbarikon, a Skythian town on the Indus and the port for the metropolis—Minnagar. Marco Polo (1298) gives a grotesque, though accurate, account of the Native indigo industry as seen by him at Calium (Quilon). “It is made of a certain herb which is gathered, and (after the roots have been removed) is put into great vessels upon which they pour water and then leave it till the whole of the plant is decomposed. They then put this liquid in the sun, which is tremendously hot there, so that it boils and coagulates, and becomes such as we see it. (They then divide it into pieces of four ounces each, and in that form it is exported to our parts.)” Athanasius Nikitin (1408) (a Russian traveller) speaks of Kanbat (Cambay) where the indigo grows. Vasco da Gama (1498), Varthéma (1503), and Barbosa (1510), who all visited Gujarat and the west coast of Bombay, make no mention of indigo, from which circumstance it may be inferred to have been a comparatively unimportant industry. Garcia de Orta (1563), however, gives a short account of its cultivation and manufacture in Western India. He calls it the Anil of the Arabs and Turks, the gâli and nil of Gujarât, and remarks that it is tested for purity by burning, when there should be no sand in the residue, and by being so light that it may float on water. Acesta (Tract. de las Drogas, 1624, 206) describes the Anil of Gujarât. Barrett (1584) mentions indigo from Zindi and Cambaya. It is not apparently referred to in Baber’s Memoirs. It is first mentioned in the Ain-i-Akbari, 1590 (Gladin, transl., ii., 28, 41), as produced at Agra. Linschoten (Voy. E. Ind., 1598, i., 61–2; ii., 91) speaks of “Anil” or indigo as it “groweth only in Cambay and is there prepared and made ready, and from thence carried throughout the whole world.” So again, he says, “Anil or indigo by the Gouserates is called gait, by others nil: it is a costly colour and much carried and traffiqued into Portingall: it groweth in India in the kingdom of Cambay; the heare be very rosenary, and is sowed like other hearees, and when the season serveth is pulled up and dried and then made wette and beaten, and so certaine dayes after dried againe and then prepared.” (In passing it may be here pointed out that the passage just quoted implies that at the time Linschoten wrote, the dry-leaf process was pursued in Gujarat.)

François Eyraud (Voy. E. Ind. (ed. Hakl. Soc.), 1601–10, ii., 339, etc.) repeats the account given by Linschoten. In The First Letter Book of the East India Company, 1605–6, Birdwood and Foster quote a letter of instructions to purchase Indico of Lahor (Lahore), Serchis (Sarkhej, 5 miles S.W. of Ahmedabad) and Belondri (Ballabbi, a village 20 miles from Bhavanagar). Finch (Travels in India, in Purchas’ Pilgrimes, 1607, i., 429) affords the first definite conception of the indigo industry of India, or rather of Agra and Fatehpur Sikri, and from him perhaps dates the conception of the plant being an Indigofera:—“The herb Nell, groweth in form not much unlike Gises or Chich-pease, having a small leafe like that of Senna, but shorter and broader, and set on a very short
foot-stalk; the branches hard and of a woodie substance like unto broome. It usually groweth not above a yard high, and with a stalke at the biggest (which is at the third yeares) not much exceeding a mans thumbe. The seed is included in a small round c十足 about an inch long, resembling Foenigiaum, save that it is more blunt at both ends, as if it had been cut off with a knife. It carreth a small flower like that of Heart-s-ease, the seed is ripe in November, and then gathered. The herb once sowne dureth three years, being cut every year in August and September after the raines. That of one yeere is tender and thereof is made Note, which is a weigthy reddish Nil sinking in water, not come to its perfection: that of the second yeere is rich, and called Cyree, very light and of a perfect violet colour, swimming on the water: in the third yeere the herb is declining and this Nil is called Catteld, being a weightie blackish Nil, the worst of the three. This herb being cut the month aforesaid, is cast into a long cistern, where it is pressed down with many stones, and then filled with water till it be covered, which so remaineth for certain dayes, till the substance of the herb be gone into the water. Then they let the water forth into another round cistern in the midst of which is another small cistern or center: this water being thus drawn forth, they labour with great staves, like batter or white starch, and then let it settle, scumming off the clear water on the toppe: then labouring it afresh, and let it settle again, drawing forth the clear water, doing this oft, till nothing but a thick substance remaine: which they take forth and spread on cloth to dry in the sunne: and being a little hardened, they take it in their hands and making small balls, lay them on the sand to dry (for any other thing would drink up the colour), this is the cause of the sandy foot. So if rain fall, it loseth its colour and glosse and is called Alitde. Some deceitfully will take of the herbe of all three crops, and steepem them altogether, hard to be discerned, very knavishly. Four things are required in Nil: a pure graine, a violet colour, his glosse in the Sunne, and that it be dry and light, so that swimming in the water, or burning in the fire, it cast forth a pure light violet vapour, leaving a few ashes."

Sir Thomas Roe (Embassy to the Court of the Great Mogul, 1616, i. 270) speaks of the rise in price of Agra indigo and of the sales being effected under charle (or fardles). The chart of Biana indigo has been computed as being equal to six maunds. Of the same year, Foster (E. I. C. Letters, iv., 241) records the following curious passage:—— "Indigo is made thus. In the prime June they sow it, which the rains bring up about the prime September: this they cut and it is called Neuty, and it is a good sort. Next year it sprouts again in the prime August, which they cut and is the best indigo, called Jerry. Two months after it sprouts again, which they cut and thereof they make the worst sort; and afterwards they let it grow to seed and again indigo. Being cut, they steep it 24 hours in a cistern of water; then they draw it into another cistern, where men beat it six hours forcibly with their hands till it become blue, mixing therewith a little oil; then, having stood another day, they draw off the water and there resteth settled at the bottom pure indigo (which some to falsify mix with dirt and sand); which they dry by degrees, first in cloths till the water be sunk from it and it be curdled; afterwards they dry it in round goblets."

Here we have a distinct reference to the indigo plant having been grown for two or three years without being uprooted or re-sown. H. A. Bailey of Etawah describes the system that exists to-day in Shahabad, which in some respects resembles the old method (E. I. C., Lc. iv., 356). This system has long since been abandoned in the indigo districts proper, the change possibly denoting new stock, when that system was unnecessary. The "Neuty" crop is doubtless the "Note" of Finch, both words being probably derived from naudhá (the young plant); and "Jerry" being the "Cyeree" of Finch, both words doubtless being derived from jari, which would mean "sprouting from the root" (jar). With the change in the system of cultivation both these terms have become disused and forgotten. Mandelslo (Travels, in Olearius, Hist. Muscovy, etc., 1638, 83-4) gives a most curious account of the cultivation and manufacture of indigo in Gujarant (Ahmedabad) which (as with Linsehotten's account above) involves acceptance of belief that the method of manufacture pursued was that known as the Dry-leat. His description of the flower being like that of a thistle was either a mistake (the plant being confused by Mandelslo with Carthamus) or the plant used at that time was not Indigofera. The former seems the more plausible explanation. The passage may be usefully quoted in full:—— "The best indigo in the world comes from about Amadabath from a village called Chirchees, whence it derives the name. The herb of which they make it is like that of yellow Parsnip, but shorter, and more
THE INDIGO PLANT

History

bitter, sprouting forth into branches like a Reed, and growing in kind years, six or seven feet high: the flower is like that of a thistle, and the seed like that of Fenugreek. It is sown in June and cut in November and December. It is sown but once in three years, and the first year the leaves are cut off within a foot of the ground. The stalks are taken away, and the leaves are set adrying in the Sun, and that done, they are set soaking, for four or five days, in a stone-trough, containing about six or seven foot water, which is ever and anon stirred, till such time as the water hath suckt out the colour and virtue of the herb. That done, they let out the water into another trough, where they suffer it to settle for one night. The next day, all the water is taken away, and what is left in the bottom of the trough is strained through a coarse coath, and is set adrying in the Sun. And this is the best Indico; but the country people adulterate it, by mixing therewith a certain earth of the same colour. And whereas the goodness of this Drug is discovered by its lightness, they have the cunning to put a little Oyle into it, to make it swim upon the water."

Adulteration.

Mixed with Oil.

Rotation.

"The second year, the stalk which was left the year before shoots forth other leaves, but they are not so good as those of the first. Yet is this preferred before Gyngey, that is, wild Indico. It is also the second year that they suffer some part of it to grow up to seed. That of the third year is not good, and consequently not sought after by foreign Merchants, but is employed by the inhabitants of the country in the dyeing of their Coaths. The best Indico is almost of a violet colour, and hath somewhat of its smell, when burned. The Indosthans call it Anil; and after it hath been in the ground three years, they suffer the Land to lye fallow for one year ere they sow it again."

Terry's Account.

Terry says of Gujarat in 1622, "The indico we bring thence is good, and a rich commodity. It is there made of leaves not bigger than those of our Gooseberry bushes, and the shrubs that bear those leaves are about their bigness. These leaves they slip off from the small branches of those bushes, which grow with round and full heads without prickles. The leaves thus stripped off, are laid in great heaps together certain days till they have been in a hot sweat; then are they removed and put into very great and deep Vessels fill'd with sufficient quantity of water to steep them in, where they leave their blue tincture with their substance; this done, the water is drained out into other exceedingly broad, but very shallow Vessels or Vats, made of Plaister (like to that we call Plaister of Paris) which will keep in all the Liquor till the hot Sun in short time extracts the moisture from it; and then what remains in the bottome, is a Cream about one quarter of an inch thick, which suddenly becomes hard and dry, and that is our Indico, the best sort whereof comes from Biana, near unto Agra, and a coarser sort is made at Cirkeeese, not far from Amadzamas; about which two places, are a very great number of those shrubs planted, which bear those leaves."  

Bengal Indigo.

Tavernier (Travels, ed. Hakl. Soc., 1665, 367). Francis Bernier (Travels, 1656, 283) makes mention of the Anil or Indico of Delhi. Tavernier (Travels, 1670 (ed. Ball), ii., 8-12) of all the early European authors gives perhaps the most detailed and accurate account. He discusses the production in Gujarat (Sharkoj, Ahmedabad, Surat, and Broach), of Golconda, of Agra (Biana, Indoua and Corsa) and of Bengal. He then adds that the Dutch Company convey the Bengal dye to Masulipatam, and that the Bengal and Indigo dyes can be purchased at 30 per cent. less than that of Agra. The reference to a Bengal indigo at the date in question is certainly remarkable. His account is too lengthy for quotation, but it will richly repay perusal. He describes the steeping vats, the use of oil, and the drying in the sun discussed by other travellers. Hove (Tours in Gujarut, etc., 1787, 107-8) gives full particulars of several plantations visited by him. The plant he says, was usually sown in the beginning of the rains and suffered to grow for two seasons. The first crop is cut at the end of the rains and the last about March or April. So late as 1820 we read of indigo planting having existed in Gujarat, and a number of unused pits near old villages and among the buried cities of the Satpuda mountains bear silent testimony to the former important industry of indigo manufacture. 

Hove's Account.

Rheede's Account.

Rheede's (Hort. Mal., 1678, i., 101-2, t. 54; ix., t. 30) gives a brief account of the indigo industry of the Malabar coast and furnishes two pictures, which thus leave no doubt that the plant or plants to which he alludes were species of Indigofera. Sir W. Hedges, during his agency of Bengal, wrote a diary, 1681, which deals with his tours of inspection through Hugli, Malda, Dacca, Balasore, etc., and discusses the

666
articles of merchandise there met with. It is noteworthy that he makes no mention of Indigo. We are thus led to believe the cultivation and manufacture of indigo, which in time became one of the most important of Bengal industries, could not have existed in the districts visited by Hedges. But we learn it was established in Tichu originally by the Dutch, for we read of their having owned the Singia concern in 1791. It would seem, however, from Tavernier's allusion to Bengal indigo that a Native industry had existed a little earlier. But shortly after Hedges' report a change was effected, owing to a Resolution of the Directors of the East India Company. European planters were brought from the West Indies to Bengal to undertake the cultivation of indigo. In 1790 indigo factories were accordingly established in Jessore. Hardly, however, had the industry been thus organised when it was ruined, for we read in Sir W. W. Hunter's Imperial Gazetteer of India that "English indigo planters have forsaken the districts of Hughli, the 24-Parganas, Dacca Fairdpur, Rampur, and Pabna, now dotted with the sites of ruined old factories." The industry had thus been established and ruined in Bengal.

It is perhaps hardly necessary to continue this series of quotations much further by supplying a correspondingly detailed selection regarding Africa, Egypt, the West Indies, America, etc. The following may, however, be of value to persons interested in the history of indigo manufacture:

Rochefort (Hist. Nat. et Mor. des Isles Antilles, 1658, 98) speaks of the indigo being produced from a plant which rises only about a foot and a half from the ground. It has small leaves of a light green colour which turn yellow. The flower is reddish. It grows from seed. Its odour is very disagreeable, unlike the Madagascan species, which has small flowers of a whitish-purple colour and a pleasant smell. Pomet (Hist. Gen. des Drogs., 1694, 151-6; also Engl. ed. with annot. from Lemert and Tournefort, 1712, 89-91) gives a brief description and an engraving of the plant, and these leave no doubt that it was an Indigofera. It is sown, he tells us, by the Americans in holes a foot distant; and in two months' time the plant will be ready to cut, and if left for three months will yield both flower and seed. "Indigo is a meal or flour," he observes, "made by means of water and oil-olive out of the leaves of the astil or indigo plant; for there is a difference betwixt that made of the leaves and of the small branches. The choice of the former sort is that which bears the surname of Sorquisse (Sarkhej)." They cut this said herb with a sickle when the leaves begin to fall upon touching them; and after they have stripped them from the branches, they put them into sufficient quantity of water, which is in a vessel called the steeping Vat, then letting them infuse thirty-six hours; after which they turn the cock in order to let the water run off, which is tinged of a green colour, inclining toward blue, into a vessel of the nature of a churn, which is worked by the labour of several men, by means of a Rouller or Turner of Wood; the ends of which run pointed, and are hooped with iron; this they work "till the said water abounds with a lather, then they cast it into a little oil-olive; to wit, one Pound into such a Quantity of the Liquor as will yield seventy pounds of indigo, which is the quantity now sold in a barrel; and as soon as the said oil is thrown in, the Lather separates into two parts so that you may observe a Quantity curdled as milk is when ready to break; they then cease churning and let it stand to settle, which when it has done some time, they open the Pipe or Cock of the Churn, in order to let the water clear off, that the meal which is subsided may remain behind at the Bottom of the Vessel like clay or Loos A Wine. Having decanted it thus, they put it into straining Bags of Linnen to separate what water was left, then they convey it to the Chests or Boxes that are shallow to dry it, and being dried, it is what we call Indigo." Pomet furnishes (plate 35) an admirable picture of an indigo factory which shows the water tank, the steeping vat, boiling vat and evaporating vat. The mechanical contrivance for churning or beating the liquid is also shown, but the author makes no reference in the text to his plate, and it would appear accordingly to have been copied from some still earlier author. Père Labat (Voy. aux Isles de L'Amerique, 1724, i., 90-8, t. 90) gives a long and interesting account of the indigo industry which was translated into English by Philip Miller and given in his Gardener's Dictionary (1st ed., 1731) under the name astil; from the brief, apparently, that it was fully representative of the industry as a whole. But Labat deals very nearly exclusively with the indigo of Martinique, and his description, like that of Pomet, is more characteristic of the Antilles and the West Indies than of India proper. In two months' time, says Labat, the first crop of cuttings can be taken, and if the rain continues, subsequent

cuttings may be made every six weeks, and the plants continue to bear for two years.

Browne (Hist. Jam., 1789, 302-5) describes two forms—the wild indigo and the Guatimala indigo. He views the wild as only the survival of a still earlier cultivation, the buildings of which often “remain very perfect to this day.” Browne gives interesting particulars of the “best engine” seen by him for beating; this was in design much the same as some of the contrivances patented in India a century later. He is one of the first authors to mention the use of heat in drying the indigo. “The Magma or mud” is by some put into a cauldron and heated over a gentle fire, but not so far as to boil, and is then emptied into little “pezinbrick” bags to drain; by others it is not heated, but immediately put into the like bags to drain. Edwards (Hist. British West Ind., 1793, ii., 280-8) speaks of three species of indigo, viz. the wild, the Guatimala, and the French. Of these the “French surpasses the Guatimala in quantity but yields to it in fineness of grain and beauty of colour.” Lunan (Hort. Jam., 1814, i., 410-26) gives a most instructive account both of the plant grown and the method of manufacture pursued in Jamaica, but quotes very largely from both Browne and Edwards. The plants are regularly laid in the steeper with the stalks upwards, which, he says, hastens the fermentation. None of these West Indian writers, let it be specially noted, speak of the dry-leaf process—the whole plant is carried at once to the steeping vats. After being beaten by various contrivances a little clear lime-water is gradually let in to augment and precipitate the fascula. Too large a quantity of lime would render the indigo hard and of a greyish colour. The fascula is placed in bags and allowed to drain; these are then placed within a press and the remainder of the water squeezed out. The dye is next removed from the bags, placed on a table, cut into square cakes and dried in the shade—the sun being regarded as hurtful.

The East India Company published in 1836 a series of reports and letters regarding the indigo industry, the preface to which records (what may have been inferred from the above series of quotations) the migration from and return again to India of the industry. That work will be found of the greatest possible interest, and should be consulted for historic details. Mr. Minden Wilson has written in the Indian Planters’ Gazette a series of graphic historic sketches of the introduction of Indigo in Bihar. From these it would appear that Mr. Grand, the husband of the lady who subsequently married Prince Talleyrand, was one of the founders of the industry. Wilson gives the dates of several concerns—Contai was opened out about 1778 and Singia in 1791; but the last mentioned, as already stated, originally belonged to the Dutch East India Company. These are representative, the Tirhut industry having been mainly established between 1778 and 1800. The Court of Directors of the East India Company sustained severe losses, however, by their endeavours to re-establish the Indian industry, though they obtained the satisfaction of knowing that they had been successful. In time the truth of the complaint to all, and hoped that their servants might find in indigo “a mode of remitting their fortunes to Europe which would be legal, advantageous and adequate.” For twenty-two years (from 1780 to 1802) the Company directly supported the indigo industry and placed India once more in the foremost rank among the indigo-producing countries of the world. They, however, continued to make purchases of indigo for the purpose of remittances, and to ensure the supply they even made advances to the special factories that had contracted to sell their produce to the Company. About this time also it was recognised that the industry could not be regarded as successfully established in Bengal so long as it was exclusively held by the Anglo-Indian community. It was accordingly arranged that purchases should be made from, and advances given to, factories owned by Natives, provided the security was “sufficiently respectable and the quality fit for the European market.”

But the story of the indigo industry is more entertaining historically and more pathetically instructive than that of almost any other Indian agricultural or industrial substance. The main facts may, therefore, be here briefly recapitulated:—There is abundant evidence in support of the belief that when Europeans first began to purchase and export the dye from India, it was procured from the Western presidency and shipped for the most part from Surat. It was carried by the Portuguese to Lisbon and sold by them to the dyers of Holland. It was the desire to secure a more certain supply of dye-stuff that led to the formation, in 1631, of the Dutch East India Company, and shortly after to the overthrow of the Portuguese supremacy in the East. The success of the Dutch merchants

668
ENGLISH INDIGO-DYEING

INDIGOFERA

Stock Improvement

aroused the jealousy of Europe. The woad growers and merchants of Germany, France and England were threatened with ruin, and to protect them nearly every country passed edicts rendering the importation or use of indigo a criminal offence punishable by death.

In 1608 England learned the art of indigo-dyeing, and in the reign of Queen Elizabeth its use was permitted along with woad. Curiously enough this mixing of woad with indigo survives to the present day, and to meet this demand a small amount of the woad is grown here and there over Europe, and even in England. The opposition to indigo was, however, so strong that it was again, on the pretext of being poisonous, prohibited, and in 1660 Charles II. had to procure dyers from Belgium to once more teach the English the art of using the dye. As already shown, the effect of the persistent export of the dye from India, conducted by the East India Company, had the effect of stimulating the Spanish, French, Portuguese and English colonists to make strenuous efforts to produce the dye in many countries outside India. And so successful were they that for a time they ruined the ancient Indian traffic. But Macpherson (Hist. Europ. Comin. Ind., 1812, 200) speaks of the East India Company having voluntarily given up the importation of indigo into England "in order to avoid a competition with the British Colonists in the West Indies and the southern provinces of North America. About the year 1837 most of the planters in the West Indies, particularly in Jamaica, gave up the cultivation of indigo in consequence of the high duty imposed upon it"; "the planters of Carolina and Georgia were never able to bring their indigo to a quality equal to that of Guatemala or St. Domingo." But political difficulties occurred with America and France, and at the same time sugar and coffee had proved even more profitable in the West Indies than indigo. The impetus was thus given for a re-establishment of the Indian traffic, and, as one of the many surprises of the industry, the province of Bengal was selected for this revival. It had no sooner been organised, however, than troubles next arose in Bengal itself through misunderstandings between the planters, their cultivators, and the Government, which may be said to have culminated in Lord Macaulay's famous Memorandum of 1837. This led to another migration of the industry from Lower and Eastern Bengal to Tirhut and the United Provinces. Here the troubles of the industry did not end, for, just as indigo had ruined "the Waid Herrn," so the researches of the chemical laboratories of Germany threatened the very existence of any natural vegetable dye. They first killed the madder dye of Europe, then the safflower, the lac and the ai dyes of India, and are now advancing rapidly with synthetic indigo, intent on the complete annihilation of the natural dye. Opinions differ on many aspects of the present vicissitude; meantime the exports from India have seriously declined, and salvation admittedly lies in the path of cheaper production both in cultivation and manufacture. These issues are being vigorously faced and some progress has been accomplished, but the future of the industry can scarcely help being described as of great uncertainty. The issue is not the advantage of new regulations of land tenure, but one exclusively of natural versus synthetic indigo.

Improveinent of Stock.—Sir Edward Law (formerly Finance Minister of India), in a letter to The Pioneer in December 1905, refers to his views regarding the future of the indigo industry:—"It would appear to be assumed," he says, "that because unfortunately the production of indigo continues to fall off, my belief in the possibility of recovery of the industry is a mistaken one. In my last budget speech in March 1904, I enumerated the following improvements as necessary to effect a reduction in the cost price of indigo and thereby secure a profit to growers and manufacturers:—(1) that the plantations should be placed on a sound financial basis, and cease to remain in a position where requirements for cash in seasons of dear money could only be satisfied by transferring profits from the pockets of the planters to those of the money-lenders; (2) economy in management; (3) selection of seed and propagation of the qualities yielding the highest percentage of indigotin and best suited to local conditions of climate and soil; (4) rotation of crops to obtain good profits from the land when not under indigo, and thereby reduce the cost of cultivation of the plant; (5) chemical improvements in manufacture."
it can be stated that all the improvements I indicated as necessary have been carefully and persistently tried, and that still natural indigo cannot be made to pay, I shall with great regret have to admit that I have been wrong."

There would seem no doubt that each one of the conditions of improvement indicated by Sir Edward are of vital importance; and what is more to the point, hardly any of them have been successfully and completely investigated. A considerable advance would appear to have been attained recently by Bloxam, in his chemical studies of the dye. Leake commenced research into the races of the plant grown and the localisation of the dye within the plant tissue, but his studies were brought to a sudden termination, when on the threshold of possible practical results, through the severance of his connection with the Indigo Planters’ Association. It is understood that a start has also been made by the new research station under the direction of the Inspector-General of Agriculture, from which much may indeed be expected in the future. The planters themselves, in their anxiety for alternative crops to be grown on the land when not under indigo, are concerned with an issue of great practical value.

Leake has obligingly furnished for this work a review of his own results and those of other workers in the path of indigo-plant improvement, the passages from which will be indicated by quotation marks.

*Present Position of the Industry.*—“It may be affirmed that the methods employed for the production of the dye are very crude. The fluctuations in the daily outturn are very large, and all attempts to control the yield have so far proved unavailing, if not prejudicial. This is only one way of confessing our ignorance of the steps of the process. So long as the planting community enjoyed a practical monopoly this inability to control was of little moment. A fall in the quantity of dye produced implied a corresponding rise in price. With the introduction of the synthetic product a short yield no longer meant enhanced price, and this fact, associated with a series of bad seasons, has reduced the margin of profit to a vanishing point. If natural indigo is to compete successfully with its synthetic rival, there is no longer room for the losses which the fluctuations above noticed necessarily involve. A study of the manufacture of indigo reveals how little at present is known of the chemical and bacterial changes involved. Until these have been worked out, little can be hoped for from improvements in the methods pursued. One fact alone is evident, namely that only a fraction of the latent dye-forming power is developed.

“For the present, therefore, the planters must look elsewhere to find relief from the severe competition of the synthetic product. The two lines that suggest themselves and which are, to a small extent, receiving attention, are the introduction of supplementary crops and the increase in the yield of plant per acre (cultivation) as opposed to the increase in the yield of dye per unit of plant (manufacture). The first of these falls outside the province of this article. The second falls naturally under two heads (1) improvement of the present plant *I. sumatrana* by seed control, etc.; (2) introduction of other and richer stocks.

“(1) For the same reason that the *mahai* (indigo manufacture) cannot profitably be altered at the present time, it is also impossible to progress in any process of selection of stock, and, as long as it remains impossible
YIELD ESTIMATED TO STOCK

INDIGOFERA
Stock Improvement

to estimate the dye-yielding capacity of the plant, this must remain so. This, however, does not afford the sole possibility for improvement. The migration of the cultivation of Indigofera has already been noted. With this migration has arisen a complete separation of the seed-producing districts, and at the present time it is no exaggeration to say that a planter does not know from what district his seed comes. Investigation has shown that the seed-producing area can be separated into two main divisions, each characterised by a very distinct type of plant. The first of these areas includes the Western Panjáb and Indus valley, and the plant here is stunted, flowers early, and possesses a very marked and characteristic alternate arrangement of the branches and leaves. The second area includes the Eastern Panjáb and the United Provinces, in which the plant is tall, bushy, and flowers late. Comparing these:

<table>
<thead>
<tr>
<th>Yield of plant per acre</th>
<th>Western Area</th>
<th>Eastern Area</th>
</tr>
</thead>
<tbody>
<tr>
<td>Leaf percentage</td>
<td>90 maunds</td>
<td>140 maunds</td>
</tr>
<tr>
<td>Yield of leaf per acre</td>
<td>62.5 &quot;</td>
<td>54.4 &quot;</td>
</tr>
</tbody>
</table>

"Since the leaf is the main dye-yielding part of the plant, it is obvious that large benefits are likely to be derived from a limitation of the seed-producing area.

(2) "For some years attempts have been made to introduce other species of Indigofera; and that species which has yielded the most promising results is I. arrecta, Hochst. It must be borne in mind, however, that Java indigo does not fetch the price of good Bengal indigo, although the percentage of indigotin is very high in the former, and that this may mean a specific inferiority in the dye obtained from I. arrecta.

A difficulty in obtaining a good germination has alone checked the general cultivation of this plant. The defect has, however, been traced to the large percentage—between 90 and 96—of 'hard' seed. With the introduction of a seed-treating machine this difficulty has been removed and I. arrecta will probably be extensively cultivated" (Leake) (see p. 661).

The Localisation of the Indigo-producing Substances in Indigo-yielding Plants.—The following is a brief abstract of the contents of the paper on this subject: "Some attempts have been made to trace the function and place of the indigo-yielding substance in the plant metabolism. For instance, Molisch tentatively ascribes to it a position among the anabolic products, and attempts to establish a direct relation between its formation and the chloroplasts. His arguments are largely based upon the localisation of indigo when precipitated within the tissues. He traces a relationship between the chloroplasts and the grains of indigo thus precipitated. This relationship is difficult to uphold, as the present writer has endeavoured to show. The substance may be found in such tissues as pith, xylem-parenchyma, phloem, fibrous cortical tissue, epidermis and in embryonic tissue, even in the embryo sac. In chlorophyll-bearing tissues, it is difficult to trace any relationship between the chloroplasts and the precipitated grains of indigo. By this method of localisation it is impossible to bring conclusive evidence to prove the absence of a relation between the indigo-yielding substance and the chloroplasts. To establish such a relation other lines of investigation will have to be resorted to" (Leake).
INDIGOFERA

THE INDIGO PLANT

CULTIVATION.

Area and Production.—Perhaps one of the most surprising features of indigo cultivation is the variation of the period of occupation of the soil. In some localities the crop is obtained in three months from time of sowing, and from this as a minimum up to as much as eighteen months every possible period is manifested. Speaking generally it may be said that the system of taking several cuttings a year and allowing the plant to occupy the soil for two or even three years seems to have been discontinued—possibly as a consequence of the change that has taken place in the stock now chiefly grown. In the upper provinces, especially where irrigation prevails, indigo occupies the soil in annual rotation with wheat or rice, and is regarded as a catch crop that greatly improves the soil. So much is this the case that indigo has often been recommended as a green manure to be grown temporarily and ploughed into the soil. But in Lower Bengal, on the other hand, the spring-sown crop calls for attention at the very time of the principal rice sowings, and it is therefore an unpopular crop with many cultivators. But a far more serious difficulty has arisen in the production of artificial indigo. The seriousness of this aspect may be at once exemplified by the figures of area and yield. In 1892-3 the area in all India was 1,218,766 acres and the yield 179,056 cwt.; in 1894-5 the corresponding figures were 1,688,042 acres and 237,494 cwt.; in 1896-7, 1,608,901 acres and 168,673 cwt.; in 1898-9, 1,010,318 acres and 139,320 cwt.; in 1900-1, 990,375 acres and 148,029 cwt.; in 1902-3, 645,511 acres and 79,207 cwt.; in 1904-5 the area was 473,757 acres and the outturn 56,200 cwt. Thus in twelve years the area under the crop and the yield decreased to one-third their former magnitude. The most recent forecasts indicate that the area decreased still further in 1905-6, viz. to 583,600 acres with a yield of 46,500 cwt., but the estimated area for 1906-7, namely 452,800 acres, has shown a slight improvement in yield of dye—69,700 cwt.

Land Tenure.—“It is impossible, in the space at disposal, to do more than touch upon the system of land tenure. There are commonly three systems throughout the indigo district of Bihar at present under European control. In the first of these the planter is the absolute possessor of the land, known as zera land. In the second, as the result of the lease by the zamindars to the planters of certain villages, the factory claims some portion—usually two to three cottas per bigha—of the highlands for the cultivation of indigo. The portion assigned for indigo is usually changed every two or three years. In both these cases the cultivation is effected by labour hired by the factory. In the third, the raiyat, under no compulsion, puts a portion of his land into indigo and sells to the factory the plant—either on a valuation of the standing crop or measurement of the amount cut.
BENGAL PRODUCTION

"The area in which the cultivation of indigo reaches the highest development is Northern Bihar, the chief districts of which are Champaran, Muzaffarpur, Darbhanga and Saran. In these districts the concerns are entirely under European management. In other areas the specialisation in the methods of cultivation and manufacture is not carried to the same extent. It will be sufficient, therefore, to refer in detail to this area alone, and in the case of other areas to draw attention merely to the points of divergence" (Leake).

BENGAL.—Area and Production.—In 1904-5 the total area under the crop, according to the Agricultural Statistics, amounted to 223,100 acres, and the outturn to 24,300 cwt. Cultivation reaches its highest development in Northern Bihar, the chief districts of which are Champaran, which in 1904-5 had 84,000 acres; Muzaffarpur, 35,000 acres; Darbhanga, 32,900 acres; and Saran, 18,000 acres. The final forecast for Bengal in 1906 estimates the total area as 137,800 acres and the yield as 1,328,400 lb. (11,816 cwt.). By way of contrast it may be added that the area devoted to the crop in Bengal during 1894-5 was 629,100 acres, which yielded 104,485 cwt. of dye.

Bihar.—"As cultivation is at present practised, indigo forms a '16-anna' crop. Preparation of the land commences at the end of the rains early in October, as soon as the land is cleared of the previous crop. It is thoroughly ploughed and finally levelled by the application of the choki or hanghar—a log of wood with the lower surface flat or hollowed, drawn by two or four bullocks. Usually the land is again ploughed and levelled or 'compacted' after a few days—a process which may be repeated as many as four times. In the intervals between the ploughing, gangs of coolies with short sticks are sent over the land. These men collect the stumps of the previous crop, weeds and such like matter, thus clearing the land, and at the same time use their short sticks to break down any clods.

"The whole of this process is aimed at reducing the surface soil to a state of fine division which will admit a further compacting to be readily effected. It is clear, therefore, that the extent to which the land is alternately ploughed and 'choki-ed' will depend on the nature of the surface soil. In the high, light (sumbe) lands a relatively small number of ploughings will be sufficient; while in the low-lying clay (mattyar) lands, a greater number will be required before a sufficiently fine texture is obtained. When the soil is reduced to a sufficiently fine state of division, the plough is no longer used and the choki is only applied at intervals—two or three times a month until the time of sowing.

"The reasons for the adoption of these somewhat intricate processes will become plain when certain peculiarities of the soil and climate of these districts are explained.

"Indigo is sown at the commencement of the hot weather—late February or early March. Since the end of the previous rains—early October—only an inappreciable amount of rain has fallen, for in these districts the average total rainfall from November to May, inclusive, is under three inches. The planter, therefore, is entirely dependent on the moisture retained by the soil from the previous rains, both for the germination of the seed and for the support of the young plant until the break of the rains in June. It will be readily understood that, with the temperatures and low atmospheric humidity which prevail at the time of sowing, the surface soil would soon lose all moisture unless this be constantly replenished by
INDIGOFERA
Bengal

Soil.

a supply from the deeper layers. Throughout the area the soil consists of an extremely fine alluvial deposit which extends down to and below the water-level—20 feet approximately. It is this unusual condition which makes a rapid capillary movement of water possible. Unless, then, the superficial four or five inches which have been disturbed by the plough are compacted to an extent which will allow the capillary rise of water to take place with a degree of rapidity sufficient to keep pace with the evaporation of moisture caused by the sun's heat, germination and subsequent growth of the plant will be impossible. It is to produce the necessary degree of compactness in the superficial soil that the above processes are adopted.

"Throughout this period—November to February inclusive—the lands are kept scrupulously 'clean' by constant weeding. Sowing, as already stated, usually commences in late February or early March. The exact date is dependent chiefly on the temperature, and it is the usual custom to wait till a night temperature of 60° is recorded. Once sowing is commenced, it is carried on with the utmost speed possible. Under the most favourable conditions the increasing day temperature will soon deprive the superficial soil of its moisture, and it is necessary—if the plant is to survive—that it shall have developed a sufficient length of root to be no longer dependent on such moisture. The seed is sown by means of drills, each drawn by two bullocks. Briefly, they consist of a trough, containing the seed, into which small wooden wheels dip. When the drill is in motion these rotate and pick up three to four seeds by means of shallow holes cut at regular intervals in their circumference. The seeds are thus carried forward and dropped down a slot, by which they are guided into a shallow furrow formed by a share situated in front of the slot. Each drill has six shares, corresponding to six wheels set at regular intervals, and thus sows six lines. As soon as the seed is sown a light choki is passed over the field and the seed is thus brought into intimate contact with the moist soil at a depth of about one inch from the surface.

"At the present time 8, 12 and even 20 seers (40 lb.) are sown per bigha (seven-eighths acre). There is no doubt that this is excessive, and it is difficult to understand how the practice has arisen. It is quite possible, with good seed, to obtain a yield in no way inferior to that normally obtained when using only four seers (8 lb.) per bigha. During the hot weather, growth is slow, but with the break of the rains this rapidly increases. The commencement of cutting depends to a large extent upon the date at which the rains break, but usually takes place about the middle of June. The low-lying crops are first cut, both because the more abundant moisture has given greater growth and because delay in cutting causes considerable risk of loss from sudden flooding. Two crops are normally obtained except when the plant is growing in the river-bed, where the rise of the river renders only one possible. These two cuttings are known respectively as the morhun and khunti cuttings. The crop is entirely hand-cut, and the cut plant is loaded into bullock carts and dispatched to the factory with the least delay possible. Immediately after the morhun crop is cut the land is ploughed. This, without damaging the crop, renders the surface open and uneven, and subsequent rain is retained in greater abundance. After the second cutting the land is ploughed and sown with a rabi crop or prepared, as before, to receive indigo in the following season. On arrival at the factory the carts are weighed, and the weight of plant is obtained approximately by difference."

674
PRODUCTION IN UNITED PROVINCES

INDIGOHERA

Cultivation

Lower Bengal.—"The chief crop of indigo in Lower Bengal is obtained from the annually inundated tracts of land. The seed is usually sown broadcast upon the muddy banks left by the retreating water during the first part of October. In the case of the higher lands only is the plough used and the land, to a certain extent, prepared. The crop is cut in the following June and July" (Leake).

In the districts of Bihar south of the Ganges, Patna, Gaya and Shahabad, the system of cultivation is closely allied to that pursued in the United Provinces. The soil is non-retentive of moisture, and the sowings are carried on chiefly during the rainy season in July, August, and September. The early rainy-season sowings are called asarhi, and the crop from these is cut in September and October. The later sowings continue to grow throughout the year and are reaped in July and August, when the crop is known as khunti, but that name is also applied to the second year's crop from the early sowings.

UNITED PROVINCES.—Area and Production.—The area in 1904-5 was 107,516 acres; 98,695 acres in Agra and 8,821 in Oudh. The estimated outturn was 8,000 cwt. These figures show a great contraction on those of the previous year. The chief districts in Agra are ordinarily Alishgarh, Azamgarh, Balandshahr, Etah, Cawnpore, Mainpuri; and in Oudh, Fyzabad. The final forecast for 1906-7 shows a still larger reduction to 40,374 acres; viz. 34,809 in Agra and 5,565 in Oudh. This represents a decrease of 75.2 per cent. on the average area of the years 1900-4, and of 83.5 on the average for 1895-1904.

Commenting on these provinces, Leake says, "In the districts forming the west of the United Provinces and the east of the Panjab, the cultivation of indigo for dye is practically extinct. The plant is, however, still grown to supply seed to Bihar. The seed is sown broadcast after the land has been irrigated and ploughed during March and April, and in those districts where dye is manufactured the plant is ready to be cut in August, but is left in the ground till December if seed is required. The process of dye manufacture, where practised, is essentially similar to that of Bihar." According to Duthie and Fuller (Field and Garden Crops, 1882, i., 43-50, t. xii.) it may be sown either in spring or at the commencement of the rains. In the first case it is called jamowa or chaiti, in the second asarhi. Jamowa indigo is ready to cut in August, asarhi a month later. Land under jamowa is as a rule ploughed up immediately the crop is cut; asarhi indigo is left in the ground till the following rains, when it springs up again and yields a khunti rap. Generally it is sown alone, though occasionally mixed with jadir (Sorghum vulgare) or arhar (Cajanus indicus), and is surrounded with a border of castor or san (hemp). A loam is prepared; but where copious irrigation is possible, much of the cultivation is on the

Areas.

lightest possible sand. Four ploughings are held advisable, though frequently in canal-irrigated districts the land receives only one. For jamowa indigo the ground must be watered before ploughing, while the asarkhi fields are not ploughed till softened by the rains. The crop must be kept free of weeds, and two weedications at least are required. The cost of cultivating an acre of jamowa indigo, to be cut in August and followed by a rabi crop, is estimated at Rs. 15-7a.

[D.E.P., iv., 410-1. C. Prov. and Berar.]

**CENTRAL PROVINCES AND BERAR.—Area and Production.**—

Only 110 acres were reported in 1904-5 as under indigo, these being in the districts of Buldana, Hoshangabad, Narsinghpur and Chanda. In Akola the seed is sown about the middle of the rainy season or latter half of July, and the plant is ready for use in October or November, when the flowers begin to form. [Cf. Sule, Monog. Dyes and Dyeing, Berar, 1896, 2.]

**PANJÁB.—Area and Production.**—The estimated area in 1904-5 was 53,000 acres, and the yield 9,900 cwt. The large interest in seed cultivation accounts apparently for the disproportion of yield to acreage. The most important districts are Multan, Muzaffargarh, Dera Ghazi Khan and Rohtak. The final forecast for 1906-7 estimates the area at 62,300 acres, as against 67,500 in 1904-5. This total is shown to be 19-3 per cent. below the decennial average. The recent effort by the planters themselves to produce specially improved new seed could have had no other consequence than to disturb and possibly curtail the demand for Native seed. The following are the returns of seed production in the Panjáb for the past four years:—1904, 1,673,800 seers; 1905, 1,785,000 seers; 1906, 3,227,600 seers; and 1907, 1,248,900 seers.

"The easterly districts of the Panjáb should be considered in conjunction with the United Provinces. In the west, however, in Multan, Dera Ghazi Khan and Muzaffargarh, the methods are very primitive, and the market supplied is the purely Native trade across the north-west frontier. The plant is sown on irrigation, and hence the date of sowing depends on that of the opening of the canals—usually during May. By September the crop is ready to be cut, after which the plant may be ploughed up or left for a second, and, sometimes, even a third, year." "Lands subject to river inundation are considered unsuited; in other words, a prejudice exists against over-inundation. The land is prepared during the cold season after the winter rains, and sowing takes place from March 1 to May 15. The field is first flooded and the seeds scattered broadcast on the water. Irrigation is given every third day till the plants are about a foot high, then every eight or ten days" (Leake). [Cf. Morris, Cult. and Manuf. Indigo in Mooltan, Gaz. Mooltan Dist., 1885-4, app. λ, 161-6; Panjáb, Dist. Gaz.]

**RAJPUTANA AND CENTRAL INDIA.**—Small quantities are grown in Ajmir and in the Native States of Jaipur, Marwar, Gwalior and Tonk. In Ajmir the seed is sown broadcast in the month of June or as soon as the rains set in. When the young plants are above ground the grass is weeded out by a process of hand-hoeing. Reaping commences about October.

**BOMBAY AND SIND.—Area and Production.**—The late Mr. E. C. Ozanne, then Director of Agriculture, Bombay, wrote in his Annual Report (1885-6, 36-7) that—"In the 16th and 17th centuries, indigo, partly of
local growth and partly brought from Upper India, was one of the chief exports of Gujarat. Towards the close of the 18th century (1777) the cultivation, chiefly for local use, would seem to have been on a very considerable scale. But in the early part of the present century it again fell off and in 1827 had almost altogether ceased. At that time, prices were high and the demand was strong.” The attempt then made to resuscitate the industry, however, failed, and “indigo has never again become a product of any importance.” In an official letter of date 1889, Ozanne, however, speaks of the indigo cultivation of Bombay having been 4,182 acres. In 1904–5 there were only 806 acres under the crop. The following account of the cultivation in Western India is an abbreviation from Mollison (Textbook Ind. Agri., iii., 279–83). The best crops are grown on gorādu soil (deep sandy loam). In the Deccan, medium black soils of fair depth are deemed most suitable. The crop is grown in the khārij (rainy) season. “Thorough tillage and a liberal application of manure are necessary. Well-rotted manure in a dressing of twenty cart-loads per acre should be given in May. The plough and harrow should be used after the first fall of rain to prepare a clean, smooth seed-bed. The crop is either sown alone or with subordinate rows of cotton. One row of cotton may alternate with two of indigo. When sown alone, the rate is 12 to 15 lb. seed per acre. The seed should be drilled if possible in June in rows 18 inches or less apart and the drill should be worked near the surface, so that the seed is not buried too deeply. The crop should, after the seedlings are well up, be intercultured two or three times with the bullock hoe and be once hand-weeded with the weeding-hook (khurpa). The first cut is ready in September–October. With favourable late rain, a second cut may afterwards be obtained without irrigation.”

The area in 1904–5 was in Sind 5,621 acres, chiefly located in Hyderabad, 3,985 acres, and Sukkur, 1,404 acres. After the land has been weeded and moistened during the inundation season in May and June, it is ploughed two or three times and the seed sown broadcast. When the plants have germinated, they are watered once a week, and this is continued till September, when the crop is ready to be reaped. A second year’s crop is raised after cutting by frequently watering the old plants. [Cf. N. B. Beyts, Gujarat Agri., 1878, 44.]

**MADRAS.—Area and Production.**—The area under cultivation in 1904–5 was 126,300 acres, and the outturn 16,700 cwt. The principal districts are ordinarily Cuddapah, which in 1904–5 had 32,149 acres; South Arcot, 28,784; Nellore, 14,618; North Arcot, 7,352; Karnul, 7,056; Anantapur, 5,098; and Kistna, 3,208. The forecast for 1905–6 shows an estimated area of 212,300 acres and an outturn of 1,896 tons. Commenting on this result, the Board of Revenue in their final report for 1906–7 show that this area is 86 per cent. more than in 1905–6, but 1 per cent. less than the average of the five previous years and 25 per cent. less than the ten previous years. Indigo appears to be cultivated under very diverse conditions throughout the Presidency. “Returns show that somewhere in the district sowing is normally being accomplished in every month of the year. This, no doubt, is due to the more even distribution of temperature and rainfall throughout the year” (Leake).

In Cuddapah, the chief indigo district, the land is ploughed and manured after it has been moistened by rain. This takes place in April if the rain is sufficiently heavy; if not, in July or August. The ground is then allowed
INDIGOFERA—THE INDIGO PLANT

Burma.

to remain till the next heavy showers, when the seed is sown in rows. In about a month weeding commences. On dry lands the crop is entirely dependent on rainfall. The first cutting is taken three or four months after sowing, and a second and third at intervals of three months after the first. After the third cutting, the plant is allowed to seed.

Wet cultivation is also carried on in the neighbourhood of tanks or wells. Near wells with a certain supply of water, cultivation is commenced in March or April. If the soil is loose, the seed is sown without any previous ploughing; otherwise, in the vicinity of tanks, the land is watered, ploughed, and smoothed by a roller. It is then manured, watered again, and the seed sown when the land has dried. After germination, the crop is regularly watered at intervals varying from a week to twenty days. Weeding commences a month after sowing, and the first cutting takes place in three or four months, the second three months later. [Cf. Shortt, Man. Ind. Agri., 1885, 98–136; Mem. on Prog. Madras Pres., 1893, 69–71; Cox, Man. North Aroth Dist., 1895, i., 273–4.]

BURMA AND ASSAM.—Area and Production.—Indigo is cultivated to a very limited extent in Burma. In 1904–5 there were 424 acres in Upper and 58 in Lower Burma. In Upper Burma cultivation is confined to the districts of Pakokku, Lower and Upper Chindwin and Sagaing, and in Lower Burma to Thayetmyo. The gravest suspicion, however, should be entertained in accepting the published figures of area as being *Indigofera*. The description given by Mr. H. G. A. Leveson, in a note on the dyes of the Southern Shan States, at all events, leaves little or no doubt that much of the indigo of that country is derived from *Strobilanthes*. In Chindwin there are reported to be two crops, the wet- and the dry-weather. The wet-weather crop is sown in June and collected in July and August; the dry is sown in October and collected in December and January. An indigo plant is also said to flourish at high elevations in the Shan States. It is remarked that when cultivated in the lower valleys it is generally under the shade of trees, and when grown on the hills, plots of ground are selected at the bottom of steep valleys. Brackish soil is regarded as the most suitable, and the ground is not manured. It is not grown from seed, but at the beginning of the rains the shrub is cut to the ground, the lower part of the stalk thrown away, and the upper part with the young leaves planted. Two or three pluckings are considered a fair average yield, though a well-grown plant may afford as many as five. Most of these statements, it may be inferred, denote *Strobilanthes*.

Turning now to Assam, the cultivation of indigo may be said to be practically non-existent. The greater part of the indigo dye of the province is the produce of *Strobilanthes flaccidifolius*, and not of *Indigofera*. In many respects Assam and Upper Burma show a closer approximation to the conditions of South and Central China than to those of India. Accordingly Assam, in the matter of this particular indigo-yielding plant, may be spoken of as the most western portion of the area of *Strobilanthes flaccidifolius*, a plant that is from there diffused east and north throughout the greater part of China and becomes one of the most important sources of the dye in that vast empire. [Cf. Leveson, Dyes and Dyeing in Southern Shan States, 1896, 2–5; Duncan, Dyes and Dyeing in Assam, 1896, 28, 29; Parlett, Rept. Sett. Oper. Sagaing Dist., 1903, 15.]

Burma.

Manures.—Generally speaking the only manure given in indigo cultiva-

Different Species.

Seasons and Crops.

Manures.
tion is the refuse of the indigo plant termed *seet*, procured from the factory. Artificial manures have made little headway, and even with the simpler fertilisers, such as lime, gypsum and nitre, there is uncertainty as to their efficacy. In this connection attention should be given to the results obtained by Mr. C. Rawson, summarised in his final report to the Bihar Indigo Planters' Association, published in 1904. As a rule indigo soils were found deficient in available phosphoric acid, and responded remuneratively to treatment with superphosphate, bonemeal or other phosphatic manures. Nitrogenous manures were generally found useful when applied along with phosphates. Dr. Hancock, working at Dalsing Serai under Mr. Bernard Coventry in 1901 (*Rept. Indigo Improv. Syndicate*, 1901), arrived at the same conclusions. The value as manure of the refuse plant (*seet*) was also investigated by Rawson, with the result that he came to believe that in many cases it was as valuable as the indigo produced by the factory. Mr. W. Popplewell Bloxam next took up the inquiry into the subject of indigo improvement by scientific manuring. In his report to the Government of Bengal, 1905, on the work carried out by Leake and himself at Dalsing Serai (in 1903-4), he summarises his experiments and results. The chief feature of these may be characterised as the supply of various carbonaceous materials to indigo soils with the view of ascertaining their effect on the growth of the nodulo bacteria. The period of Bloxam's experiments was, however, too short to allow of any very definite conclusions.  *Cf.* Voelcker, *Improv. Ind. Agri.*, 1893, 106, 112, 259, 260-1; *Rept. Cawnpore Exper. Farm*; Bergtheil, *Acc. Sc. Invest. on Indigo*, in *Rept. Dept. Land Rec. and Agri. Beng.*, 1905, vii.-ix.]

**Dangers to the Crop.**—"Under favourable conditions the young plant will appear above the surface on the seventh to the tenth day, from which time onwards it is exposed to many vicissitudes. It is no uncommon occurrence to find the destruction of the crop to be caused by a shower of rain. It has already been explained that the young plant is dependent on what may be termed 'bottom' moisture for its early growth, and on the condition of the soil which makes this available. The 'compacting' of the surface soil leaves a loose, dry layer on the surface which acts to a certain degree as a check on evaporation. The effect of rain is to do away with this dry layer and to establish a complete capillary system to the absolute surface. The ultimate result is a rapid decrease in the moisture of the superficial soil, which may ultimately be reduced to below the limit at which life can be supported. Under these circumstances the crust must be broken even at the cost of destroying half the crop. This is usually effected by the use of a light rake, or, in the case of a very light crust, by brushwood drawn over the surface. A prolonged spell of hot west winds, such as are common during April-May, in spite of the precautions taken to conserve the moisture, reduces this to below the needful minimum, and in this way the greater part of the crop may be lost."

"As regards pests little can be said. The larvae of numerous *Leptodore* feed on the indigo plant, but in only one case are the ravages sufficient to cause serious damage. Under favourable conditions the larvae of *Agrotis segetis* appear shortly after the young plant has broken through the soil, and before what is known as the '7-leaf' stage is reached. Plants attacked will be entirely stripped of their leaves, and a second sowing may be necessary. In bad seasons this may also happen, and necessitate a third sowing. It seems probable that the ravages of this pest are only
serious in those lands which have been sown in indigo for several years in succession, and that a reasonable system of rotation would reduce the injury to a negligible quantity."

"Of other insect pests which assume dangerous proportions, there is an *Aphis* and a *Thrips*, but little or nothing is known of the life histories of either. They both attack the young plant, rendering it stunted, and the latter, by destroying the mesophyll of the cotyledons and first foliage leaves, may kill the entire plant" (Leake). [Cf. Lefroy, *Caterpillar Pests of Indigo in Bihar*, in *Agri. Journ. Ind.*, 1906, i., pt. iv., 338-50.]

**Yield.**

**Outturn and Yield.**—"Owing to the numerous variations in the exact area denoted by the term *bigha*, and to the confusion consequent thereon, it is almost, if not quite, impossible to determine with any degree of certainty from the published returns what is a normal yield of plant and dye. Under these circumstances it seems best to give the returns for a particular concern for which the figures are available and which, being situated in the centre of the indigo districts of Bihar, may fairly be taken as normal. The period from which the averages are derived covers a term of eleven years, viz. from 1892-1903. This shows an average of 80 maunds of plants per acre for the *morhun* cutting, and 35 maunds of plants per acre for the *khunti* cutting, while the dye manifests an average of 16 lb. per acre for the year, in the proportion of 11 lb. for the *morhun* and 5 lb. for the *khunti* cutting. The fluctuations are, however, very wide, *e.g.* for plant per acre 168 to 48 maunds, and for dye, 25 lb. to 7½ lb" (Leake).

**MANUFACTURE.**

**WET PROCESS.**—"For the manufacture of dye from the plant, the wet process is now almost invariably adopted. Briefly this consists in the extraction from the plant of the dye-yielding principle by steeping in water, and the precipitation, from the extract so obtained, of indigo by exposure to air—oxidation. As the amount of plant which must be daily steeped comes to some hundreds of cartloads, there are certain essentials which must be considered in choosing a site for a factory. Chief among these is an abundant supply of water; and a factory will never, therefore, be found at a distance from a stream or large lake, from which water can be pumped into a large tank—*khazanah*—placed at the highest point of the factory. From this tank channels conduct water to the steeping vats, a row of brick and cement-lined basins, usually about 20 feet square and 4 to 5 feet deep, and about 15 in number. Below these, and corresponding with them in number, are a second row of slightly shallower vats called the beating vats.

"The plant, on arrival at the factory, is loaded into the steeping vats and, as soon as each vat is full, is battened down by means of beams attached to pegs set in the sides of the vat. Water is now run in until the plant is just submerged, and steeping is allowed to proceed for a period varying from 12 to 14 hours. The liquor, which has by this time become yellowish green and almost fluorescent, is now run off into the lower, or beating vat.

"Beating is effected in various ways, the sole object being to obtain as thorough an oxidation as possible. In the more primitive method 10 to 12 coolies enter the vat and proceed to beat the liquor with short sticks to one end of which flat discs of wood are attached. The process is complete after about 1½ hours’ continuous beating. With the introduction
of machinery the hand beating has been to a certain extent replaced by wheel beating. Where this is employed, there is a single beating vat which runs the length of the range of vats and is divided along its length by one or two walls, the number depending on whether one or two beating wheels are employed. These walls stop short of the two ends of the vat and are simply employed to give direction to the circulation set up by the wheels. The wheels themselves consist of small flat disc of wood attached to the ends of a number of spokes radiating from the axle. By this method beating is complete in about one hour. More recently the beating has been replaced by blowing a mixture of air and steam through the liquor; and, later still, in 1902, this process, modified so as to blow ammonia through the liquor, was introduced by Rawson. Neither of these latter processes have, however, been universally adopted, and the wheel beating is still most commonly employed.

"After beating is complete, the liquor is allowed to stand until the precipitated indigo—the mal—has settled, leaving a clear, red, supernatant liquor. This 'maila pani' is drained off and the residual 'mal' is pumped into boilers where it is mixed with clean water and boiled, either by the direct action of heat or by injecting steam. The boiling and subsequent stages in the manufacture take place within the factory building. When the boiling is complete, the contents of the boilers are run on to the 'table.' This consists of a heavy canvas sheet which has been previously wetted and spread on a support of split bamboo. The cloth acts as a filter, allowing the clear water to drain off and retaining the indigo as a thick paste which is now transferred to the press. This is a square wooden box, the walls and bottom of which are perforated by numerous holes. The interior is lined with damp cloth and the mal is then poured in to a depth of 8 or 9 inches. The lid, which fits the interior accurately, is then put on and screwed home by means of a screw worked by a long lever. This is turned at intervals during 5 to 6 hours, in which time the mal will be pressed into a hard cake 3 to 3½ inches thick. The sides of the press are now removed and the cake is transferred to a table where it is cut by wire into cubes of about 3 inches. These are removed and placed on open shelves to dry in an airy room. The air admission is so regulated that slow drying is effected. This is essential if cracking and subsequent breakage of the cakes are to be avoided. During the process of drying, the cake becomes covered with a dense growth of mould. Before packing this is brushed off by coolies. The final stage consists in packing the dried and cleaned cakes into specially constructed cases which are weighed and forwarded to Calcutta for disposal" (Leake).

**DRY PROCESS.**—The wet method just described by Leake is that which is almost universally employed, though in Madras the dry-leaf process is still pursued to a limited extent. From the historical chapter given above it will be seen, moreover, that during the first century of the industry as fostered by the East India Company, the dry process was apparently universally adopted. It was even upheld that to that fact was attributable the high merit of the Indian as compared with other indigoes—the stems and twigs used in the wet vat system detracted, so it was then believed, very greatly from the merit of the dye. During the second century, when the industry had been conveyed from the West Indies back to India, or rather to Bengal, the wet process was alone that employed. It is significant that throughout all this rise and fall of the
European industry in India, the Natives should have quietly continued their own methods of manufacture, oblivious of or indifferent to the numerous patent processes and appliances brought out by their European rivals. By the dry method the bundles of freshly cut plant, instead of being conveyed directly to the factory, are dried and the leaves separated from the stem by beating. When kept dry the leaves turn in the course of a few weeks from green to a blue-grey colour. They are then subjected to steeping and fermentation, when the indican present in the plant splits through hydrolysis into indigotin and indiglucin. The fine green liquor thus obtained is then drawn off to the beating vat, where the matured indigo is precipitated and subsequently concentrated by boiling and compressed into cakes and dried in the usual way. But for the adulteration so largely resorted to by the Native manufacturers, it seems fairly certain the dry-system indigo would be fully as valuable as the wet, and in some respects have distinct advantages. This is exemplified by the fact that it is preferred even in localities where the difficulty of drying becomes serious. For a small manufacturer it has the great advantage of being attended to at the most convenient time.

The rationale of indigo manufacture may be briefly and pointedly told. Fermentation and hydrolysis of the indican found in the steeping vat takes place. The indigotin produced is reduced by the indiglucin to hydrindigotin (indigo white), and this dissolves in the alkaline liquor. Through the beating that follows the hydrindigotin is reoxidised, and indigotin precipitated—being insoluble in the alkaline liquid. The yield is about 0·2 per cent. of the weight of the plant. The addition of ammonia to the vat is frequently practised, with the result that the yield is largely increased, as the formation of ammonia by the fermentative breaking down of the indigo is thus hindered. The indigo obtained in this manner varies greatly in quality. Its content of indigotin ranges from 20 to 90 per cent., the average being 40 to 50 per cent. The remainder consists of ash, 5 to 20 per cent.; water, 2 to 8 per cent.; indirubin, 2 to 4 per cent., and various amounts of indigo-brown, indigo-gluten, and carbohydrates. The value of the blue depends on its content of indigotin and indirubin.

[Cf. Blount and Bloxam, Chem. for Engin. and Manuf., 320.] It is believed the presence of indirubin gives the more pleasing result of the natural as compared with the synthetic dye.

Mr. W. Popplewell Bloxam (who has devoted much attention to the study of the chemistry of indigo) read a highly instructive and valuable paper before the Society of Chemical Industry (Yorkshire Section) on August 15, 1906, and still more recently a further paper before the London Section on November 30, 1907. The last mentioned is written by Bloxam in collaboration with Dr. R. Gaunt and Mr. F. Thomas, and is specially described as an analysis of indigo and of the dried leaves of I. arrecta and I. sumatrana. It is, therefore, desirable that readers anxious for information of the nature indicated should consult the papers mentioned. But it may be useful to give here the few concluding remarks in the first, since these seem to give an indication of the direction and purport of Bloxam's investigations:

"From these results, it will be seen that if the percentage of indigotin contained in the whole plant (ordinary Indian varieties) be taken, as seems reasonable, at 0·6 per cent., then from consideration of the weights of plant steeped and the indigotin recovered in the finished cake, the highest
efficiency attained does not reach 50 per cent. of the total indigo (grms. of indigotin obtainable, whilst the average efficiency of the ‘mahai’ is 25 per cent., falling thence to 12·6 per cent. (cake No. 2). The attention of the Government of India will be called to this wasteful method of manufacture, with a view to the long-needed improvements being introduced to India without delay.” Concluding the second paper, Bloxam and his collaborators observe: — “Being now in the possession of some 150 grms. of crystallised indican, we are undertaking a scientific study of its quantitative conversion, by various methods, into indigotin— with the view of improving the process of manufacture at present in use in India. The results of our experiments all tend to show that considerable improvement remains to be made in the efficiency of the indigo manufacture, and point to the fact that the efficiency of the process is far lower than is currently stated.” Bloxam submitted his final Report of the Research Work on Indigo to the Government of India in 1908.

SYNTHETIC INDIGO.—It would be impossible to deal here with the discovery and production of synthetic indigo. As a matter of historic interest it may be mentioned that Perkin was (in 1856) the original discoverer of the coal-tar dyes, but, like Green’s discoveries still later, they were not fully appreciated until they had reached the Netherlands and German laboratories. Hence for a good many years past the artificial dyes have proved formidable rivals to the natural colours, and even in the case of indigo have begun to curtail the world’s demand for the Indian article. Already the exports from India have been reduced very seriously. Germany, for example, has practically ceased to import vegetable indigo, and her exports of the artificial products to all countries were last year valued at 25,000,000 marks (£1,250,020). This is remarkable, seeing that the first commercial manufacture was only made in 1897. According to a report issued by the Badische Anilin and Soda-Fabrik Company, their profits were in 1903, £583,787, and in 1904, £544,936. Thus it would appear probable that large sums have been realised from the sale of artificial indigo. The imports of synthetic indigo are mainly from the Netherlands. These came to 14,691 cwt., valued at £143,613 in 1902; 17,752 cwt. in 1903; 19,458 cwt. in 1904; 32,246 cwt. in 1905; and 39,042 cwt., valued at £147,325 in 1906.

TRADE IN INDIGO.—In a dispatch dated 1792, the Board of Directors congratulated the Indian Government that, as the British imports of Bengal indigo increased, those from the Spanish and French colonies declined, while at the same time a large export trade from Great Britain to the Continent had been established. That re-export trade amounted in 1790 to close on one million pounds of the dye. Such a brilliant result, when contrasted with the depression that has been cast over the industry, within the past few years, is highly significant. But
with the detailed statement of former transactions, given in the *Dictionary*, it may suffice to review here, and very briefly, the returns of the past few years:—

*Exports.*—The bulk of the factory-made indigo is exported. India uses up only the most inferior grades of the dye. The returns of foreign trade thus very nearly express the total production. The year 1894-5 showed the highest production credited to the Indian industry, viz. 237,494 cwt., produced from 1,688,042 acres. Up to that point the prosperity was almost phenomenal—a century of advancement, in spite of numerous local upheavals. But the year following the first commercial production of synthetic indigo the crash came, and from that time there has been nothing but continuous curtailments. From 1894-5 down to 1906-7 the record is, in fact, a very melancholy one. The exports in 1894-5 were 166,308 cwt., valued at Rs. 4,74,59,153, and in 1895-6 they were 187,337 cwt., valued at Rs. 5,35,45,112. But the twelve years following show a continuous decline, until in 1906-7 the exports were only 35,102 cwt., valued at Rs. 70,04,773. Commenting on this subject, J. A. Robertson (Rev. Trade Ind., 1904-5, 28-9), at that time Director-General of Statistics in India, wrote: "The unremunerative level to which prices have been forced down by competition of synthetic indigo has reduced the indigo plantations of Bengal to less than half the area they occupied ten years ago, and over the whole of India the reduction in that period was 66 per cent. Planters in Bengal are strengthening their position by cultivating other crops in addition to indigo, and they can carry on a contest for supremacy with synthetic indigo for many years."

"The season of 1904 gave a very poor yield, the deficiency compared with the previous year being estimated in the official reports at 31 per cent. in Bengal and 45 per cent. for the whole crop. The total exports of 1904-5 are less by 18-4 per cent. in quantity, and 22-4 per cent. in value, than the exports of the previous year. The fall in the average price was thus 4 per cent., and in Calcutta the fall was more marked in the better kinds than in the ordinary qualities."

Turning now to the countries which have drawn on India for their supplies of indigo, Great Britain formerly headed the list. The exports from India to Great Britain in 1875-6 came to 72,494 cwt.; in 1883-6 to 64,204 cwt.; in 1895-6 to 66,215 cwt.; and in 1898-9 (the year after the production of synthetic indigo) they dropped to 30,973 cwt.; since which date they have steadily declined until in 1904-5 they were only 10,743 cwt.; in 1905-6, 7,749 cwt.; and in 1906-7, 7,942 cwt. The record of the United States is somewhat similar, though on a smaller scale. In 1875-6 the share taken by the States came to 4,089 cwt.; ten years later it became 20,737 cwt., and from then a decline has been observed until in 1905-6 the amount taken was only 1,530 cwt., and in 1906-7, 1,258 cwt. Egypt, on the other hand, has preserved a fairly constant market, but it has to be explained that Egypt takes mainly Madras dry-leaf indigo. In 1875-6 it drew 577 cwt.; in 1885-6, 11,601 cwt.; in 1895-6, 13,995 cwt.; in 1903-4, 15,375 cwt.; in 1905-6, 9,702 cwt.; and in 1906-7, 9,195 cwt. With most Continental countries the decline in the demand for Indian indigo has been most marked. Germany took in 1895-6, 16,929 cwt.; in 1903-4, only 1,776 cwt.; in 1905-6, 487 cwt.; and in 1906-7, 523 cwt. France procured in 1895-6, 21,011 cwt.; in 1903-4, 1,975 cwt.; in 1905-6, 970 cwt.; and in 1906-7, 541 cwt. Japan, which for several years had been one of the
chief markets, almost ceased to import in 1904–5. This, it is believed, was largely a consequence of "the differential taxation which took effect from April 1, 1903 and imposed an extra tax, equal to 1·55 pence per lb., on Indian indigo, which both Java plant indigo and German synthetic indigo escaped, placing an insupportable burden on the trade; but now that Indian indigo has been treated on the most-favoured-nation basis by the Convention with Japan, which came into force on March 15, 1905, there may be some revival of the trade. German synthetic indigo has, however, now acquired such a dominant position, and its higher percentage of colouring matter still retains for it such advantage by reason of the duty being charged by weight, that India will find it difficult to recover lost ground" (Robertson, l.c. 29). The exports from India to Japan in 1906–7 were 1,800 cwt. [Cf. Rept. Beng. Chamber of Comm., 1903–4, 163–8.]

Internal Trade.—Turning now to the shares taken by the provinces of India. In 1885–6 the total exports were 132,495 cwt., of which the Bengal share was 76,109 and the Madras 45,828. Ten years later (1895–6) the total exports were 187,337, of which the Bengal share was 111,714 and the Madras 62,425 cwt.; in 1903–4, 60,410, of which Bengal furnished 29,858 and Madras 24,414 cwt.; in 1905–6, 31,186, of which Bengal supplied 19,062 and Madras 7,756 cwt.; and in 1906–7, 35,102, of which Bengal contributed 19,309 and Madras 11,159 cwt. The exports across the land frontier are not very important. In 1904–5 they came to 4,873 cwt., valued at Rs. 4,70,203; in 1905–6 to 5,275 cwt., valued at Rs. 5,26,431; and in 1906–7 to 3,518 cwt., valued at Rs. 3,47,341. The most important receiving countries are Seistan and Dir, Swat and Bajaur. Formerly a large trade was done in exporting indigo-dyed goods from India. The only survival of this is the export of blue cloth from Pondicherry to French China—a survival due, apparently, to the French protectionist enactments in favour of her colonies.

Imports.—A startling peculiarity of the present phase of the Indian traffic in indigo may be said to exist in the circumstance that a small supply of the dye is annually drawn from the Straits, from the United Kingdom, Belgium and Japan. There is no mention of synthentic indigo being imported, and the small foreign supply may be to some extent returns of Indian indigo. The imports in 1905–6 were 1,244 cwt., valued at Rs. 1,12,243; and in 1906–7, 2,392 cwt. and Rs. 97,152.

With the exception of the silkworms, the bees, the cochineal, the lac and the gall-forming insects, very few others can be regarded as of economic value. Unfortunately a very large number of insects force attention through the depredations they effect on crops, stores of food, industrial materials, manufactures, woodwork, etc. Maxwell-Lefroy has set forth in a lucid manner the difficulties that beset the entomologist in India who may have entrusted to him the investigation and solution of the pests of the fields and forests or the discovery of beneficial insects. The insects have to be identified and in many cases scientifically named, then their life-histories worked out, before practical suggestions are possible. Throughout the present publication the effort has been made to record the results
hitherto attained under the names of the products concerned, such as Corchorus (Jute), Canellia (Tea), etc. But in addition, the following special articles deal with insect economic products:—

Bees', Bees'-wax, Dammar and Honey (see pp. 123-9).

Coccus Cacti, Cochineal (pp. 347-9).

Silk (pp. 992-1013).

Tachardia Lacca (pp. 1053-6).

Besides these, however, there are a few other insects that have attracted attention. Perhaps the most important is the Locust. This often proves so destructive that strenuous efforts become necessary to restrain it. In order to aid in their identification, Maxwell-Lefroy has recently published an interesting account of the life-histories, with full-page illustrations, of the two locusts known to India, viz. the Bombay Locust and the North-West Locust. (The following papers have appeared in *The Agricultural Ledger*:—Gunther and Cotes, *Dried Locusts as Food for Caged and Game Birds*, 1893, No. 2; *The Automatic Locust Catcher*, 1895, No. 15; Stewart Stockman, *A Plague of Grasshoppers in the C. Prov.*, 1903, No. 3, 56-85; Maxwell-Lefroy, *Mem. Dept. Agri. Ind.*, 1906, i., No. 1; 1907, i., 125.) Sly (*Agri. Journ. Ind.*, ii., pt. ii., 208) gives a brief forecast of a report shortly to appear on the results attained in India with the locust parasitic fungus.

The wing-cases of the beetle *Buprestis vittata* are largely employed for ornamental purposes in India, and are especially worked up in articles of dress produced in Madras and Hyderabad, or are used in khās-khās fans, etc. [ Cf. Mukhorjii, *Art Manuf. Ind.*, 309, 313, 380; Watt, *Ind. Art at Delhi*, 1903, 161, 198, 408.]

**D.E.P.**

I. *aquatica*, Forsh.; Rec. Bot. Surv. Ind., ii., 121, 185, 243; iii., 81. The *kalmi*-sāk, *ndī, gandhīk*, nāṭikā bōjī, sōrkārī vāli, etc. An aquatic species common throughout India but especially abundant on the surface of tanks in Bengal. The young shoots, leaves and roots are universally eaten as a vegetable, and the plant is for that purpose often semi-cultivated. The juice is believed to have emetic properties and to be useful in opium poisoning. [Cf. *Pharmacog. Ind.*, ii., 540; Dutt, *Mat. Med. Hind.*, 1900, 302.]

I. *hederacea*, Jacq.; Rec. Bot. Surv. Ind., iii., 244. The *nīl-kalmi*, *bāunra, bīlādi*, *kādd-dāna, kākṣātān-virāi*, etc. An annual hairy twiner, cultivated in India, but also found wild. The seeds known as *kādd-dāna* and *mīrči* are purgative and resemble jalap in their action. They were made official in the Pharmacopoeia India in 1868. The market rate is about 4 annas per lb. Hooper (*Rept. Labor. Ind. Mus.* (Indust. Sec.), 1905-6, 32-3) says that the seeds contain 8-05 per cent. of resin resembling *convolutine*, but in addition are rich in albuminuous substances and contain 14-02 per cent. of a nauseous fat—a disadvantage in internal administration. [Cf. *Pharmacog. Ind.*, ii., 530-4; Henry, *Econ. Bot. China*, 1893, 49; Firminger, *Man Gard. Ind.* (ed. Cameron), 1904, 476.]

**Jalap.**

I. *Purga*, Hayne. Jalap. A climber, native of the Mexican Andes, at altitudes from 5,000 to 8,000 feet above the sea. In its native habitat rain falls almost daily, and it flourishes best in shady woods with a deep rich humus soil.

In India it is cultivated on Dodabetta in the Nilgiri hills, and in the North-Western Himalaya at Mussourie. The crop is an exhausting one. Formerly the plant was grown among the cinchona trees, but this system has been abandoned, since while the jalap flourished the cinchona was injured. Plants may be obtained from cuttings set under shade in a moist, sandy soil; but for cultivation on a large scale the smaller tuberous roots may preferably be used. These are placed
one foot apart and at a depth of about six inches within trenches filled with farm-
yard manure. As the plants grow, stakes require to be fixed for them to climb
on. A return may be expected in the third year, and every third year there-
after. In Octocumandu it has been found that an acre of jalap yields 5,000 lb.
of green tubers, or say 1,000 lb. of powder. The drying process is a difficult one,
as there is frequently considerable loss through mouldiness and fermentation.
It is said this may be prevented by cutting the tubercles in slices.

Medicinally, jalap is well known as a hydragogue purgative, its action being
due to certain resinous principles. The selling price has been given at about
2s. 3d. per oz. (Cf. Nicholls, Textbook Trop. Agri., 1892, 237-40; Hooper,
Effect of Phosphoric Man. on Growth of Jalap (Reprint from Pharm. Journ.),
Chem., 1900, ii., 349; Pharm. Soc. Mus. Rept., 1895-1902, 62-3; Pharm.
Journ., 1904, lxxii., 284-5.)

Sweet Potato

SWEET POTATO

I. Batatas, Lam.; Duthie and Fuller, Field and Garden Crops,
1893, iii., 12, tt. 87-8; Rec. Bot. Surv. Ind., ii., 41, 120, 185; iii., 80, 245.
Sweet Potato, mila-dūl, ranga-dū, chine dūl, shakarkand, vallikilāngu, etc.

Habitat.—Presumably a native of America, but is extensively cultivated in
India. Two forms are met with, one with red, the other with white tubers.
Evidence points to its having apparently reached the Pacific Islands in prehistoric
time. A return to its cultivation in the second or third century B.C. is
ascertained. A. Gray (Scient. Papers, 1889, i., 317-20), reviewing the account given in De
Candolle’s Origin of Cultivated Plants, gives full particulars of the literary evidence
in favour of an American origin. The first mention of the plant appears to be
by Peter Martyr, who in the 9th book of his 2nd Decade (written about 1514),
gives Batatas among the fruits of the province of Uraba, Darien, and in his
3rd Decade names them among the plants growing in Honduras when Columbus
landed in 1502. Other early Spanish travellers, e.g. Cieca de Leon, Jean de
Lery, etc., also refer to the finding of sweet potatoes in Peru and Brazil. Clusius,
moreover (Rar. Strip. Hist., 1576, ii., 297-9), states pointedly that they grew
wild in the New World and adjoining islands, whence brought to Spain. Nothing
very definite can be learned of its introduction into India. The plant is figured
and described by Rheede (Hort. Mal., 1683, vii., 53, f. 50) and by Rumphius
( Herb. Amb., 1750, v., 370, t. 130). Carey (As. Res., 1808, x., 18) discusses the
method of cultivation pursued in Dinajpur, and Roxburgh (Fl. Ind., 1., 483)
spokes of the red sort as cultivated all over the warmer parts of Asia.

Cultivation.—The area under the sweet potato in India cannot be
definitely ascertained. It is grown all over the country from the Panjab,
the United Provinces, Rajputana, Central India, the Central Provinces,
Bengal, Assam, Bombay, Madras and Burma. In Bengal it is more
important in the eastern tracts, such as Bogra and Bhagalpur, than in the
western and central divisions. Taking India as a whole, it is planted
from August to November and reaped from December to May, the varia-
tions being a consequence of local climatic conditions and methods of
propagation. A full account of its production in Bombay is given by
Mollison (Textbook Ind. Agri., 1901, iii., 193-7), of which the following
summary may be accepted as true of India generally. The best soil is a
light friable one, well prepared by deep tillage. The crop does not
thrive unless the land be naturally dry. It is generally grown during the
cold season and under irrigation, but on light, dry land a rain crop may be
produced. The land is prepared during the monsoon by frequent plough-
ings, and in September farmyard manure at the rate of thirty cart-loads
per acre is given. Before planting, irrigation beds are formed of various
sizes according to local circumstances.

Planting usually takes place in October-November. The crop is
propagated by cuttings from fairly mature portions of the stem, each
with three nodes or leaf-buds. Two nodes are placed underground, 2
SWEET POTATO

to 3 inches deep, while the other node is left free. The cuttings are usually placed along ridges, though sometimes in flat beds. The ridges are about 18 inches apart and the cuttings are deposited one foot apart on each side of the ridge, half-way between the crest and the bottom of the furrow. Cross furrows are also drawn which form channels for irrigation. Weeding should be attended to and the crop watered every eight or twelve days. Care must also be taken to prevent the plants rooting at the nodes, for otherwise small tubers of no value will be formed at the points of attachment and these will deduct from the growth of the large tubers at the main root.

Yield.—If planted in October–November the crop should be ripe in April and the tubers lifted at once, else much damage will be done by rats and white ants. The vines or haubus are reaped before the tubers are dug. A good crop may yield six tons per acre, worth about Rs. 300. The cost of cultivation in the Surat district Mollison gives as Rs. 134.

Sugar and Alcohol.—The sweet potato contains more dry starchy and sugary matter than the ordinary potato, but less nitrogenous substance. Analysis shows it to possess about 10 to 20 per cent. of sugar and about 16·05 per cent. of starch. It is said to be an excellent source of alcohol, 100 kilos of tubers yielding about 12 to 13 litres of absolute alcohol.

Recently it has been largely cultivated in some parts of the world as a source of sugar. By the Natives of India it is commonly used as food, either cooked in curry or boiled, roasted or fried.

PRODUCTION.—Iron is commonly said to exist in nature in two great classes of workable ore—(1) Carbonates and clay ironstone, and (2) Oxides, like hematite and magnetite. The Carbonates consist essentially of two kinds: (a) those in which the salt is crystalline and little admixed with earthy matter, and (b) those in which a larger or smaller amount of clay is intimately intermixed with the ferrous carbonate. The former is spathic iron ore and the latter argillaceous ore or clay ironstone. Clay ironstone exists in large deposits in many coal measures and is then known as black-band. The Oxides may be spoken of as of three kinds (a) anhydrous ferric oxide; (b) hydrated ferric oxide; and (c) a mixture of ferrous and ferric oxides such as the magnetic oxide of iron. Hughes Buller has recently sent from Baluchistan a natural mineral known as khaghil or lagh, which is employed as a dye. This has been ascertained to be an impure sulphate of iron. “The most abundant iron ores are the minerals magnetite and hematite which occur in numerous places with quartz, making quartz iron-ore schists which are generally members
of the Dharwar and other Archeean schist series. The most conspicuous examples of this class occur in the Salem district and the Sandur State in the Bellary district of the Madras Presidency, and in the Chanda, Raipur, and Jubbulpore Districts of the Central Provinces. The chief ore now used at the Barakar iron-works for the manufacture of pig-iron is clay ironstone, containing 45 to 48 per cent. of iron, and occurring as nodules in shaly formation separating the Barakar and Rániganj stages of the Dámuda series in Bengal” (Imp. Gaz., 1907, iii., 149–6).

Notwithstanding the fact that rich deposits of one or other of these various iron ores exist here and there all over India, and have, from the most ancient times, been worked up in a desultory manner by the Natives, still there has been but one successful attempt on European lines and by modern appliances. Indeed some of the recent investigations conducted in India would seem to establish belief that few of the important supplies of ore are of sufficiently high merit to defray the cost of carriage to Europe (or even to Indian centres of fuel supply) and leave a margin of profit. The opinion would thus appear to have been borne home that the expansion of India’s iron production must, for the present, be looked for in the immediate vicinity of fuel supplies.

South India.—Some few years ago many persons urged that if it paid to convey Spanish ore to England to be there made into “pig” which in the ordinary course of trade was profitably carried even to India, it must of necessity pay to convey the rich ores of Madras to the coal mines of India to be there worked up in competition with the imported foreign metal (Watt, Mem. Res. Ind., 1894). It was also even upheld that the time might soon arrive when England would have to look to Salem for its supplies of magnetic ore. In his presidential address to the Iron and Steel Institute (of May 1893), for example, Mr. W. Richards suggested that Indian ores could and should be substituted for Spanish. And still further it was loudly proclaimed that with some co-operative organisation of the Forest Department, South India might easily supply charcoal in such abundance and at such a price as to admit of production of iron after the fashion pursued in Styria and certain districts of America. These and other such opinions led to various technical investigations and reports on the part of experts employed both by private individuals and by Government. The Secretary of State for India, for example, submitted the then available information to Mr. Jeremiah Head, formerly President of the Institution of Mechanical Engineers, for favour of his views, the result being a most valuable contribution dated May 2, 1896. This is concluded as follows:—“I regret to have to say that in my opinion it is not at present practicable to conduct an iron industry at or near Salem upon the methods pursued in Styria and certain districts of America where charcoal is employed.” It was perhaps but natural that with a subject which had not passed from the stage of personal opinion to that of ascertained results, some at least of Head’s statements would be challenged. His final conclusion, in fact, has by no means been universally accepted in India, and the accuracy of the information on which he based his calculations of cost of production of iron, as also the supply of crude ore for direct export to Europe, has been called into question. The Board of Revenue, Madras, for example, observed that “If it can be shown that Mr. Head’s estimate can be safely reduced to Rs. 50 per ton f.o.b., as the Board believes that it can be, and freight can be obtained at 15s. per ton, the estimate taken by
Mr. Head (at page 18 of his report), it will be possible to deliver Kanjamalai pig-iron in England for £3 15s. 10d. per ton, being 5s. 2d. below the minimum value of imported Swedish pig, £1 4s. 11d. below the maximum, and 12s. 3d. below the average. The same iron could also compete still more favourably with Swedish pig imported into Madras, Calcutta and Ceylon.  

In 1898 a consignment of Kanjamalai Salem ore was sent to England to be tested along with Indian coke supplied for that purpose. The experiment was conducted by Messrs. Bolckow, Vaughan & Co. at Middlesborough, with the result that it was found to contain only 40 per cent. magnetic iron—in fact, that it was not worth exporting. This led to an acrimonious correspondence in the public press, in which it was affirmed that the sample sent was not selected ore but an average of the whole rock, and thus contained much that ordinarily would never be conveyed from the mine to the smelting furnace. It was urged that the results of previous investigations (such as those conducted by Dunstan, Imp. Inst. Tech. Repts., 12–22) showed a much higher average merit. Six samples examined gave 56.95 average, with the highest 70.06 and the lowest 36.44 per cent. of iron.

The Porto Novo Iron Company, founded by Mr. Josiah Marshal Heath, was the earliest and perhaps the most persistently worked concern in India. It was founded in 1830, changed hands more than once, and was finally dissolved and its privileges surrendered to Government in 1874. For thirty years a large quantity of iron was manufactured, and failure, as Major R. H. Mahon says, was not due to lack of iron ore or its quality, but to inexperience, defective machinery, and want of capital. He is, moreover, strongly of opinion that all existing difficulties will be overcome and iron production from the South Indian supplies made an industry of the greatest possible value. Persons interested in this subject should therefore procure Mahon’s admirable report. It would thus seem that the whole subject needs to be even still further investigated before it can be regarded as satisfactorily disposed of one way or the other.

Central Provinces and Orissa.—Hardly less satisfactory are the results of the inquiry made regarding the iron supplies of the Central Provinces. The report of investigations conducted by Mr. E. P. Martin and Prof. Henry Louis (on behalf of the Right Hon. Sir E. Cassel) will be found in The Agricultural Ledger. Speaking of the Jabbarpur district, more especially the Agaria ridge, these distinguished investigators say “the entire district undoubtedly contains considerable quantities of ferruginous material, but the latter is nowhere concentrated into what may be called a workable ore deposit showing the essential characters of steadiness and persistence which are indispensable in a deposit that is to form the basis of an important industry.” The conclusion arrived at may be said to be that considerable though the iron resources of the district are, they are not such as would warrant the erection of iron and steel works with any prospect of commercial success. In the Mayurbhanj State, in Raipur and in the Chanda districts, Messrs. Tata, Sons & Co. of Bombay organised prospecting operations on a large scale and employed Mr. C. P. Perin and Mr. C. M. Weld as their experts. As a result it has been decided to erect iron and steel works near Kalimati on the Bengal-Nagpur Railway with the intention of using the Mayurbhanj ore in conjunction with fuel from the Jherria Coal Field. It may thus fairly well be assumed that this new departure marks an era in the metal industries of India.

A Company known as the Tata Iron and Steel Company, Ltd., was
INDIAN FOUNDRIES

Iron smelting

Bengal. — It has, however, to be admitted that so far as actual results are concerned, the ore utilised in India is very nearly confined to that worked up by the Bengal Iron and Steel Company in its works at Barakar. In the *Review of Mineral Production*, Holland gives the ore raised in Bengal during 1898 to 1903, which shows for the six years an annual average output of 57,678 tons valued at £8,338, and a value per ton of £2-89s. Up to the present time, he observes, the Barakar Iron and Steel Company has manufactured pig-iron only, of which two blast furnaces have turned out 35,000 tons of pig-iron a year. Since then a third blast furnace has been added and an unsuccessful attempt made to manufacture basic steel. The history of past adversity and present prosperity of the Barakar works is the story of the failure of unskilled impersonal enterprise contrasted with skilled individual energy when combined with capital and commercial acumen. Their subsequent production was 65,115 tons in 1904; 97,698 tons in 1905; and 69,397 tons in 1906.

**FOUNDRIES AND INDUSTRIES.** — Iron and Brass Foundries are not separately returned, so that they have to be dealt with conjointly. They are scattered all over the country, but with the exception of the Barakar Iron and Steel Company, the railway and engineering workshops and foundries of Calcutta, Bombay, and certain other large towns, few are of any importance. In 1903 there were 78 foundries in all India giving employment to 22,568 persons, and in 1904, 89 employing 24,256 persons. Three years previously the corresponding figures were 70 and 17,980, so that there has been a considerable expansion; but these returns take, of course, no cognisance of the village blacksmith nor the workers in brass and copper. In the Records of the *Geological Survey of India* (1906, xxxiii., pt. i., 12-3) it is stated that the value of Bengal ore works out to an average of Rs. 2-4a. (3s.) per ton. For the rest of India, the ore being of a higher quality and raised at places often distant from the railways as well as the ports, a higher average prevails, say Rs. 4. The returns for 1904 show 71,608 tons of ore used, valued at £12,617. In the Central Provinces there were 441 small direct-process furnaces at work. [Cf. *Railway Ind.*, 1905-6, 115.]

**Local Manufactures.** — The exports and re-exports are not of sufficient importance to necessitate separate treatment. A feature of great potentiality that bids fair to foster local manufacturing enterprise, is the decision of the Indian Railway Board to place Indian engineering firms in a position to tender publicly for a portion of the annual requirement of stock. The tenders are to be confined for the present to the supply of frames and bodies only, the requisite wheels, axles, springs and draw-bars to complete wagons being indented for from England as heretofore. Subject to the material being satisfactory, iron and steel of Indian manufacture should be used whenever possible.

691
**Indigenous Industries.**—There would seem to be "no doubt that the existing manufacture of wrought iron by a direct process was widespread in the country before the date of the most ancient historic records, while the manufacture of the ancient wootz anticipated by many centuries the cementation process, developed in Europe, for the manufacture of the finest qualities of steel." "The Native iron-smelting industry has been practically stamped out by cheap imported iron and steel within range of the railways, but it still persists in the more remote parts of the Peninsula and in some parts of the Central Provinces has shown signs of slight improvement" (Imp. Gaz., 1907, iii., 145). According to Mr. Syed Ali Belgrami, the Nizam's Dominions furnished the material from which the famous Damascus blades of the Middle Ages were made. To this day Hyderabad is noted for its swords and daggers. Holland observes that so far as official returns are concerned, the Central Provinces show the highest production of iron, viz. from 2,400 to 4,800 tons; but there is also a sensible industry surviving in Bijawar, Panna and Orchha amongst the Central Indian States, as well as in Mysore and in some parts of the Madras Presidency. "Steel is made, both in the form of ingots by the carburisation of wrought-iron in crucibles, and, on a much smaller scale, by the decarburisation of cast-iron shot in a small open hearth."

The antiquity of the Indian knowledge in iron may be judged of from the famous pillar at the Kutab near Delhi; from the numerous examples that exist of wrought iron; from the hammered and perforated door panels both in iron and brass to be seen at the ancient palaces and tombs; and from the superb collections of arms preserved by the princes and nobles. Burma has for many years been known to have attained high proficiency in wrought iron. Near the Arakan pagoda of Mandalay numerous workshops exist for the production of the iron thees or the umbrellas placed as weather-cocks on the pagodas of Burma. At the pagodas, balustrades in iron are also frequently used, and this demand has given birth to a fairly large import trade in very inferior cast-iron imitations of fine old Burmese designs in wrought iron. Of Western India, Baroda is noted for its wrought-iron balustrades. The engraving and carving of iron and steel was some years ago an important industry in India, and Kanara, Madura, Malabar, Vizagapatam and Mysore were famous for their works of this class. The art is still practised at Udaipur, Jaipur, and Jodhpur, Hyderabad, Deccan, and Kach are famed for their arms; and the gold and silver damascened soft-steel wares such as armour, swords, shields, caskets, etc. (koftgari work) of Sialkot, Serhoi, Jaipur, are traded in all over India and largely exported. The decline of the Sikh power and the modern change in the methods and materials of warfare struck, however, a deadly blow at the damascening art, and a serious decline both in the amount and quality of the work has for years past been manifest (Ind. Art at Delhi, 1903, 14-45, 460-2).

**Trade.**—Imports.—It is difficult to give anything like an accurate conception of the total traffic in iron. The local production is but imperfectly known; an error must therefore always exist. A large number of articles that are partly constructed of iron are sure to be returned under other headings, but the figures under hardware and cutlery, iron, steel, machinery, railway plant, rolling stock, locomotives, etc. (Merchandise and Government Stores), give some idea of the vast magni-
TRADE IN IRON AND STEEL

The imports shown under these headings were collectively in 1899-1900 valued at Rs. 13,34,14,503; in 1901-2 at Rs. 15,11,06,431; in 1903-4, Rs. 19,58,09,778; in 1904-5, Rs. 20,30,66,366; in 1905-6, Rs. 23,01,10,532; and in 1906-7, Rs. 26,86,49,605 (£17,909,973). Thus the traffic is by no means unimportant, but it may be useful to direct attention to certain items of it that more especially may be called Iron. The imports of Cast-Iron were in 1899-1900, 263,563 cwt., valued at Rs. 7,95,040; in 1901-2, 291,422 cwt., valued at Rs. 8,73,347; in 1903-4, 531,953 cwt., valued at Rs. 13,84,888; in 1905-6, 636,163 cwt., valued at Rs. 16,17,966; and in 1906-7, 667,285 cwt., valued at Rs. 18,43,167. Practically the whole of these imports came from the United Kingdom, the only other country of importance being Aden. Of Bar-Iron, the imports were in 1899-1900, 499,678 cwt., Rs. 30,07,124; in 1901-2, 850,106 cwt., Rs. 49,67,024; in 1903-4, 650,409 cwt., Rs. 35,74,266; in 1905-6, 781,360 cwt., Rs. 39,89,904; and in 1906-7, 606,604 cwt., Rs. 35,18,998. Under the heading of Steel-Bars the imports were in 1899-1900, 500,676 cwt., valued at Rs. 39,21,024; in 1901-2, 974,038 cwt., Rs. 54,93,840; in 1903-4, 1,115,933 cwt., Rs. 59,49,191; in 1905-6, 1,963,574 cwt., Rs. 95,42,895; and in 1906-7, 1,402,762 cwt., Rs. 74,92,013. The iron and steel bar traffic Belgium has practically usurped the United Kingdom and for some years past poured into the country large quantities of cheap stuff that has found a ready and expanding market. Of Pipes and Tubes in 1899-1900 the imports were 257,118 cwt., Rs. 25,32,277; in 1901-2, 322,520 cwt., Rs. 29,40,404; 1903-4, 821,783 cwt., Rs. 57,81,098; 1905-6, 514,060 cwt., Rs. 38,19,850; and in 1906-7, 668,539 cwt., Rs. 51,17,286. In this traffic the British manufacturer more than holds his own, the only important competitor being the United States. Of Sheets and Plates (all kinds) the imports in 1899-1900 were 1,104,289 cwt., valued at Rs. 1,04,42,871; in 1901-2, 1,298,985 cwt., Rs. 1,22,15,307; in 1903-4, 1,636,592 cwt., Rs. 1,45,60,655; in 1905-6, 1,783,999 cwt., Rs. 1,59,41,040; and in 1906-7, 2,190,764 cwt., Rs. 2,20,45,396. The supplies come mainly from the United Kingdom, the only other country of importance being Belgium, the trade from which would appear to be declining.

These illustrations may be accepted as fairly representative of all the special headings of the iron trade proper. Space cannot be afforded to indicate the traffic in the manufactures that are only partially made of iron, such as machinery, railway plant, etc. It may have been observed that a steady rise is taking place in the imports. Even the figures exemplified are sufficient to show that there is room for a large iron manufacturing industry; and when this is established, the production of rails, rolling stock and machinery would soon follow in the wake of the furnace and the foundry.

**ISCHÆMUM ANGUSTIFOLIUM**

**THE BABOI PAPER-GRASS**

**Baboi**

The baboi, *bhabar*, *bhabar*, *bhabar*, *babni*, *sabai*, *baggar*, *ban-kush*, *bankas*, *som*, *moyia*, *backhorn*, etc. A perennial grass plentiful in drier tracts of India, from Chota Nagpur and Rajmahal to Nepal and Garhwal, also throughout the plains northward, viz. in the Central Provinces, Central India and Rajputana to the Panjab, Kashmir and Afghanistan, ascending to altitudes of 7,000 feet. The grass, from the most ancient times, has, in the localities where it abounds, been extensively used for making ropes, string and mats (see p. 776), and utilised in the construction of rope bridges, and to some extent takes the place of jute in agricultural sacking.

**Identification.**

*Bhabar* is often associated with the sedge *Eriophorum comosum* (D.E.P., iii., 266), and the two doubtless are sometimes used mixed together, but for many years it was incorrectly supposed that *bhabar* was *Eriophorum*. Sir D. Brandis was the first to recognise that Royle, Wallich and others were in error in overlooking the grass *Ischænum* as the most important, if not the true bhabar. Stewart (*Journ. Agri.-Hort. Soc. Ind.*, 1863, xiii., 203), while acknowledging his indebtedness for this correction, expressed the opinion that the grass should, in the future, play an important part as a paper material—he was thus apparently the first to suggest that use for the grass. Duthie led to a true identification botanically, and Sir George King pioneered the trade as a paper material (see pp. 865-8). In the *Annual Report for the Botanic Gardens of Calcutta* for 1893-4, he tells us that he had sent home, in 1873, samples of the grass to a paper-maker in Scotland, who reported favourably on it, and again in 1877 had furnished the late Mr. Routledge, through the India Office, with a consignment for experiment in Sunderland. Investigations were also made in India from 1882, the first by Mr. Deveria, and finally by the Bally Mills Company, Ltd., and others, until the grass became firmly established as a paper material.

**Paper Material.**

The *Kew Bulletin* and the *Indian Forester* have devoted much attention to this subject for some years past, and the *Annual Administration Reports of the Forest Department* have recorded the measures taken to foster and extend production. [Cf. *Gamble, Ind. For.*, 1893, app., xix.; *Fischer, Ind. For.*, Nov. 1903, xxix., 516.] The grass has thus been systematically placed before the public. It has, in consequence, become an assured paper material, restricted alone by the insufficiency of the supply. The attempt has accordingly been made to cultivate the plant in localities more accessible to the paper-mills, thereby lowering the ruinously heavy freight charges. More or less successful experiments of this kind have been conducted in Poona, Mysore, Hyderabad Deccan and in Hyderabad Sind. Systematic cultivation has also been undertaken in Manbhum, Birbhum and Murshidabad. In Poona it has been announced that the yield is 24 cwt. of dry grass per acre. It was, however, ascertained that when grown on soils of a better class than in its wild habitat or under warmer and moister conditions, it tends to flower too profusely, and this lowers its value as a paper material. A consignment sent in 1898 from Poona to London, by Woodrow, was accompanied with the statement that it could be delivered on board ship at Bombay at Rs. 40 per ton.

As marking the progress made, the following jottings, taken from official and other publications, may be here given. In the *Bengal Forest Department Report* for 1895-6, we read that the grass had been fairly extensively planted in Sahibganj, and that the produce sold readily at 12 to 14 annas a maund, and fetched at the mills Rs. 1-4 to Rs. 1-7, the railway freight being not over

---

**694**
3 annas 6 pies a maund. Mr. Wild, while Conservator of Forests in Bengal, devoted much attention to the supply of paper materials to the Calcutta mills, and among other subjects took up the study of bhabar. He then wrote, "When it is understood that the Calcutta mills turn out 360 tons of paper a week, or an equivalent of, say, 500,000 maunds a year, there is room for wood pulp as well as grass. It is believed that a consignment of 200 tons of pulp left Calcutta for Glasgow in 1896, at £4 2s. per ton. If the cost could be reduced to £3 10s. per ton—and there seems no reason why it should not—it would, it is thought, compete with esparto. Surprise has been expressed that the planting community in India does not pay attention to the cultivation of grasses, etc., for paper-making. There is evidently profit in it, and what is more, with the output of paper mills increasing every year, the demand, for some time to come, will be expansive."

In Murshidabad, according to Mr. B. C. Bose, Assistant Director of Agriculture, Bengal, it is now planted in clumps along the borders of mulberry fields. "Two cuttings are taken in the year, one in September and the other in March. With irrigation three or four crops can be had. This is at any rate the experience in Poonia. The March crop is cut after the grass has flowered, and yields very inferior fibre. No steps are taken to remove the flower stalks, no doubt owing to the cost of picking them out. The September crop does not flower, and yields the best fibre. The people look upon the formation of the flower stalks as a necessary evil, which they have no means of checking." The Calcutta mills draw their supplies from Sahibganj, Chota Nagpur and Nepal (the Terai), the last mentioned having, in recent years, contributed fairly largely. The Report issued by the United Provinces and Oudh for 1898–9 affirmed the annual production to be 200,000 maunds. The cutting in these provinces is said to commence at the end of October. That supply is very largely made use of in cordage.

**ISINGLASS, GELATINE, GLUE AND GELOSE.**—There are commonly said to be five classes of Gels:—(a) Calcareous (pp. 713–4); (b) Gelatinous (animal, p. 543); (c) Glutinous (vegetable, p. 293); (d) Resinous (see Tachardia lacea, p. 1063); and (e) Mixed Materials, non-resinous. With the first mentioned lime is essential, and they are collectively designated Mortars. Gelatine is prepared from animal flesh, bones, skins, hoofs and horns. It is a purer article than glue, which is made, as a rule, from the parings of hides and the refuse of the tan-yard generally. A mixture of glue and shellac is often used in India, the lac preventing the penetration of moisture, which softens and renders ordinary glue often useless. There is no chemical difference between gelatine, glue and isinglass. The purer transparent forms are used for culinary purposes. Fish-glue made from fish-bones is largely employed in India, and may be had all over the country, but no information exists as to the centres of production or the methods of manufacture. Edible Swallows' Nests may be described as Indian gelatine (see Birds, p. 138). Gelose is prepared from several Algae, designated in India as agar-agar, and in European commerce as China Moss. The best-known example is Gracilaria tichonoides (D.E.P., iv., 174–5). Numerous glutinous cements and pastes are in use in India, the commonest of all being made with the water obtained on boiling rice. [Cf. Glue:—Hoey, Monog. Trade and Manuf. N. Ind., 176–7; Notter and Firth, Theory and Practice of Hygiene, 1896, 808; Journ. Soc. Chem. Indist., 1904, xxiii., 1189–92; Isinglass:—Day, Sea Fish and Fisheries of Ind. and Burma, app. cxxl–cxlvi.]

**IVORY AND THE MANUFACTURES THEREFROM**

ELEPHANT.—No account of Ivory would be complete without some mention of the Elephant. In the Dictionary will be found a fairly detailed account of the Indian species. From the most ancient classic times this sagacious and most useful animal has been known, and the methods of capturing and taming it can hardly have been changed materially for the past two thousand years. The Hindu god Ganesha (son of Siva) is represented with an elephant's head on the body of a man. In the Rig Veda the elephant is the animal with a hand, and in the Atharvan he is the mightiest of animals. In the wars of the Ramayana and the Mahabharata, elephant corps were employed and India's Vahan is the elephant Airavat. According to Monier Williams (Buddhism, 23–4, 84, 525), the elephant is with the Buddhists the most sacred of animals. Among European writers, Megasthenes (300 B.C.), Strabo (25 B.C.), Arrian (Indika, 150 A.D.; ed. McCrindle, 213) and Asian (250 A.D.) give full particulars regarding the manner of hunting and capturing the elephant, the degree of its domestication and its use in warfare. Strabo (B. 1, 41–3, 704–7) gives a chapter on the kheddahs that might be read as an abridgment of Sanderson's corresponding chapter in Thirteen Years Among the Wild Beasts of India. The African elephant appears to have similarly been tamed, and the Carthaginians employed them as fighting animals. The inscription at Adulis (recorded by Cosmas, 545 A.D.) alludes to this special use. [Cf. Vincent, Periplus, app. 56.] During the ascendancy of the Roman Empire, elephants became quite common in Europe; but they ultimately disappeared, and for several centuries seem to have been altogether forgotten, and what is most significant, the African elephant, since the fall of Carthage, has hardly since been in such a complete state of domestication.

Poring over a gap of several centuries, little is said even of the Indian elephant, till Abd-er-Rezaak (Narr. Journ. Ind., 1442, in India in 15th Century, Majer, transl.), 27, 36 describes the elephants owned by the King of Vijayanagar near Bellary, and the method of capturing and taming them then prevalent. Nicolò Conti, speaking of Ava (Travels in the East, in India in 15th Century, 11–2, 37), alludes to the white elephant owned by the king. Athanasius Kirinius (Travels in India in 15th Century, 12) discusses the elephants seen by him. Varthema (Travel., 1510 (ed. Hakl. Soc.), 125–31) gives a most graphic account of the city of Vijayanagar and vivifies the ruined elephant stables, which in their desolation are to-day objects of special inspection by the curious. Garcia de Orta published at Goa the first edition of the Colloquies (1563, xxx.), and in that work we are given the Arabic name fil, the Deccan name ati, the Kanarese aceti, the Malabar aue, and the Eithopian yiembro. Mention is made of the large amount of African ivory annually imported into Camay, and of the existence of wild elephants in Orissa, Bengal, Tartary, Ceylon and Siam. This is followed by Acosta (Tract. de los Drganos, 1578, 417–48), who gives for the time when produced two admirable plates showing the wild and tame elephant with its war howdah. In the Voyage of Linschoten, some additional useful facts are told of Indian elephants. Barber (Memoirs, 1525 (Leyden and Erskine, transl.), 315–6) enumerates and briefly describes the animals and plants seen by him in India which he regarded as peculiar to that country, and assigns the first place to the elephant, which he speaks of as abundant in parts of the country where, during the memory of living man, no wild elephants have been known. Abul Fazl (Ain-i-Akbari, 1590 (Blochmann, transl.), 117, etc.) details the particulars of the Emperor's elephant stables, and of the rearing of that animal under domestication. Barbosa (Coasts East Africa and Malabar (ed. Hakl. Soc.), 167–8) furnishes an account of how elephants were caught in Ceylon and exported to India. Subsequent to the dates mentioned, many European authors have contributed to the stock of present-day knowledge regarding this most useful animal. [Cf. Pyrard, Voy. E. Ind., etc., 1601 (ed. Hakl. Soc.), ii., 343–6; Clusiuss, Hist. Exot. Pl., 1605, 166, 260; Terry, Voy. E. Ind., 1622 (ed. 1777), 134 (gives a long and most interesting account of the domestication and uses of the elephant in India); Mandelslos, Travels, 1662, in Olearius, Hist. Muscovic., etc., 51; Tavernier, Travels Ind., 1676, ii., 161, 317; Thevenot, Travels in Levant, Indostan, etc., 1687, pt. iii., 45; Ovington, Voy. Suratt, 1689, 191–4; Fryer, New Acc. E. Ind. and Pers., 1672–81, 35, 96, 211; Milburn, Or. Comm., 1813, i., 63; etc., etc. For recent works consult citation given in the D.E.P., iii., 208–9; also Journ. Bomb. Nat. Hist. Soc., 1895–7, x., 133–5; The Elephant in Burma, 1897–8, xi., 322–6, 355; 1903, xiv., 151–5; Jardine, Elephant Shooting, xiv., 100–2; Blanford, Fa. Br. Ind. (Mammalia), 463–7.]
CAPTURE OF ELEPHANTS

Distribution.—The elephant frequents the forest-clad portions of India and Ceylon from about Dehra Dun in the north along the foot of the Himalaya to Assam, Chittagong, Burma, Siam and Cochin-China, also in the forests of the Deccan, the Western Ghats, Mysore and South India. As a rule the elephant does not ascend much above 5,000 feet, but in Manipur and the Naga hills (Japvo) it has been met with at close on 8,000 feet. The chief centres of capture are in Assam (Garo hills more especially), in Mysore and Ceylon. It is generally affirmed that while all the Indian elephants constitute but one species—apart from that of Africa—there are several very distinct races such as those of Nepal, Assam, Burma and Mysore. The Nepd animal is small and especially adapted for life in a hilly country; the Shan elephant is tall, massive and handsome, but like the Ceylon race is often tuskless. Those of Burma and Chittagong are small and well suited for hilly countries, while the Assam animal is large and massive, hence better adapted for hunting purposes. The Natives classify the recognised races into kumeriah, the royal or princely, the thoroughbred; mirga, a tightly built and long-legged, arched-backed animal, suggestive of the deer mirga; and dvusada, the intermediate of the two former and the ordinary domestic or working elephant, the mirga being used in quick marching.

In India the animal is caught purely and simply for domestic purposes and is never (as in Africa) ruthlessly destroyed on account of its ivory. It is now captured exclusively by the kheddah system, and never by the cruel methods in pits, etc., formerly pursued. But there seem indications that, far from being exterminated, the Indian elephant is increasing in a higher ratio than the captures, and that the time may come when it may be necessary to keep the multiplication under control, so as to protect the cultivation of the tracts adjacent to the forests.

The chief Indian mart where elephants are offered for sale appears to be Sonepoo, near Patna, the mela there held being some time in October or November. An elephant costs about £40 to capture, and may be sold for £150. A full-grown elephant will weigh from 3 to 3½ tons, and stand from 7½ to 9½ feet at the shoulders. It is an adult at twenty-five years (but a calf may be obtained at thirteen to sixteen years), and its full age is 120 years. The only pace of the elephant is the walk, capable of being increased to a fast shuffle of about fifteen miles an hour, but for short distances only; it can neither trot, canter nor gallop. It cannot jump, can never have all four feet off the ground at one time, and hence a trench 7 feet wide is to it impassable, though the step of a full-grown animal is 6½ feet. The elephant will eat 600 to 700 lb. of green fodder, but is usually under-fed, getting 250 to 400 lb., and is fed mainly on leaves and boughs of trees. Most of its ailments proceed from unsuitable or insufficient food.

IVORY (ELEPHANT'S TOOTH).—Mention has been made of the fact that the Ceylon elephant has frequently no tusks. In India a tuskless male is called a mukna. The tusks of the Asiatic animal are considerably less valuable than the African. As a rule, the nearer the equator, the larger, finer and more expensive the ivory; but there are in addition many local manifestations. African ivory is closer in grain and not so liable to turn yellow nor to warp and split as the Indian; moreover, the ivory of the east coast of Africa is superior to that of the west. By "dead ivory" is meant ivory that has been found on the ground or

697
INdian Uses and Trade

Stored for a considerable time, until it has lost the oil or gelatine that gives elasticity to "green ivory." All the finer and more expensive ivory carvings are, as a rule, done on the best African ivory; and even in inlaying, the hair lines are invariably in the bluish-white African article, the larger patches being in the dull chalky Indian quality. For the microscopic structure of ivory, consult Hanausek (Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 422-8).

Perhaps one of the oldest samples of Indian ivory on record is that mentioned by Stein (Ancient Khotan, 1907, 209, 222, pl. xlviii). This was found in the Khotan oasis and dates from about the 8th century. As a curiosity, it may be mentioned that in the armouries of the Indian princes a large number of daggers will be found, the hafts of which are made of fossil or of walrus ivories. Some of these weapons have often histories that carry them back for one or more centuries; hence the traffic in conveying these special forms of ivory from Siberia or even from Greenland to India, mostly by tedious land routes, must have existed long anterior to the present methods and channels of commerce. For the microscopic appearances of the various fossil and other ivories, confer with Hanausek (l.c. 426-9).

Centres of Ivory Carving, etc.—There are four localities in India and one in Burma that may be spoken of as specially noted for their artistic ivories. These are Delhi in the Panjab, Murshidabad in Bengal, Mysore and Travancore in Madras, and Moulmein in Burma. Here and there all over the country ivory carvings and ivory turnery are met with, but the five localities named produce by far the best work. The chief artistic workers in India are Hindus.

Ivory Turnery, though less artistic, is even more widespread than carving: in fact, most towns have a few workers of this class. Small articles are made by them, such as bracelets (bangles), chessmen, antimony boxes, etc., etc. Some of the better known localities are Agra, Alwar, Bikanir, Jodhpur (more especially Pali), Amritsar, Ludhiana, Patiala, Tippera, Tirupati, Godavari, etc. With the Sikh the use of a comb is almost a religious observance. It is no wonder, therefore, that in Amritsar and other towns of the Panjab, ivory combs of great beauty are to be had. Here and there fabulous sums are expended on special chairs, houdahs and thrones made of ivory, or rather veneered with ivory; so also in the purchase of mats and fans woven by threads cut from the tusk. Ivory mats are often made at Delhi, Bharatpur, Murshidabad, Tippera, etc.

Ivory Inlaying.—In many parts of India wood is inlaid with ivory, but there are three localities that are specially noted for the superiority of this class of work. These are Mysore in South India, Hoshiarpur in the Panjab, and Monghyr in Bengal. Bone is sometimes used as an inferior substitute for ivory in inlaying.

Trade in Ivory.—The exports of Ivory (raw and manufactured) from India appear to have been declining for some years past. In 1876-7 they were valued at Rs. 55,582; in 1886-7 at Rs. 48,311; in 1896-7 at Rs. 60,501; but for the years 1901-7 they have been Rs. 27,740 in 1901-2; Rs. 27,827 in 1902-3; Rs. 26,795 in 1903-4; Rs. 26,956 in 1904-5; Rs. 44,655 in 1905-6; and Rs. 49,583 in 1906-7. The imports, on the other hand, seem to fluctuate very greatly, but on the whole the supply of raw ivory seems to be declining and manufactures increasing. Thus the raw and manufactured ivory imported in 1876-7 were valued at Rs. 24,55,637 (raw accounting for Rs. 24,15,514); in 1886-7
MACHLÁ-KA-DANT

the figures were Rs. 28,81,190 raw and Rs. 1,46,762 manufactured; ten years later (1896–7) the total of both kinds was only Rs. 23,19,229; and in 1903–4 the figures returned were raw ivory Rs. 18,20,766 and manufactured Rs. 2,35,809; in 1905–6, raw Rs. 14,52,379, and manufactured Rs. 2,41,699; and in 1906–7, raw Rs. 12,71,754, and manufactured Rs. 2,24,984.

Thus India is by no means self-supporting in the matter of ivory, but, as shown above, it has for several centuries procured large supplies from Africa. In Indian commerce ivory is spoken of as "elephant's tooth," but a second substance is called "fish tooth." This is of a dirty oily yellow colour, with the texture looking as if crystallised into patches. The significance of being called in every language of India by the same name is suggestive of a foreign origin. It is, as already explained, highly valued for sword and dagger hafts, and is more extensively so used than ordinary ivory. It would appear to be mainly if not entirely the so-called fossil ivory of Siberia—the ivory of the mammoth—a substance that has lain for countless ages in the frostbound drifts of Liakoff and New Siberia. It is also just possible that a fair proportion of the machlā-ka-dant of India is hippopotamus or even walrus ivory, the latter, along with fossil ivory, having found its way to India across the land frontier. In fact, from the antiquity of the daggers, etc., with fish-tooth hafts, it seems highly probable that the traffic in the commodity mentioned was a very ancient one—alone destroyed by the growth of fire-arms.

Walnut.

Timber.
Burrs.

JUGLANDS REGIA, Linn.; Fl. Br. Ind., v., 595; Gamble, Man.
Ind. Timbs., 662-3; Brandis, Ind. Trees, 619-20; JUGLANDÆÆ. The
Walnut Tree, ahkrôt, akhor, kalbshing, kôl, dûn, uqgh, ùtchha, etc. A large
deciduous tree of the Himalayan forests from Afghanistan to Bhutan
at 3,000 to 10,000 feet, and the hills of Upper Burma; also cultivated on
the Himalaya, the Khasia hills, and occasionally in gardens on other
temperate tracts.

The utilisation of the walnut and, accordingly, its cultivation in India date
from very remote times. Its chief value lies in its timber. The most important
use of the wood is for gunstocks, and as the European supply is becoming exhaus-
ted, Gamble points out that it is a matter for serious consideration whether
the tree should not be more extensively and systematically cultivated in India.
In Kashmir and throughout the Panjâb it is used for ornamental carving, turnery
and fancy work. The average weight is about 4 lb. per cubic foot. The huge
warts or "burrs" growing on the stem are also exceedingly valuable, the wood
of which is prized by cabinet-makers for veneer work. It is said that a good
burr may be valued at about 20s. per cubic foot. These burrs have at times
been largely exported from Kashmir to France, and Lawrence (Valley of Kash-
mir, 1895, 352-4) mentions that in one year countless numbers of trees were
destroyed by cutting out the burrs, for which a large demand then existed.
The bark is employed as a Dye and Medicine and is exported to the plains, where
it is used for cleaning the teeth. The fruit, which ripens in July to September,
is an important article of food in Kashmir and the North-West Himalaya generally
and is largely exported to the plains. The kernel yields a good description of
oil, while the rind is employed for tanning and dyeing. Lastly, the twigs and
leaves are utilised as FÖDDER. [Cf. Moorcroft, Travels Himal., 1841, ii.,

Serving; Fl. Br. Ind., ii., 613;

Duthie and Fuller, Field and Garden Crops, 1883, ii., 48-9, t. xlviii;
546-7; Prain, Beng. Plants, 1903, i., 519; Cucurbitaceæ. The kaddu,
lauki, tumri, kodu, tikta lâu, tumba, iro, kundânuga, etc. A climbing plant
found wild in India, the Moluccas and Abyssinia. As a result of cultivation
the fruit assumes many different forms, the best known of which are the
Pilgrim's Gourd, the Bottle Gourd, the Trumpet Gourd, and the Calabash.

This plant is extensively grown in many parts of India for its Fruit and
succeeds best on heavily manured soil. Sowing may take place as early as
February or as late as July, but for rainy-season crops two sowings are made,
the first in April, the second in June. It is best to sow the seed where the plants
are to grow, and about six feet should be left between each. The cultivated
forms are all eaten both by Europeans and Natives. By the former, the fruit is
boiled when young and used as a vegetable marrow; by the latter it is sliced and
cooked in curry, or the pulp is eaten with vinegar or mixed with rice. The dried
shell of the bottle-shaped gourd is used by the Natives for holding water or as
oil bottles, while the small wild form, tumri, is used for making the strung
instrument, the sitar, and the wind instrument, bin. The seeds yield a clear,
LARD AND TALLOW

LARD AND TALLOW.—The rendered fat of the pig forms the valuable commercial product Lard. A similar substance prepared from cattle and sheep is Tallow (see Live Stock, p. 754; also Oils, pp. 813-4, 819). Space cannot be afforded to deal with these substances separately. Speaking of lard, the best is the so-called Leaf Lard. This is derived from the fat surrounding the kidneys, and from the fleshy layers below the skin. In European trade two other qualities are prepared from the softer and more fusible parts of the fat, and are known as second and third quality lard.

LARD.—The following information regarding the manufacture in Calcutta

LARD

Lythcoefficient also resistance Banerjei, Cooke, Nagpur (in cattle in regions. attacked however, varies soon limpid etc. There general mechanical Hope refers to this tree. The average weight from about 40 to 45 lb. per cubic foot. A report is given by Unwin in Imp. Inst. Tech. Repts., 292-3; also in Agri. Legd., 1897, No. 9, 181-3) on various mechanical tests made on a block of this timber. He gives the following results:—weight, 41.77 lb. per cubic foot; resistance to shearing along the fibres, 382.4 lb. per sq. inch; coefficient of transverse strength, 5.22 tons per sq. inch; coefficient of elasticity, 544.1 tons per sq. inch; crushing strength, 2762 tons per sq. inch.

There appears to be no trade in this timber carried on in the provinces of India, except Assam. Of the Garo hills it is said that all the timber removed is exported to Bengal, and that the price of a standing tree is Rs. 6. In Cachar about 20,000 cubic feet are exported yearly to various places in the Sylhet district, and the price averages Rs. 1-2 per cubic foot. [Cf. Unwin, in Ind. For., 1898, xxiv., 89-91; Woodrow, Gard. in Ind., 1899, 318; Agri. Legd., 1902, No. 1, 43.]

L. parviflora, Roxb.; Duthie, Fl. Upper Gang. Plain, 1903, 353; Rec. Bot. Surv. Ind., 1904, iii., 59. The bakh, sida, dhaura, nana, bondara, chenangi, tsambelai, zaung bale, etc. A large deciduous tree common almost all over India, except in very dry regions. It is of considerable economic importance since the timber is in demand for general purposes such as house-posts, beams and rafters, door and window frames, agricultural implements, carts and boats. It also yields a good charcoal. The average weight is about 53 lb. per cubic foot. The bark has been employed in tanning and as a black colouring agent. It also yields a fibre used in Chota Nagpur for ropes, and the gum is said to be sweet and edible. The tree is one of those on which the tamar silkworm is reared.

LARD AND TALLOW—The rendered fat of the pig forms the valuable commercial product Lard. A similar substance prepared from cattle and sheep is Tallow (see Live Stock, p. 754; also Oils, pp. 813-4, 819). Space cannot be afforded to deal with these substances separately. Speaking of lard, the best is the so-called Leaf Lard. This is derived from the fat surrounding the kidneys, and from the fleshy layers below the skin. In European trade two other qualities are prepared from the softer and more fusible parts of the fat, and are known as second and third quality lard.

LARD.—The following information regarding the manufacture in Calcutta
is communicated by Mr. I. H. Burkill, from information derived from Mr. S. Francis, superintendent of the pig slaughterhouse, Calcutta. Formerly lard was made by three large firms and several small houses, but lard-rendering is now carried on by a few small Native concerns only, and these are situated round the municipal pig slaughterhouse. With the disappearance of large and responsible firms, the quality of the lard has degenerated. The manufacture goes on all the year, but the beginning of the hot weather is the busiest season, because then most pigs are brought in. Two kinds of pig are slaughtered; one, bred in Calcutta, is called the "China-pig"; the other, driven in from the villages of Bengal, is called the "country pig." The former is white, the latter black. The animals are slaughtered in the early hours of the morning and lard-rendering begins in the forenoon. The rendering house consists of a small room and a larger godown, where the lard is cooled and stored. The rendering is done in an iron pan about two feet across and eight inches deep, placed over a slow fire. Scraps of fat of all shapes, but none weighing more than three or four ounces, are washed in water for about two hours and then heaped up in the pan to above the level of the rim. When the lard is thoroughly melted it is poured out of the pan through a double thickness of cotton-muslin into an earthenware vessel, where it stands to set. Several times a day during setting it is stirred gently for about half an hour. The time taken in setting varies with the nature of the animal from which the fat has been obtained. Lard from the "China pig" takes about two days to set, that from the "country pig," a much less time, and the lard is of better quality. Lard thus manufactured will keep for about two months only, but formerly for a much longer time—a circumstance due apparently to the fact that fat of the freshest and best quality is not always used.

The best quality of lard is much used in cooking and in preparing ointments, etc., the second in the manufacture of lard oil, the third as a low-grade oil in soap-making. The oil is manufactured by exposing the lard in woollen bags between wickerwork to a pressure of about ten cwt. a square inch in the cold for about eighteen hours. The oleine thus obtained is pure, colourless and limpid. It is employed as an adulterant for olive oil in France, and for sperm oil in the Eastern States of America. It is also esteemed as a lubricant and is used for illuminating. In Medicine, lard has long held the principal place as a medium for the exhibition of other substances, as ointments, etc. As an external application it possesses emollient properties, and is extensively employed in external inflammations, bruises, sprains, and in various skin eruptions.

Tallow, as already stated, is prepared from beef or mutton and goat fat, or a mixture of these. It is a harder and less fusible fat than lard. The rendered tallow is refined by boiling with water; it is often bleached by means of nitric acid, and employed as a lubricant and for soap and candle making. When intended to make moulded tallow-candles, the finest mutton suet can alone be used, but for "dips" the refuse from the moulded candles or the cheapest tallow (a mixture of all animal fats) may be employed. Hoey (Monog. Trade and Manuf. N. Ind., 174) speaks of the candle-makers of Lucknow using charbī (fat), but though he deals most minutely with the industries of that city, he makes no reference to the lard and tallow manufactures. So again, speaking of soap manufactures, he states that charbī (bullock and buffalo fat and tel, either castor or linseed) is employed.
BOMBAY TRADE IN TALLOW

Trade in Lard and Tallow.—The foreign traffic in lard appears to be declining. The exports in 1876-7 were valued at Rs. 3,22,825; in 1886-7, Rs. 1,93,823; in 1896-7, Rs. 67,900; and for the past five years they have been:—1902-3, Rs. 52,810; 1903-4, Rs. 30,526; 1904-5, Rs. 15,500; 1905-6, Rs. 18,750; and 1906-7, Rs. 15,747. Corresponding with this change in the traffic, the imports may be said to manifest an expansion: in 1899 they were valued at Rs. 26,952; in 1900-1 at Rs. 47,058; and for the past five years have been:—1902-3, Rs. 61,462; 1903-4, Rs. 70,610; 1904-5, Rs. 55,454; 1905-6, Rs. 59,536; and 1906-7, Rs. 92,370.

The traffic in tallow corresponding to the lard just given was as follows:—exports were in 1876-7 valued at Rs. 31,234; 1886-7, Rs. 54,097; 1896-7, Rs. 95,574; and during the five years ending 1906-7 were valued at Rs. 1,70,721, Rs. 2,17,828, Rs. 1,30,099, Rs. 1,11,255, and Rs. 80,404. Thus it may be said this export traffic is, on the whole, an expansion. The imports in 1876-7 were valued at Rs. 62,671, and for the past seven years have been:—1900-1, Rs. 3,46,570; 1901-2, Rs. 5,51,976; 1902-3, Rs. 3,84,402; 1903-4, Rs. 5,93,127; 1904-5, Rs. 6,80,054; 1905-6, Rs. 8,16,705; and 1906-7, Rs. 9,14,834.

Nearly the whole of the Lard exported from India goes from Bengal to Mauritius. Formerly a fair amount was consigned to Reunion and to the Straits Settlements, but for some years past both these countries have discontinued their demands. India, as shown above, imports lard, and by far the major supply comes from the Straits, and recently from China (Hongkong), but Burma may be described as the receiving province. Of the total imports in 1903-4, viz. 316,111 lb. (the largest quantity for the past five years), valued at Rs. 70,610, Burma alone took 303,727 lb., valued at Rs. 65,203. The returns of the coastwise traffic do not show lard separately from "Other Provisions," so that it is not possible to discover to what extent Bengal or the other provinces of India are competing with the Straits for a share in the Burmese market.

Speaking of the traffic in tallow, it is curious that while Bengal is the province most concerned in lard, the tallow traffic is concentrated chiefly in Bombay. The foreign exports in 1906-7 were 4,135 cwt., valued at Rs. 80,404, of which Bombay exported 3,517 cwt., valued at Rs. 69,601. Of the receiving countries, Arabia seems to manifest the most constant demand, taking 2,260 cwt. out of the total. Imports.—A curious feature of the tallow traffic may now be mentioned, namely that Bombay, followed by Burma, takes by far the largest share of the foreign supply. During 1906-7 India imported tallow to the extent of 36,837 cwt., valued at Rs. 9,14,834, and of these amounts Bombay took 23,325 cwt., Burma 6,433 cwt. The countries of supply were the United Kingdom, 19,604 cwt., and Belgium, 6,288 cwt. There is no mention of re-exports, so that India would appear to be by no means self-supporting in its lard and tallow supplies. [Cf. Hurst, Lubric. Oils, Fats, etc., 1896; 180; also Soaps, 1898, 119-20; Blyth, Food Compos. and Anal., 1903, 310-6; Leach, Food Inspect. and Anal., 1905, 451-6].

THE CHICKLING-VETCH

LATHYRUS SATIVUS

teora, tiura, churul, lakh (or lac), lakhori,-lang, etc. An annual herb which, according to De Candolle, is indigenous to the region that extends from the Caucasus to Northern India.

Cultivation and Area, etc.—This vetch is cultivated throughout India as a cold-weather crop, and has the reputation of germinating on land too dry for other rabi crops. To this fact is largely due its value agriculturally. It can take the place of other crops when the October rain has failed, and as an article of food it is remarkably cheap. Statistics of actual cultivation are not available for the whole of India, so that a complete statement of the total area cannot be furnished. The following particulars of a few provinces are, however, instructive. In 1904–5 the Central Provinces had an area of 363,504 acres, chiefly in Nagpur (163,632 acres) and Chhattisgarh (152,046 acres) districts. Berar appears to have had 14,405 acres. Bombay (excluding Sind) 18,656 acres, mainly in Broach. Sind by itself had 232,070 acres, chiefly in Larkhana district (142,014 acres). The United Provinces do not appear to have published the area recently, but some few years ago the acreage devoted to the crop was said to have been 56,100 acres. No returns of any kind are available for Bengal, Assam, Burma, the Panjab, Rajputana and Central India, nor Madras. There is no evidence, however, that these provinces materially affect the total Indian production. The two chief areas are the Central Provinces and Sind.

Tillage and Yield.—To give some conception of the methods of cultivation, yield, etc., of this pulse, the admirable account given by Mollison (Textbook Ind. Agri., 1901, ii., 29; iii., 78–80) may be here drawn upon. Lang, he says, is almost invariably grown alone, though a slight admixture may be found in gram (Cicer arietinum) fields. It thrives best on deep, retentive, black soils. In the Deccan it is chiefly a second crop in rice-fields, but in Gujarat it is the sole crop of the year. In Broach it is generally raised on low-lying fields liable to be flooded by heavy rain, all fields which become waterlogged and too wet for cotton being commonly sown with lang. Tillage operations begin by ploughing after the first fall of rain. If the rains are unfavourable for cotton, the field is kept for lang and repeatedly harrowed during July, August and September. No manure is applied, but the ground is carefully prepared, since lang grown on clean ground is a good preparation for cotton in the succeeding year. Sowing takes place in September or early in October, and the seed-rate varies from 35 to 40 lb. per acre. The seed is dropped in the plough furrows in rows about a foot apart, and the surface levelled and pressed immediately after. No weeding is required, and the crop ripens in February about four and a half months after sowing. It is reaped before it is fully ripe, formed into small heaps in the field, and allowed to dry for a week. When dry it is threshed out under the feet of bullocks and winnowed in the ordinary way. The cost of cultivation is stated to be Rs. 13–12 per acre. In a well-grown crop the weight of pulse almost equals the weight of fodder. From full average crops in Broach, Mollison found the outturn of pulse to vary from 925 lb. to 1,068 lb. per acre, and of fodder from 1,220 lb. to 1,405 lb. Lang is cultivated chiefly as a FODDER, but as it is cheap and easily grown, it is considerably used as Food by the poorer classes, principally in the form of bread, dhal, or porridge.

Evil Reputation.—Much interest has been, for a century or more, spasmodically directed to this pulse, on account of its evil reputation of causing paralysis
LATHYRUS

SATIVUS

Lathyrus

of the lower extremities, when eaten continuously for any length of time. But it might be said that the whole family of Leguminosae, much as we use them, are in some respects a suspicious family. A few years ago I gave attention to this particular pulse, and in consequence placed before the members of the Medical Congress of Calcutta (1894) the results of my inquiry. I then pointed out that it exists in two sizes, the smaller form being known in Chhattisgarh as lakhori and the larger in Nagpur and Bhandara as lakh. The former is some 30 years earlier than the latter. Its seeds are broadcasted over the flooded rice-fields (towards the close of the rains), while the latter is sown on rich black, dry soils, on land ordinarily devoted to wheat. The opinion seemed universal that while the lakhori or rice-field cultivation yielded a harmless seed, the lakh or wheat-field crop was very dangerous. There would appear to be no botanical characteristics to account for this remarkable difference.

Speaking on the dangerous property of this pulse, Major A. Buchanan, I.M.S., who has given the subject much careful study (Lathyrism Rept., 1904, 25), says, "Continued growth of rice-land teora on rice land has produced a different race. At any rate it is easy as a rule to distinguish a heap of lakh from a heap of lakhori, but there might be a difficulty in distinguishing single seeds of the two kinds. The wheat-land teora or lakh is as a rule larger." The weights of a hundred seeds of lakh varied between 245 and 110 grains, the weights of lakhori varied between 108 and 77 grains. The colour of the wheat-land teora is darker than the colour of the rice-land teora. The latter is called the yellow latri in Chhattisgarh. In that district the people consider that the yellow latri is non-poisonous, and the people of Bhandara have for many years held the same opinion. For our present purpose it may, therefore, suffice to thus indicate the two crops met with in India.

Properties of the Pulse.—Sir J. B. Fuller, while Commissioner of Jabalpur, suggested that the greater care taken by the people of Chhattisgarh in cooking this grain might account for their partial immunity from toxic action. The grain, he explained, is in Raipur commonly parched before being ground, and the husk of the grain is, moreover, separated and not eaten. This causes a loss of 25 per cent. in the weight—a loss which those in poverty are naturally averse to sustaining. The flour thus prepared is next baked into cakes (chappatti), or boiled with buttermilk into a paste known as mahera. This suggestion led to the supposition that the poison might consist of some volatile substance expelled by the dry heat, or that it resided in the husk. Mr. Cleveland suggested that teora loses its poisonous qualities when eaten along with mahua (the flowers of Bauhinia latifolia). So also many years ago Dr. Kinloch Kirk pointed out that rice be to be completely wholesome must be kept for some time. The best rices are three years old. Rice under-kept boils thick and becomes gummy, and is not wholesome. Hence it has been argued that the age of the lakh grain may similarly have something to say to its poisonous property.

The following chemical analysis of the pulse is given by Church (l.c., suppl., 13):—water 11.1, albuminoids 24.4, starch, etc. 55.3, oil 1.0, fibre 5.4, ash 2.8. The nutrient ratio is here 1:2.3 and the nutrient value 82.

Lathyrism.—Mention has already been made of the fact that it has for long been known that a form of paralysis, to which the name Lathyrism has been applied, is believed to result when this pulse is eaten continuously for some length of time. One peculiarity of the disease (in men) is that it affects adult males chiefly (1 in 10). Another, that it is the lower extremities that become paralysed. But similar results are produced when the pulse is given to horses, cattle, pigs. Investigations have been conducted at the Imperial Institute with a view to ascertain the nature of the poison, but the results so far attained have been entirely negative. The poisonous property, we are assured, is not due (as has been supposed) to a volatile alkaloid that might be dissipated by superior methods of cooking, nor to any ordinary chemical poison. Dunstan has very properly pointed out that it is by no means certain that the seeds sent to Europe for examination were actually those of the poisonous sort. But it may have been inferred from the observations already made that we have no simple method by which to ascertain when the seeds are or are not poisonous, and can but procure supplies from localities where the paralysis mentioned prevails. In no instance does the poison exist in such abundance as to give immediate indication of its presence. It is only after protracted consumption that the paralysis appears. In fact there would even seem grounds for suspecting that the plant may only be intermittently poisonous, so that no particular race or crop could be
THE HENNA PLANT

LAWSONIA ALBA
Henna

pointed out as the poisonous seed. The subject has been approached at the instance of the Imperial Institute from another point of view, namely investigations to ascertain if the pulse possesses a poisonous fungal parasite that could account for the toxic action. Prof. Percival, of the Wye Agricultural College, failed to discover any such fungus.

Recently the disease has been very prevalent in the Central Provinces, and a census showed that the number of people more or less paralysed was over 7,600. In view of this fact Major Buchanan was put on special duty to inquire into the cause of the spread of lathyrism, and to endeavour to find means for its prevention. The results of his investigations are embodied in a bulky report (to which reference has already been made). He gives the following general summary:—"It has been shown that lathyrism is due to the consumption of Lathyrus; that the disease, when it occurs in big epidemics, follows famine or scarcity; that it is chiefly confined to wheat-growing areas; that failure in wheat is an important factor in the causation; that the disease is chiefly found among the poor, and that debt is an important factor in the causation. Under certain circumstances Lathyrus is a good article of diet, and it is only when the proportion reaches or exceeds one-half of the whole ration that paralysis is likely to occur." On the other hand, Dr. A. G. Hendley (Brit. Med. Journ., 1903, ii., 707–9), after discussing fully this subject, arrives at the conclusion that "Lathyrus, whilst it may possibly cause paralysis by itself, ordinarily only predisposes to it, that it makes the subject ready or ripe for the attack of paralysis, but that exposure to severe wet and cold is required actually to excite the sudden seizure." "The attack occurs after an unusually thorough wetting whilst ploughing, watching crops at night or other field work that ordinarily falls to man's lot and not woman's."

Trade.—No particulars can be furnished of the trade in this pulse. It is known to be occasionally exported. Some few years ago a sample of what was called "matar, or Indian Grey Peas" was shown to me by a Glasgow corn-merchant. I pointed out that while this pulse was occasionally called matar, the true matar of India was the Grey or Field Pea. It is, therefore, most important that the present pulse should not be confused with the grey pea of India, which is as harmless and useful as the grey pea of Europe. The wedge-shaped pea of the present plant, flattened on two sides and marbled on the surface, should easily be distinguishable from all the peas or pulses of India, except perhaps gram (Cicer arietinum); but while gram is somewhat triangular in section it is prominently tapered below into a beak, and is devoid of the marbling of Lathyrus.

Henna.

Cultivation.

Cultivated throughout India on account of its Leaves, which yield the "henna" dye and also as a garden hedge plant. The soil is repeatedly ploughed and heavily manured, and the seed is soaked in water for twenty-five days before sowing, which takes place in April and May. The plot of land where the seeds are to be sown is formed into beds and kept flooded for some days. The seed is scattered on the water and sinks with it into the ground. For three days water is given both night and morning; after that only once a day till the plants

706
LEAD and its Salts and Manufactures. — Ball, Man. Econ. Geol. Ind., 1881, iii., 281—311; King and Pope, Gold, Copper, Lead in Chota Nagpur, 1891, 95—9, 156, 159—69; Rec. Geol. Surv. Ind., 1904, xxxi., pt. 1, 46—7; Holland, Rev. Min. Prod. Ind., in Rec. Geol. Surv. Ind., 1905, xxxii., pt. 1, 110. This metal bears among other names the following:—sisa, bindi, surb, ikam, temãtam, khai-pok, etc. It rarely occurs anywhere in the native state, and is never found in that condition in India. Its commonest ore is the Sulphide or Galena, surma, anjana. Other common ores and salts are:—Red Oxide of Lead, sandhur, segapú, temaméra, h'sang, etc.; Litharge, murdasang, marudar singhie; Carbonate of Lead, safédá, vullay, sibaydí, etc.; Chromate of Lead, peori-wilayti ( = English peori, see p. 765).

Mining. — Although lead ores have been worked to some extent in ancient times, at the present day lead-mining in India is practically in a dormant condition. Holland makes the following statement with regard to it:—"Galena alone, or with blende and other sulphide ores, is known in various parts of India and Burma, and has been worked in various places for lead or lead and silver, under past Native rulers; but the mining of lead-ores has long been extinct, and the only recent attempt calling for special mention is that now being made to develop the deposits near Pang Yung in the Northern Shan States formerly worked by the Chinese, who left behind large heaps of slag reported to be amenable to profitable treatment by modern metallurgical processes for the extraction of silver."

Manufactures. — The metal is comparatively little employed by the Natives of India as compared to its scarcerness. It is, however, occasionally used in the manufacture of certain wares and alloys, as for example in Hyderabad and Lucknow, where it is a component of the alloy of which Bi'di ware is made (Watt, Ind. Art at Delhi, 1903, 47). Both the red oxide of lead and the carbonate or white lead are commonly utilised as pigments, e.g. in lac turnery (Watt, l.c. 211—2, 231), in Afridi waxcloth (Agri. Ledg., 1901, No. 12, 400 et seq.). Red oxide is largely employed for religious purposes by the Hindus, who mark their idols and their money with it. All married Hindu women employ it as a paint to give a circular spot on the forehead. In Medicine, the monoxide or litharge, the carbonate, acetate, sub-acetate, nitrate and iodide are all official in the Indian Pharmacopoeia. All these salts, except the acetate, are applied externally only, as sedative and cooling astringents, in various skin diseases. The acetate is similarly used, but is also administered internally.

Trade. — The Imports of lead from foreign countries are very considerable.
LENS ESCULENTA
Masūr.

in 1906–7, 102,465 cwt., valued at Rs. 15,82,550. In addition, Government imported 12,301 cwt., valued at Rs. 1,58,840. The greater part of these imports came from the United Kingdom. But it has to be pointed out that the chief market is the supply of the tea industry with the sheet lead required for lining tea chests, which is admitted free of duty. This came in 1905–6 to 82,166 cwt., valued at Rs. 11,25,738, and in 1906–7, 57,307 cwt., valued at Rs. 8,76,730, and was consigned from the United Kingdom also estimated to Bengal. In the year 1906–7 the chief sources of supply for lead of all kinds were as follows:—United Kingdom, 76,230 cwt.; Australia, 16,001; France, 4,139; Belgium, 2,090; Ceylon, 2,864. The share of the Presidencies and Provinces in the imports were:—Bengal, 72,548 cwt.; Bombay, 10,772; Madras, 6,197; Sind, 4,918; Burma, 3,493.

LENS ESCULENTA, Moench. : Duthie, Fl. Upper Gangain.
Plain, 1903, 257; Prain, Beng. Pl., 1903, i., 367; Bremis Lens, Duthie & Fuller, Field and Garden Crops, 1883, ii, 13, t. xxxii.; Fl. Br. Ind., ii., 179; Leguminosae. The Lentil, masūr, channangi, mohr, chanching, kerze, adah, misurpurpur, misur-pappu, etc. A valuable pulse, grown as a winter crop all over India. According to De Candolle, it is a native of western temperate Asia, Greece and Italy, and has long been cultivated in Egypt, whence it was conveyed to India. As an article of food it has been known from the most ancient times.

Cultivation.—At the present day the lentil is cultivated in all parts of India, especially in the Central Provinces, Madras and United Provinces. The following is a brief summary of the area under cultivation and the methods pursued in those provinces about which trustworthy information can be obtained.

Bengal.
Rotation.

Cultivation. — At the present day the lentil is cultivated in all parts of India, especially in the Central Provinces, Madras and United Provinces. The following is a brief summary of the area under cultivation and the methods pursued in those provinces about which trustworthy information can be obtained.

Bengal. — Separate returns for this pulse are not recorded, hence an estimate of the area under cultivation cannot be given. It thrives best on a clay soil, since in light soils the plants wither away. In rotation following paddy (rice), the land receives three or four ploughings and the seed of the lentil is then sown October to December at the rate of about 5 seers per bigha (= one-third acre). In some parts of the country it is mixed with barley. Harvesting takes place from the middle of February to the middle of April; the crop yields about 8 maunds per acre. The cost of cultivation has been estimated at Rs. 2–10 per acre. [Cf. Basu, Agri. Lohardaga, 1890, pt. ii., 34; Banerjei, Agri. Cuttack, 1893, 83.]

Assam. — Cultivation is chiefly confined to the champaris of Kamrup, Nowgong and Mangaldai. In Upper Assam it is cultivated to a small extent in the Majuli. The crop prefers a light, loamy soil and an open situation, and generally follows a broadcasted dhu (rice) crop, and is sown in mixture with mustard. Sowing takes place within the first fortnight of November. The seed rate is 12 lb. per acre, if sown with mustard, but if sown alone, about 50 per cent. more seed is required. Harvesting takes place in March and April, and the usual yield is about 2 to 4 maunds per acre. [Cf. Agri. Dept. Assam Bull., 1902, No. 9, 11.]

United Provinces. — The area under masūr is not separately recorded, but in 1904–5 peas and masūr together occupied an area of 2,055,879 acres, distributed thus:—1,437,152 acres in Agra, 618,727 acres in Oudh. According

708
LIME

to Duthie and Fuller, cultivation is most extensive in the damper parts of those provinces. It is sown in all kinds of soil, but chiefly in low-lying land. Generally it follows early rice, being often sown while the rice stalks are standing, and is allowed to grow up amongst them. The seed rate varies with the condition of the ground, but is commonly about one maund per acre. The outturn from unirrigated land varies from 64 to 8 maunds per acre, but with irrigation may reach 10 to 12 maunds.

Central Provinces and Berar.—In 1904-5 the area under the crop was in the Central Provinces, 231,756 acres, chiefly in the Chattisgarh, Jabalpur and Nerudda Divisions, and in Berar, 13,167 acres. It is generally sown on the best black soil.

Panjab.—No statistics of area are available. In the Jhang district, which is typical of the province as a whole, it is a sailaba or inundation crop. New alluvial soils or light lands, not good enough for wheat, are selected. The land is ploughed once or twice and the seed is sown broadcast, 30 to 45 lb. per acre, from December to January. The crop is ripe in March to April. [Cf. Gaz. Panjab Dist.]

Bombay.—In 1904-5 the area was 9,791 acres, chiefly in Násik (5,097 acres) and Belgaum (2,918 acres). Māṣir is always an unirrigated rabi crop, and generally is grown alone. In Poona it is the sole crop of the year, and is rotated with dry-crop wheat. The soil is mixed black, but only of moderate depth. In September and October the land is repeatedly ploughed, and in October the seed is drilled in rows a foot apart at the rate of 20 to 25 lb. per acre. The crop ripens in three and a half months, and a good outturn is about 300 lb. per acre. [Cf. Mollison, Textbook Ind. Agri., 1901, iii., 89-90.]

Food.—In India it is eaten as dāl, flavoured with various aromatics and condiments, also as a component part of the dish called kēchāri, and is considered the most nutritious of the pulses. The young pod is also eaten as a vegetable, and the dry leaves and stalks are greatly prized as fodder. In Europe this pulse meal, mixed with barley flour or other cereal and common salt, is sold as an invalid food under the name Ervalenta or Revalenta. Leather (Ind. Food-Grains and Fodders, Agri. Ledg., 1901, No. 10, 366) gives the following chemical analysis:—moisture 8-03 per cent., oil 1-06, albuminoids 23-0, soluble carbohydrates 61-14, woody fibre 2-42, soluble mineral matter 3-54, sand and silica 0-61, total nitrogen 3-94, albuminoid nitrogen 3-68. As a Medicine, lentils have long had the reputation of being useful in cases of constipation and other intestinal affections.

LIME, MARBLE, CHALK, etc., or Calcium and its Salts and Manufactures.—Although Līme (Calcium) does not exist in a pure state, in the form of the carbonate it constitutes a by no means insignificant portion of the earth’s crust, e.g. limestone rocks. Lime-burning is the operation of driving off carbonic acid from the carbonate with the production of the oxide of calcium or Quicklime. This readily absorbs water and becomes Slaked Lime or hydrate of lime (Agri. Ledg., 1902, No. 5, 137-47). The subject may, therefore, be dealt with under two great sections—Calcium Carbonate and Calcium Sulphate.

LIME, CARBONATE OF.—This is known in India by an extensive series of vernacular names that denote the conditions (quicklime, slaked lime, etc.) and the sources (limestone, marble, chalk, shells, etc.). The most general name is perhaps the Hindustani chūndā, a word which in the various languages of India assumes numerous forms, such as chūndā, chīn, chin, chūnak, chūnāmbu, chūrna, shunnambu, sunnam,
sunna, hunna, hunu, etc. Its most general name in Sanskrit would appear to be sankha-bhasma, but certain writers give also chûnâ ("powder"), sudha, kapardaka-bhasma, sukti-bhasma, etc. Its Arabic names appear to be kils and ahû and its Persian nurkah and ahak. Chalk is very generally known as khari-matti or kharya-mitti. Unslaked or quicklime is kali-ka-chuna or simply kali or kalai, often also called ahak; limestone is kalai-ka-pattar; shell lime is sipi-ka-chuna; the lime from limestone being kattal-ka-chuna; marble is marnar; fossil corals are sang-i-yahada.

The word chûnâm, by modern usage, generally denotes, however, the beautiful plaster or cement characteristic of many localities of India, more especially in the south (see below in the paragraph devoted to Mortar and Cements, p. 713). One of the earliest European writers to use the word chûna appears to be Garcia de Orta (A.D. 1563), although fifty years previously the Italian traveller Varthéma describes the people around Calicut as eating betel leaves along with a certain lime made from oyster shells, which they call "cionama."

Sources.—There may, in India, be said to be three great groups of rocks or materials that afford lime, as follows:

(a) Limestone, Dolomite, Miloliite, etc. (Imp. Gaz., iii, 148-50).—Hardly any known geological formation in India is wholly without limestone in some form, although many of the examples are exceedingly impure and scarcely worthy of the name. Mr. R. L. Sevenoakes, in the Journal of the Queen Victoria Indian Memorial Fund (No. 2, 26-31) (a publication here utilised freely), describes some twenty different kinds of Ornamental Building Stones. Some Indian ornamental stones are of nearly equal merit to the marbles specialised below, and still others gradually decline until they have to be characterised as at most only good building limestones. The limestones procurable in many parts of Bombay and Sind, for example, are admirable building stones, though marble nowhere exists in that Presidency. The Porbandar miloliite (foraminiferal limestones) has been conveyed from Kathiawar to Bombay and even to Calcutta, and is employed in the construction of some of the more important of the recent buildings of these cities. In South India it may be said that crystalline limestones occur in Trichinopoly and Coimbatore, but of very inferior quality; good building limestones are found in Cuddapah, Karnul and Guntur, and marbles at Palnad. In the Central Provinces there are numerous examples of limestones and admirable building stones, such as those of Wardha, Nagpur, of the Vindhyan formation, such as the limestones of Katni; and in the United Provinces the crystalline limestone of Mirzapur, which occurs in the metamorphic rocks of that district. In various localities of the Panjâb good limestones and even marbles are found. Lastly a reference is essential to the limestones of Lakhimpur and of the Khasia and Jaintia hills of Assam.

The most important sources of limestone and lime may thus be grouped commercially:

1. SATNâ in Rewah and at Katnî; in the Jabbalpur district. From both localities lime of excellent quality is carried as far as Calcutta (624 and 685 miles distant), and constitutes a large proportion of the lime used in that city. 2. SYLHET.—Along the southern foot of the Khasia and Jaintia hills there is an inexhaustible supply of nummulitic limestone, which formerly supplied the whole of the demand of Calcutta and Lower Bengal,
KANKAR

and still does so to a large extent. The returns of 1904 show a supply of 123,108 tons of lime, valued at £9,496. 3. Rhotasgarh.—The lower Vindhyan limestone near Rhotasgarh is quarried to a small extent, and exported down the Són in boats; it was largely used in the works of the Són Canal. Good lime is made from the deposits at Bisra, in the Singbhum district, and has recently begun to arrive in Calcutta in increasing quantity. 4. Himalaya.—Along the foot of the Himalaya, boulders of limestone are collected and burnt in large quantities every year; the slaked lime is exported on camels and supplies a large portion of the Panjáb and the United Provinces. 5. Andaman.—There is a band of cream-coloured marble near Port Blair which may prove of economic importance, as it is about the same distance from Calcutta as Katni, and the lime is of equally good quality. 6. Other Localities where limestone is known are numerous, but at present of merely local importance, or in many cases of no value whatever. A full list of them as far as they are known will be found in the Manual of the Geology of India (1881, iii., 449 et seq.).

(b) Lime, Concretionary or Kankar: Imp. Gaz., l.c. 23.—Medlicott explained the formation of this substance as due to the evaporation of the ground water, containing in solution more or less of carbonate of lime, produced in the slow process of soil-formation by the general decomposition of rock particles. Its production is, however, very much a matter of climate, i.e. alternating periods of extreme moisture and dryness. In the vast majority of cases a layer of kankar (a word which means simply nodular stone) will be found to underlie úsar soils. This circumstance has been purposely only incidentally alluded to in the passages that deal with réh efflorescence (p. 52), because, although doubtless formed by the same processes, réh and lime have not been shown to be dependent on each other. Réh efflorescence may occur without any formation of kankar, and conversely kankar may exist within the soil without any evidence of réh efflorescence or even of an abnormal deposition of soluble alkalis.

Kankar is the chief source of lime in Upper India, and it yields an excellent and somewhat hydraulic cement. Holland (Rev. Min. Prod., l.c. 1898–1903, 102) speaks of kankar and laterite as "about the most valuable assets in building material possessed by the country." James Cleghorn (Ind. and East. Engin., June 1898, 356–7) gives the results of his study of this substance and of its practical utilisation as mortar. Very often the nodules of kankar are so abundant, at certain depths below the surface of the ground, that they become consolidated into blocks. Such blocks when obtainable are largely employed for building purposes, and were so used extensively in the Ganges Canal Works. Kankar, broken and hammered while water is poured over, is the material mainly used for road-making in the greater part of India. This circumstance gives at once a vivid conception of the abundance and extensive distribution of the substance. Kankar has been tried as a flux for iron on several occasions, but with very indifferent results. Its composition is too variable and its liability to adulteration too great to admit of its use, except where limestones are not available. "Large quantities of lime are made in various parts of India from highly calcareous surface soil."[13] "This lime when mixed [with proper proportions of sand makes most excellent mortar." (Rept. Chief Insp. of Mines in Ind., 1904, 4.)
(c) **Lime, Shell and Coral.**—All over India shells are burned for lime. Away in the interior of the country, wherever annual inundation occurs, a marvellous crop of exceptionally large land shells furnishes an abundant supply for most local necessities. In the Murshidabad district, for example, the following shells are so employed:—*Unio marginalis*, *U. flavidens* and *Ampullaria globosa*. On the coast tracts of India and Burma, immense beds of marine shells and of raised coral reefs are met with (see p. 989). Holland (l.c. 1904, 21) says that “the returns of various districts in Burma show a production of 67,461 tons valued at £11,852.” These deposits, wherever met with, are regularly utilised as sources of lime, and in South India have mainly given birth to the prosperous industry of Portland Cement manufacture—an industry that is likely to be very shorty organised near the mouth of the Ganges, where rich beds of marine shells are abundant, and may be used to supplement the Sylhet limestones. Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1904-5, 32) observes that while the proportion of lime in limestone and *kankar* is variable that of shells preserves a uniform high average. A sample of stone-lime examined contained 55-3, while a specimen of shell-lime gave comparatively 96-9 calcium carbonate.

**Industrial Uses of Lime, Limestone and Marblé.**—Lime is universally present in the ash of all plants. As a manure, therefore, it plays an important part, especially for soils rich in organic matter. [Cf. Trop. Agrist., 1906, xxvi., 70-5, 180-8.] It hastens decomposition of both animal and vegetable matter. In the form of chloride of lime (bleaching powder) it was at one time largely utilised as a disinfectant, but has been considerably displaced by more effectual and less objectionable substances such as carbolic acid. As a bleaching reagent chloride of lime is extensively employed, such, for example, as in the raising of metallic colours, in discharging Turkey reds, and in calico-printing, etc. In India lime is made into a resist paste with ordinary gum-arabic, and in that form is utilised by the calico-printer. Lime, in some form, is in fact very generally used in the dyeing and tanning industries. It is, for example, nearly universally employed by the Native manufacturers of indigo. [Cf. Monographs, Dyes and Dyeing:—Assam, 4; U. Prov., 84; Bombay, 24, 30, 34, 37; Madras, 4.] Along with sugar it is added to the dyer’s indigo vat in order to assist in the production of white indigo. Calcium carbonate is employed as an oil paint for indoor work, and as a water colour mixed with gelatine. The Afridi waxcloth workers (see Carthamus, p. 282) add lime to their roghan to reduce its liquid condition and make it dry readily. The tanner utilises it to remove the hair from hides. [Cf. Monographs, Tanning and Working in Leather:—U. Prov., 7, 9; Madras, 12, 30-4; Bombay, 15; Bengal, 10-11; C. Prov., 68.] Lime was formerly of the greatest importance to both the soap and the candle makers (in the saponification of the fats), though in Europe to-day they mostly purchase a prepared alkali. Lastly, limestone is necessary as a flux in iron-smelting. [Cf. Blount and Bloom, Chem. for Engin. and Manuf., 252; Alder Wright, Oils, Fats, Wages, etc.]

**Food and Medicine.**—As an article of (what might be called) food, it is largely used by the people of India. In other words, it is an essential ingredient in the preparation known as pán. The lime obtained from shells is objected to, however, for that purpose, by certain Hindus, on the ground that it is derived from animals. It is used in the defecation of the saccharine juices (see pp. 929, 954). The coagulation of the nitro-
MORTAR AND CEMENT

genous matter by boiling is less perfectly accomplished in the case of beet than of cane juice. The addition of slaked lime accordingly greatly facilitates that result by the formation of insoluble lime compounds. For medicinal purposes, lime enjoys a well-recognised position, more especially as the basis of the mild antacid known as "lime water." [Cf. Waring, *Baz. Med.*, 1897, 90-4; Barry, *Legal Med.*, 1902, 389, 451.]

Mortar and Cements.—By far the most important use of lime is as mortar—a cement which consists of lime, sand and water (see pp. 292-3, 695). If lime be mixed with water, a paste is formed that will rapidly harden or "set," as it is called. When dry it will, however, be found to crack and crumble to pieces. To prevent this it is mixed with sand (or in India with the fine powder made from brick known as surkhi). To obviate a too rapid evaporation of water from the mortar, it is customary to moisten the stones or bricks, when a much more durable cement is the result. If mortar be properly prepared, a thin layer is found sufficient to bind together the materials with which it is mixed.

Stein (*Ancient Khotan*, 1907) describes the stucco used in plastering the surfaces of walls made of wood, mud, and (sun-dried) bricks in buildings uncovered by him from the sand with which they had been engulfed during the 3rd to the 8th centuries. The stuccoed surfaces were found to have been frescoed very elaborately and beautifully, and in many cases statues made of mud were found to have been coated with stucco and subsequently painted. In a further paragraph reference will again be made to Stein's discoveries in connection with plaster of Paris (see p. 718). It would thus seem fairly certain that advanced knowledge existed in Eastern Turkestan of certain uses of lime long before that material came into use as a cement in stone and brick construction. The oldest constructive buildings in India, such as the Chulikyan temples of the Deccan, have the stones so fitted into each other or are of such massive blocks that they have remained in their positions for centuries without cement of any kind having been used. It seems thus fairly certain that the use of cement in house-building was subsequent to the date of the temples named. [Cf. *Papers Relat. to Magnesia Cement*, Mad. Govt., 1826-37; Butler, *Port. Cement*, 1899.]

There are commonly said to be the following classes of cements:—
(a) calcareous; (b) gelatinous; (c) glutinous; (d) resinous; (e) mixed materials but non-resinous. The first mentioned are those with which the present article is more immediately concerned, such, for example, as the mortar already indicated. A hydraulic cement, or Portland cement as it is called, is in other words a cement which has the property of setting under water. This is obtainable from certain limestones that naturally contain from 10 to 25 per cent. of alumina, magnesia and silica, or may be artificially manufactured by mixing 65 to 80 parts of chalk or other pure lime with 20 to 35 parts of river mud or clay and a little oxide of iron, say 3 to 14 per cent. These ingredients are thoroughly mixed in water, dried slowly, calcined, and then reduced to a powder. In India, Portland cement is at present mainly manufactured in the Madras Presidency, and more recently works have been started in Bengal, but in other provinces it is occasionally prepared, and chiefly from argillaceous kankar to which a certain proportion of fat limestone is added. But it is a striking peculiarity of these hydraulic cements that
their adhesive power is diminished by mixture with sand. When used as a stucco the sand employed must be perfectly free from loam, and the surface must not be painted over (if that be so desired) until the cement has been thoroughly dry for some months.

It may further be added that if Portland cements have more than 4 per cent. magnesia they rapidly decompose when kept under water. A cement with a basis of white magnesia in place of clay is sometimes known as “White Mortar.” There are large deposits of magnesite and of magnesium limestones (dolomites), especially near Salem in South India, and these it is understood have recently been taken advantage of by the Madras Portland Cement Company in the preparation of a cheap, easily applied and rapidly drying plaster that takes a fine polish. In the public press it is not uncommon to read the certificates of “Arbuthnot’s Portland Cement” as being “equal to the best-known brands of English Portland Cement.” Mr. C. S. Middlemiss wrote in 1896 a most interesting report on the magnesite areas of the Chalk Hills near Salem (Agri. Ledg., 1896, No. 15). Papers written by James Cleghorn (Ind. and East. Engin., May 1894, 320–1; 1898, ii, 210–11; iii, 32–3; iv, 28, etc.) will also be found to contain much useful information regarding magnesian cements. [Cf. Blount and Bloxam, Chem. for Engin. and Manuf., 1900, 132–42; Min. Indust. in U.S.A., 1900, 75, 82; Gilmore, Hydr. Cements, 1–334, etc.]

Chūnām.—Incidental mention has already been made of the fact that an admirable polishing and exceedingly strong cement (sometimes spoken of as chūnām) is made in several parts of India. There are various methods of preparing this substance, but these all practically agree in the circumstance that some saccharine substance is combined with the lime as well as powdered marble, plaster of Paris or steatite. The sugar most commonly employed for this purpose is the jaggery obtained from the cocoanut palm. The milk of that palm is also mixed with lime in the preparation of a very superior whitewash. It is believed that the sugar promotes the solubility of the lime, thus allowing of a finer and more complete state of division.

A special art of some parts of India, as, for example, in Bikanir, consists in carving cemented surfaces into rich floral designs that may be subsequently gilded or painted. [Cf. Ind. Art at Delhi, 1903, 95–6.]

Cement Materials.—Lime or some of its salts (such as plaster of Paris) is largely employed in combination with glutinous and resinous materials in the formation of cements. The rice-water is in India commonly mixed with a certain percentage of pure lime in the preparation of a strong cement which is employed to join the various parts of musical instruments in place of glue. Instead of rice, the dough of fine flour may be kneaded in water until gluten only remains. To this should then be added a small quantity of pure lime. The cement thus prepared is largely used for all forms of woodwork, and has the special merit of resisting damp. It is generally known by the name sūjī. Lac combined with borax forms a convenient cement to be used where exposure to water or moisture is unavoidable. Cutlers’ cement consists of rosin, bees’-wax and brickdust and plaster of Paris, or simply rosin and plaster of Paris. Dr. Fleming, in his Account of the Salt Range, says the Natives use plaster of Paris, mixed with pure lime, to produce their finest
qualities of shining marble-like chünám. It is also largely employed as a whitewash.

For the materials employed along with lime in the formation of special cements, the reader is referred above (pp. 292–3) and to the respective positions in this work of the articles there indicated.

Marble.—The best-known marbles are those of the Aravalli series, which include the quarries of Jodhpur (Makrana), of Tonkra in Kishengarh, of Kharwar in Ajmir, as well as of Raialo in Jaipur, all in Rajputana, and of Jabalpur in the Central Provinces. Within a radius of eight miles around Makrana there are something like 100 quarries, but of these only 15 are at present worked. They vary in depth from 30 to 75 feet, and follow the vein. The marble is excavated by blasting, and is then cut into the required size by steel saws. It is hauled to the surface on wooden rollers, and by manual labour. The quality of the stone is generally better according to the depth it is worked, but owing to the crude appliances used for hoisting to the surface, deep mines are impossible. The dust and fragments produced during mining operations at Makrana are burnt into lime, and this quality is much appreciated for the finer kinds of plastering. [Cf. Journ. Queen Vict. Ind. Mem. Fund, March 1904, 19–25.]

Colours.—The white marbles of Raialo are highly valued for filigree screens (jāli), of which numerous fine examples exist at Abu, Agra, Ahmedabad, Delhi, etc. The yellow marble of Jaisalmir (khattu) is a pure yellow, not white and yellow veined. It is used in the tomb of Ghayas Beg and his wife at Agra, and is so abundant as to be locally worked up as an ordinary building stone. The black marble found at Bainslana is carved into statues and toys. The black material in the inlaid work of the Taj and other Mughal buildings is a calcareous shale found in the lower Vindhyan series at Chitor. The handsome, mottled, green marble of Motipura in Baroda State, as also the grey and pink marbles of Narwār in Kishengarh State, are much admired and largely used for ornamental purposes. The onyx-marble of Nurpur and Shahpur, Panjab, is famous. This is a cream-coloured rock streaked cloud-like with purple, hence its name bōdal (cloud). An exquisitely beautiful variety of onyx-marble is found near Jhuli in Baluchistan, too remote from civilisation to admit of its utilisation. The marbles and limes of Narnaul in Patiala State are also well known. [Cf. Rec. Geol. Surv. Ind., 1906, xxxxi., 59–60.] It is commonly believed that the reason why the marble used in the Taj and other buildings has remained for three hundred years without getting tarnished is due to its coarseness of grain and chemical purity. A coarsely crystalline dolomite marble occurs near Mirganj, 11 miles west of Jabalpur, but it includes numerous crystals of tremolite, and its use for tombstones at Jabalpur shows that it is of inferior quality as a marble stone when exposed to the weather. In Burma the beautiful semi-transparent white marble so extensively employed for the figures of Gautama is obtained chiefly from the Tsygen hills in the Madeya Sub-division of the Mandalay district and near Sagaing.

Uses.—Marble is thus in extensive demand for the decoration of sumptuous dwelling-houses, palaces, temples and mosques, and in the construction of idols, ornaments, toys, etc. A highly instructive account of its uses in the buildings of Agra will be found in the (Agra Gazetteer 1884, viii., 684–716, 728–35). In the Ain-i-Akbari mention is made
of the skill of the Indian stone-carvers, but not of the art of stone inlaying. Both arts were, however, greatly improved during the time of Akbar's son and grandson. The use of marble became, in fact, the dominant feature of the new school of architecture that assumed such stupendous proportions with the Mughal rulers of India. Perhaps one of the most pleasing and at the same time surprising features of that great school of Indian architecture might be said to be the marvellous filigree screens (jali work), in sandstone or marble, that take the place of the glass windows of European buildings. Keene (Stone Indust. of Agra) gives a very accurate and impressive account of the screens at Fatehpur Sikri (constructed 1581 A.D.). "The outer screens," he says, "are so minutely pierced that they actually look like lace at a distance, and illuminate the mortuary chamber with a solemn half-light which resembles nothing else that I have seen." In Agra a fairly extensive industry exists in the preparation of screens, tables, fancy boxes, picture frames, plates, vases, etc., as also models of the Taj and other ancient monuments. These are mostly done in white marble, inlaid with agate, carnelian, carnelian, chalcedony, jade, jasper, lapis-lazuli, topaz, turquoise, bloodstones, garnets, rubies, sapphires, etc., by some of the best of the stone-carvers, and selenite is so plentiful that it is supposed to have sprung into perfection with the tomb of Itmad-u-Daula and the Taj (A.D. 1627-1658), and to have almost immediately thereafter gradually declined until at the beginning of the 19th century it had practically disappeared. It is said to have been revived by Dr. J. Murray about fifty years later. It has flourished ever since, the goods produced in Agra being carried for sale by the traders in Indian art wares all over India.

[D.E.P., iv., 195-7.]

**LIME SULPHATE: GYPSUM, Plaster of Paris.—** This is the hydrous calcium sulphate generally known as Gypsum; when in a fine grained condition, Alabaster; and when in transparent crystals, Selenite. On being calcined it parts with some of its water and then constitutes Plaster of Paris. The powder thus produced on the addition of water gradually sets, and as it does so expands slightly. It is this property that has made plaster of Paris so exceedingly valuable for making casts and moulds. In India sulphate of lime is known by an extensive series of names such as kulnar, kurti-salisit, kársí, sang-i-jeráhat, surma safed, makol, jirah, etc. Plaster of Paris is generally known as gach.

Occurrence.—In the Madras Presidency it has been met with abundantly, but in an impure form, in the cretaceous rocks of Trichinopoly. Masses of gypsum and crystals of selenite are occasionally found in the clays of Chingleput. In Nellore, crystals of greater purity than those found near Madras have been recorded as fairly prevalent. In Bombay, selenite occurs in the marine deposits near the city, also in Kathiawar and in some parts of the Deccan. Very excellent gypsum is found in Kach. In Sind, deposits frequently 3 to 4 feet thick occur near the top of the Gaj beds of the Kirthar range. The Mud Gorge, on the Harrai route to Quetta, owes its intractable character to the circumstance that much sulphate of lime is there present, and very largely in the anhydrite
condition. This absorbs water and thereby expands 33 per cent. The adjacent materials are in consequence continuously displaced, and the Mud Gorge may, therefore, be said to be in a state of constant change.

In Rajputana, at Nagor in Jodhpur, a bed of gypsum probably not less than 5 feet thick has been worked to some extent. A similar occurrence is worked at Jamsar in Bikanir State. While excavating a well at Falod, gypsum of a very pure kind was found, but at too great a depth to be of much value. In the Panjab (Bannu district) the mineral occurs in Kalabagh and in Khasor, but it is not utilised. The Kohat district contains gypsum in great abundance. Ball says "it might be obtained by open quarrying in any quantity, but is not worked." The Salt Range possesses gypsum in enormous quantity, associated with rock salt. The Spiti Valley has gypsum of a snowy whiteness. In the United Provinces deposits of gypsum have been reported as met with in Dehra Dun, Kumaon, and Garhwal. Middlemiss (Rec. Geol. Surv. Ind., 1889, xxii., pt. 2) gives a full account of the gypsum of Nehal Nuddi in Kumaon. [Cf. Hayden, Mem. Geol. Surv. Ind., xxxvi., pt. 1, pl. 16.] The Pioneer (July 27, 1888) announced that gypsum had been found at a locality some 19 miles distant from Haldwani, a station on the Rohilkhand and Kumaon Railway. In Burma gypsum has been found, but not in sufficient quantity to be of much commercial importance.

Industrial and Agricultural Uses.—For a great many years gypsum has been regarded as a manure of exceptional merit, especially for leguminous crops and for certain soils. It has recently been found to vastly increase the yield of indigo, so that a large demand seems likely to arise for it. The reader should consult the observations already made (p. 53) regarding the use of this salt as a neutralising agent, or rather one which so modifies the physical conditions of the soil as to bring it into a culturable state. Of manures that contain gypsum mention may be made of "superphosphate," which is a mixture of calcium sulphate with an acid phosphate of lime—the essential manurial constituent. It is prepared by the treatment of phosphatic minerals with sulphuric acid (Mukerji, Handbook Ind. Agri., 1901, 569-71).

The next most important use for gypsum is the numerous methods of utilising plaster of Paris. In 1852 Dr. Buist drew attention to the interesting fact that the Natives of Sind had, from ancient times, been in the habit of casting lattices and openwork screens to be used within houses to allow of free circulation of air. The Marwaris very cleverly make what might be called stained-glass windows by taking two lattice screens, made of plaster of Paris, of identical pattern, and placing between these fragments of coloured glass so arranged as to bring out the desired colour in design. The screens are then firmly fastened together and the pieces of glass secured in their positions by a thin layer of liquid plaster being run over the lattice upon which the glasses have been arranged before pressing home (on the top) the second layer of lattice. In many parts of Rajputana and of the Panjab the walls and ceilings of palaces are richly ornamented, in arabesque design, with glass. These are silvered behind or backed with plated metal discs or with coloured tinfoil, or they are painted on the surface and embedded singly or collectively in wooden frames, within a plaster, which consists mainly, if not entirely, of plaster of Paris. This work might be described
as a kind of mosaic, and from the fact of pieces of glass (shishah) being used, has come to be spoken of as shish-mosaic. The famous Shish-mahal (the Palace of Glass) at Agra, the Shish-mahal at Lahore, and the Shish-mahal in the ruined city of Amber (near Jaipur) are perhaps the best examples of this class of work. Mr. L. Kipling very truly says, "The effect of the shish or mirror mosaic, though brilliant, narrowly escapes the charge of vulgarity," so that it is not much to be regretted that the art may be said to be hardly practised at the present day. [Cf. Plaster of Paris work in *Ind. Art at Delhi*, 1903, 95–6.]

While it would thus seem that certain uses of plaster of Paris have been well known to the Natives of India for a considerable period at all events, a knowledge in the art of casting figures, ornaments and toys in that material is of comparatively recent date, and originated with the modern Schools of Art. While that is so, it is surprising to learn from Stein (Ancient Khotan, 244, etc.) that the whole of the stucco work discovered by him consisted very largely of plaster of Paris. Moreover, he tells us that the figures, idols, etc., had in many instances been moulded and elaborations accomplished in the form of extra figures, etc., by a process of appliqué. Grooves had been made on the plaster background to allow of the attachment of these extra mouldings, which were finally fused into their positions by liquid plaster. Since plaster of Paris moulding is quite modern in India proper, the ancient people of Khotan must have either discovered that art spontaneously or learned of it through their dealings with other than Indian races (see p. 713). So late as 1885, while engaged supervising the preparation of life-sized statues or models of ethnological subjects that were required for the Colonial and Indian Exhibition, I experienced the greatest possible difficulty in inducing the Krishnagar modellers to substitute plaster of Paris for clay. I procured a supply of gypsum from the Salt Range, had it fired in Calcutta, and found that it yielded a most excellent modelling plaster, and at a cheaper rate than I could purchase the imported article, which alone had been previously procurable in Calcutta. But my clay-modellers struck work, and I had to import others from Lucknow, and thus successfully threaten them with dismissal, before I could induce the Krishnagar men to resume operations. I mention this circumstance as showing the quality of the Indian plaster of Paris and its recent use in castings.

Alabaster, where met with, is largely utilised in the manufacture of ornaments and toys. The dark-green form procured from Garhwal is regularly made into elegant cups and sancers and even large bowls that are much admired by the richer Native gentlemen of Northern India. The same material, drawn from various sources, is to some extent utilised by the stone-carvers in Agra and other centres of that industry. [Cf. Blount and Bloxam, *Chem. for Engin. and Manuf.*, 1900, 131–2.]

**Trade.**

*TRADE IN LIME, MARBLE, ETC.*—With a country that possesses so many rich deposits of lime and marble, it is surprising to read of the large foreign imports that regularly take place. In the Calcutta press may be seen, almost daily, advertisements of dealers prepared to supply the “Best Italian Carrara Marbles” and “Best Belgian Jet Black Marbles” (*Journ. Soc. Arts*, 1901). So again, it is not uncommon to find mention of the coloured marbles of Montarrenti, Montalcino and Caldana, which
are unrivalled in Italy for the beauty of their tints. It is well to remember
that many of the columns, altars and floors of the Tuscan cathedrals,
which are the admiration of the world, were constructed of these marbles.
Mention is also frequently made in the Indian press of the Greek
marbles, especially those of the Pentilikon quarries near Athens, and
from the famous quarries in Thessaly, from which the genuine
“Verde Antico” marbles were obtained. Many of the marbles met
in Indian household ornamentation have been derived from
European quarries.

The official returns of foreign trade adopt two headings, under which
lime, marble, etc., are included. These are “Stone and Marble,” and
“Building Materials,” such as “Cement” and “Chalk” and “Lime.”
The imports of Stone and Marble have ranged from 204,205 to 362,554 cwt.
during the five years 1902-7, or a valuation of from 2 1/2 to 4 1/2 lakhs of rupees.
The chief item in point of bulk is stone from Arabia and Mauritius, used for
road-making in Calcutta; and in point of value, marble from Italy to
the extent of an average of 2 1/2 lakhs of rupees for each of the years
named. Turning now to the Chalk and Lime. The quantity imported is
annually about 30,000 to 50,000 cwt., valued at about Rs. 30,000 to 36,000,
and comes almost exclusively from the United Kingdom and is received
mainly by Bengal. The Exports from India have never exceeded 53,000
cwt., or a valuation of just under one lakh of rupees. These consignments
go mostly from Madras to Ceylon. Of the Cements a very different
story has to be told. The totals (during 1902-7) have ranged from
646,356 cwt. in 1902-3 to 1,785,428 in 1905-6, valued at from 13 1/4 to 32
lakhs of rupees. In 1906-7 the imports were 1,714,506 cwt., valued at
Rs. 30,87,484. Fully three-quarters of the supply comes from the United
Kingdom, and the balance mainly from Belgium, France and Germany.
Bengal takes very nearly half the imports: the remainder goes to Bombay,
Burma, Madras and Sind in the order named. Of the internal traffic in
Stone and Lime very little can be learned. The rail and riverborne
returns of minerals show a steady progression from an import of 6,733,264
cwt. in 1902-3 to 12,744,352 cwt. in 1905-6, with 12,149,239 cwt. in
1906-7. Taking the last year the chief receiving centres for Marble and
Stone were:—Madras Ports, 3,443,282 cwt. (chiefly from Madras Presi-
dency); Calcutta, 2,040,834 cwt. (from Bengal); and the United Pro-
vinces, 569,874 cwt. (from Rajputana and Central India). Chalk and
Lime:—Calcutta, 1,606,523 cwt. (from Assam, Eastern Bengal, Raj-
putana and Central India, Central Provinces and Calcutta); and the
United Provinces, 244,421 cwt. (from the Central Provinces and Nizam’s
Territory). Lastly, Others—a total of 66,986 cwt. Thus Assam and
Madras are the chief sources of the lime traded in over India, but Bombay
and Burma seem to be entirely self-supporting, as there are practically
no records of interchanges from or to these provinces.

LINUM USITATISSIMUM, Linn., Sp. Pl., 1st ed., 1753, 277; Mathiolus, New Kreutertum., 1563, 130 with plate; also Epitome (ed.,
Camerarius), 1586, 200-1 with plate; also C. Bauhin, Opera, 1598, 333-4 with plates; Linschoten, Voy. E. Ind., 1598, i., 80; Greaves, Pyra-
midogr., 1646; Celsius, Hierobotanicon, etc., 1747, ii., 283-312; Jones,
1808, 11; Dict. des Sciences Nat., 1823, xxvi., 479-93; Billerbeck, Fl.
D.E.P., v., 2-77. Linseed
and Flax.

The above, out of the library of books that might be cited as dealing more or less fully with the subject of Linum (Linseed and Flax), may be consulted by the reader desirous of botanical, historical and industrial details. The names given to these products in Europe and Asia are so extensive and varied that only those of most frequent use can be here mentioned:—linseed, linum, lein, lin, lino, linu; flax, vlas, flachs, etc.; aisi, aish, alish, tisi, chilna, pesu, bijri, keun, zighir, javasa, atasi, alash, masina, mushina, auma, ksumá, undžiggar, kattan, zagh, pishta, etc., etc.

Species and Races.—The Linseed and Flax Plant is cultivated throughout the plains of India, and up to altitudes of 6,000 feet above the sea. According to De Candolle (followed by most other botanical writers), it is indigenous to certain localities situate between the Persian Gulf and the Caspian and Black Seas. A consensus of opinion also favours belief that originally the perennial flax (Linum angustifolium) was the plant that in Europe was first cultivated for its fibre—a plant that is wild south of the Alps; and further that its displacement from popular favour took place about the close of the Stone Age of European history.

There is no evidence of L. angustifolium ever having been met with in India either wild or cultivated. It would seem highly likely (as recently pointed out to me by Mr. J. R. Drummond) that the economic information recorded in the Dictionary under L. strictum may be incorrect—the plant intended to be denoted as cultivated in Afghanistan having very possibly been one of the numerous races of the ordinary linseed. That being so, the only truly wild Linum within the Indian area, at all related to the oil-yielding L. usitatissimum, is L. perenne, Linn.—a species found in Western Tibet at altitudes of 9,000 to 13,000 feet. This is reputed to have been occasionally seen under a crude cultivation, the seeds being valued on account of the oil they contain.

Thus we are left completely in the dark, not only as to when and where the substitution of L. usitatissimum for L. angustifolium took place in Europe, but as to the origin of the stock that now affords the linseed of Indian commerce. According to some writers L. usitatissimum, the modern flax-yielding plant of Europe, was derived from India.
LINUM
USITATISSIMUM
Ksuan Fibre.

FLAX AND LINSEED

History.—While the classic records of India certainly do make mention of atasi, umà, ksuaná, etc., etc., no account, either of the oil-seed or of the fibre, is such as to remove all possible doubt that linseed and flax were undoubtedly indicated, but it can be said that greater certainty prevails regarding the oil than the fibre. In the Institutes of Manu (bk. ii., 41) we read that the garments of students should consist of skins above and of fabrics of hemp, flax (ksuaná) or wool below. So again (bk. v., 121), a man who knows the law is likened to purified linen cloth (ksuaná). Lastly a Brahmin, if he be compelled to make his living as a trader (bk. x., 87), must not sell dyed cloth or garments of hemp, flax (ksuaná) and wool. Thus there would seem no doubt that the word ksuaná is of frequent occurrence, and that it denoted a fibre which was purified (bleached, doubtful). Kálidásá speaks of the white colour of the cloth. But whether ksuaná originally denoted linen or silk, or rhea, or Catapris, or some such fibre, but not necessarily linen, seems a doubtful question. Most commentators have, however, accepted the name ksuaná as linen, and often with an atmosphere of such assurance as to convey the impression that there was no doubt, and could be no doubt, as to its determination. But if that view be correct it is, to say the least of it, curious that to-day the only use of the plant, known to the people of India, is as a source of linseed and linseed oil, not of fibre (ksuaná) or garments of the same. In fact, it is the all but universal belief that the linseed plant will not yield fibre of sufficient merit to repay the expense of its separation and purification. Are we to suppose, then, that since classic times a complete revolution has in India taken place, and that cultivation as a source of oil-seed is comparatively modern—a consequence possibly of the Muhammadan conquests of India, if not of European commerce? Or is the other explanation more acceptable, namely that the passages above indicated refer to an entirely different plant (possibly cotton) or denote experience obtained and opinions held prior to the invasion of India, and, therefore, prior to any knowledge of the plant as a source of oil? Mr. F. W. Thomas (Librarian to the India Office) draws my attention to the fact that in Skruarta (800 n.c.) atasi oil is spoken of as having a slight smell of flesh; of its being used like that of hemp and sesamum for poultices; and of its being pungent, light, penetrating and laxative. These are characters that would seem to denote linseed, so that the atasi of Sanskrit authors stands a better chance of having been linseed than the umá or ksuaná of being flax. Dutt (Mat. Med. Hind., 1900, 292) simply gives, in an appendix to his work, the name atasi as the Sanskrit of Linum; mosina, its Bengali; and tisi, its Hindustani; so that it may be inferred to have been a drug, in the opinion of the Sanskrit authors, that was unworthy of special consideration.

The oil is occasionally mentioned, however, in the Ain-i-Akbari and in a few other such publications, but on the other hand all the early European travelers in India whose evidence is generally regarded as of value historically, are singularly silent regarding both linseed and flax. Rheede, Rumphius and Burmann make no mention of any species of Linum. The East India Company's Records, as published by Birdwood and Foster (First Letter Book, 1600 to 1619), the subsequent six volumes of Letters Received by The East India Company, as also the still more recent work, The English Factories in India, 1618-21, prepared by Foster, do not contain any references to linseed or flax. Milburn (Or. Comm., 1813), who deals with all the articles traded in between England and the East Indies, China and Japan of that date, makes not the slightest allusion to linseed or flax, though he deals with sesamum castor and other oils and oil-seeds as exported from India. Next to nothing of a historic character can, therefore, be recorded of the early production and trade in linseed. The only point at all conclusive is that the Muhammadans seem more closely connected with the origin of the traffic than the Hindus.

Buchanan-Hamilton (Stat. Acc. Dina). (written subsequent to 1807), 174) enumerates "Flax or Linseed, mosina" among his agricultural crops of Bengal, and makes no observations regarding it. Neither in his Journey through Mysore, etc., 1807, nor in his Account of the Kingdom of Nepal (1819) does he refer to either flax or linseed. Aimalio (1826) says there was then a good deal of flax being cultivated in Upper India, especially in Bengal, for making oil; he then adds,—"of late years it has also become an object in the lower provinces." Carey (As. Res., 1808, x., 18) was apparently one of the first authors who wrote definitely regarding Indian linseed. He says that the oil is mixed with mustard to such an extent that it is "unfit" for painting or the other useful purposes.
to which it is applied in Europe. Of flax he says the Natives know nothing of its use to make thread. In 1825 Thornton brought out the second edition of Milburn's *Oriental Commerce*, in which work it is stated that "flax is very generally cultivated in Bengal and Bihar for the oil which is obtained from the seeds, the stalks being rejected as useless." [Cf. Rawlinson, *Hist. Ancient Egypt*, 1881, i., 62-3.]

Thus, from the observations already made, it may be inferred that the study of the production and utilisation of *L. usitatissimum* resolves itself into two sections, Flax and Linseed. These cannot of course be exhaustively dealt with, but I shall dispose of Flax (to India infinitely the lesser important product) first of all, and in a very few words.

**FLAX AND LINEN.**—The possibility of combining the production of linseed with the supply of flax has been spasmodically raised in India every now and again during the past hundred years or so. An important series of experiments and investigations were in consequence conducted in 1790 to 1810; another in 1840; and still a third in 1872, the object being not so much to ascertain whether a profitable combined seed and fibre industry could be organised, as to ascertain whether flax could become a commercial product of India at all. In the *Proceedings of the Honourable the East India Company*, preserved in the records of the Board of Revenue, Bengal, of date 1805-7, are many interesting details of the early experiments. Six Arab flax-dressers were sent from Bassora to Bengal, but failed to produce good fibre from the plants raised from the seed specially imported from Bassora. Roxburgh, in 1801, and again in 1806, gave accounts of the experiments he had conducted at the Company's Hemp Farm near Calcutta. An army of writers, down to Royle's time, may be said to have recorded their theories or narrated their experiments. On each occasion of special investigation, the results obtained were not deemed encouraging. But more recently still a new phase has arisen that may in the future assume some importance. The demand for cheap cordage, to be used as "binders," has suggested the possibility that the stems of the linseed-yielding plants (while they doubtless do not contain fibre of sufficient merit and abundance to justify being elaborately separated, cleaned, and placed on the market as Indian flax) may still by a simple method of preparation afford a cordage fibre that, as a catch crop, might undersell even jute. At present the stems of the linseed plant are not used in any way, and if they could be turned into a profitable by-product a great boon would doubtless be conferred on the Indian cultivators.

Vesque (Traité de Bot. Agri. et Indust., 1885, 495) very properly observes that climate exercises a considerable influence on the qualities of fibre or seed produced. In warm countries the fibre is least abundant, but the seed crop profuse. He then adds that the seeds obtained from a fibre crop may be useful for oil, but they are imperfectly formed and can never be used for reproduction. Conversely, if the seeds be fully developed, the fibre is all but ruined. If the combination crop of flax and linseed be in India seriously contemplated in the future, the plants would have to be sickled close to the ground or pulled up by the root, the seeds being thrashed out and the stems subsequently treated for their fibre. But the question of all others that naturally arises is this—can the same plant yield both products profitably? Would it not be preferable to grow separate crops?

Extensive experiments would very possibly have to be conducted by the various Governments of India in order to ascertain the conditions
necessary for a combination crop. It would have to be discovered whether a stock could be evolved a little richer in fibre than that presently grown, but which would still yield a fair crop of seed. The class of soils suited, the seasons of sowing, the methods of cultivation, and the period at which the harvest should be made, etc., etc., are some of the issues of importance that the Indian cultivators could not be trusted to investigate and solve for themselves. Then the methods and appliances required for separation of the fibre would have to be demonstrated, and above all, the final conclusion made abundantly clear, namely that the proposed departures from the time-honoured usages, in linseed cultivation, were in the raiyats' best interests, and that the vastly increased cost of seed to acre, the new expenditure in fibre-extracting appliances and the extra labour involved, could all be justified by the much greater returns obtained.

In testing these and many other such aspects of the proposed new departure, the experience gained in the past (very nearly futile) experiments would have to be carefully borne in mind and the shortcomings guarded against. These results will be found in the Dictionary (v., 10–35) and it will be seen that the idea of utilising the fibre of the linseed plant is by no means new, but that several persons have unsuccessfully tried to obtain a useful fibre from it. For example, we read that some years ago the late Mr. Savi of Mohesgunge in Eastern Bengal found the stems of linseed too thin and woody to afford fibre. In Assam the Director of Agriculture, we are told, made some experiments in 1901 to ascertain if flax could be produced in that province. The plants grew well enough but were laid by heavy rain, and when taken up the fibre was found to be rotten. The following year better results were obtained, but the want of proper machinery, to separate the fibre, resulted in a report that denoted imperfect work rather than defective crop. In the report for 1904 it is stated that as the sowings had been made in spring, the crop had to ripen in July during the middle of the rains. It was accordingly contemplated to try an autumn sowing, notwithstanding the risk of frost. The report adds, "By sowing the crop in autumn it may grow and ripen in dry weather and escape the baneful influence of the monsoon rains."

Recent Experiments.—It may now be stated that the Bihar Planters' Association have recently taken interest in the possibility of flax-growing being usefully resorted to by the indigo planters as a supplementary crop. At a meeting of the Dundee Chamber of Commerce (Sept. 20, 1904) this subject was alluded to with much interest, and a reference made to a committee having obtained an audience of His Majesty's Secretary of State, with the express object of urging this matter as specially worthy of the attention of the Government of India. The samples procured from Bihar were pronounced such as to suit a large portion of the trade. It would thus seem that within the past few years the question of flax-production alone, as well as of flax and linseed combined, have been once more engaging the attention of many persons, and it may be said that it will be a fortunate circumstance if a solution of the problem be at last found and a new and prosperous industry given to India, in continuation of the already long list of those that owe their existence or development to British commercial enterprise. It must never be forgotten, however, that linseed is at best a risky crop, and one that is resorted to by the
RAIYAT for rent-paying purposes, but only when necessity occurs and favourable conditions are likely to prevail.

Since the above was penned there has come to hand a report of the experiments recently conducted in Bihar, written by Bernard Coventry (Agri. Journ. Ind., i., pt. iii., 192–200). It would appear that a few indigo concerns have experimented with flax during the past four years, and Coventry’s remarks are apparently the result of experience gained. The following extract may be accepted as conveying the chief facts:—

“There is as much fibre in the plant grown in India as at home, namely, about 20 per cent. of dried straw. The average yield of retted and dried straw at Dooria shows at the rate of 2 maunds of seed, was 40 maunds per acre, and the percentage of fibre obtained from the straw was 15 per cent., or 6 maunds of fibre per acre. This should have given 4½ maunds of good fibre and 1½ maunds of tow, that is to say, the proportion of good fibre to tow should have been as three to one, but in point of fact it was only half good fibre and half tow.”

“The flax from the first year’s experiments fetched £30 a ton, the second year £35, and this year it is expected to fetch £40 a ton, owing to its better quality. The price of tow was about £10 a ton. The cost of production, including cultivation, seed, manufacture, shipping, insurance, and other outlay expenditure, amounts to Rs. 62 per acre. Taking the 6 maunds of fibre to have sold at £25 a ton including tow, equal to say Rs. 13 per maund, we have a gross return of Rs. 78 per acre and a profit of Rs. 16.”

Coventry contends accordingly that the cultivation of the plant has been accomplished successfully, but concludes his report almost in the words used by Dr. Jameson in 1859, viz., “All that is required in market a useful crop in India are some good instructors to show how the fibre is to be prepared and fitted for the market, and good seed and machinery.”

Lastly, Coventry, like most other writers on this subject, adds, “There are two separate but closely connected problems for investigation: first, the possibility of establishing a new industry for the growth of flax as a fibre crop for the production of high-grade fibre alone; second, the possibility of introducing a system whereby fibre, probably of a lower quality, could be produced in combination with the existing large cultivation of linseed for oil-seeds.” Students of this subject will find the information furnished by Hanausek (Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 73–7) highly instructive. They should also consult the recent results by Finlow (Dept. E. Beng. and Assam, 1906–7, app. ii.).

It has been often urged that, even if the separation of a fibre should prove unremunerative, the stems might become of great value to the paper-maker. But the crop is well known to be an exhausting one, and on that account is often barred by many leases, hence an effort should be made to overcome these objections by improvements in manuring. Fowls are known to fatten very rapidly if allowed to stray over linseed fields, and a certain percentage of linseed-cake is the world over recognised as one of the very best food materials for prolonging and improving the milk of cows, especially when butter manufacture is an important consideration. It has, in fact, been remarked that along the foot of the lower North-West Himalaya, linseed is at times sown mainly as a cattle food for milk buffaloes—the oil being only a secondary consideration. In this connection, however, attention may be drawn to a brief note by Leather

(Cyanogenesis in Plants, in Agri. Journ. Ind., i., pt. iii., 225) on a poisonous property at times possessed by the linseed plant. He mentions a case where cattle ate some immature linseed as fodder with the result that fifty-two died in a few hours. A specimen of the plant sent for examination contained a cyanogenetic glucoside, and yielded prussic acid when crushed in water.

LINSEED AND LINSEED OIL.—The seed obtained from the cultivated L. usitatissimum is known as Linseed, the oil expressed therefrom is Linseed-oil, and the cake Linseed-cake.

The object being to promote flowering, not to produce long, straight, fibre-yielding stems, the seed is sown much thinner than is generally the case with European flax. The result of this special cultivation has been to develop several well-marked Races, all of which possess one characteristic—a much-branched stem. There are two readily recognised kinds, namely a white-seeded and a red-seeded, and of each of these at least two grades with either "bold" or "small" forms of the seed. The latter may be only a condition of defective cultivation or immaturity of crop, but commercially the bold seed is the form of greatest value. The subject of the cultivated races of linseed is, however, too imperfectly understood to allow of more being at present said regarding them than that many distinct forms exist. It would, therefore, be the most obvious course to pursue, in any attempt at new developments of the linseed traffic, to improve the stock by careful selection in the direction desired, rather than to attempt the acclimatisation of exotic stocks. It is well known that the quality and yield of oil varies greatly in the seed of one country as compared with that of another. The white-seeded form has usually white coloured flowers, the brown-seeded blue flowers. Moreover, the white seed has a thinner shell, and contains nearly 2 per cent. more oil than is the case with the red. These facts have led to many inquiries as to the white-seeded plant being grown separately and the seed sent into the market pure. The demand for such pure seed has never, however, been so large and constant, nor the hopes of increased price sufficiently encouraging, to tempt producers to give the attention to the subject that would be necessary. Moreover, it is said that the quality indicated is not constant. In other words, under altered conditions, the white-seeded plant may produce red seed and thus frustrate the production of a pure crop. [Cf. Leather, Effect of Change of Climate on Amount of Oil in Linseed, in Agri. Journ. Ind., 1906, i., pt. iv., 413-4.]

Area under Linseed.—Very often linseed is grown as a mixed crop, being sown along with other oil-seeds and the two reaped together and used in the production of well-known blends of oils. At other times linseed constitutes lines through or borders to other crops, so that the greatest difficulty often prevails in determining the actual area under the crop. This is more especially the case in the United Provinces. But when grown mixed, the crop is all but universally intended for home markets, the crop grown for export being usually pure.

To the Natives of India a drying oil is of no consequence since they do not require an oil with that property, hence the frequent admixture with mustard-oil seed, which greatly reduces the value of the produce from the standpoint of a drying oil. But such admixture is more often than not accidental, through produce being purchased that was not intended for the foreign market. Voelcker (Improv. Ind. Agri., 1893, 285) discusses
LINUM USITATISSIMUM

Official Returns:

Areas.

During the past fifteen years the crop has fluctuated very greatly. Thus in 1891-2 it was 3,211,000 acres pure and 545,000 acres mixed; in 1895-6 it was 2,954,093 pure and 560,000 mixed; in 1899-1900, 1,648,903 pure and 409,000 mixed; in 1903-4, 3,609,079 pure and 592,000 mixed; in 1904-5, 3,747,400 pure and 647,000 mixed; in 1905-6, 2,700,400 pure and 567,000 mixed, while the Final Memorandum issued by the Commercial Intelligence Department estimates the area for 1906-7 as 3,028,200 pure and 633,000 mixed. Analysing the returns for the year 1905-6, by way of illustration of the distribution of production, we learn that Assam had 55,709; Eastern Bengal 103,000; Bengal 726,500; Agra 185,034; Oudh 60,880; Bombay 139,623; Central Provinces 812,068; Berar 96,703 acres, the balance on the total area being in Madras, Panjab, Rajputana and Central India, and lastly Burma. The highest of all the unimportant areas is usually Madras, which in 1905-6 had 21,099 acres; and Sind the lowest, with 3 acres under the crop.

Production.

PRODUCTION.—It may now be useful to devote a few pages to a series of notes on the linseed of the chief areas of Indian production:

Bengal.

1. Bengal (Including Eastern Bengal).—As already indicated, Bengal, of all the provinces of India, has usually the largest extent of land under this crop, though in the year specially dealt with it had less than the Central Provinces. The districts of Bengal that in 1905-6 the greatest acreage of linseed were Darbhanga, 138,500; Gaya, 50,000; Nadia, 49,000; Saran, 72,000; Champaran, 66,300; Muzaffarpur, 41,200; Jessore, 29,000; Murshidabad, 29,100; Bardwan, 22,600; Noakhali, 22,000; and Backerganj, 20,000 acres. It is thus a crop that may be spoken of as produced most abundantly within the indigo districts. At all events it is mainly grown, so far as Bengal is concerned, in Tihut and Bilaspur districts. It requires more or less the same soil, in fact, as wheat and gram. The land should be prepared in September, and thorough and deep ploughing is desirable. Before the close of the monsoons the sowings are usually completed. The seed rate has been given as 8 to 12 lb. to the acre. If sow n late, irrigation may be necessary, but when the plant is in flower rainfall is injurious. The crop is harvested by the end of February or the beginning of March and the seed extracted by flailing. Six to eight maunds of seed (say 500 to 700 lb.) is the average produce per acre. The straw is useless as fodder, and indeed it is even said that green plants eaten by cattle have been known to prove fatal. The seed is held to yield one-fourth of its weight of oil. The cake is regarded more valuable as food for milch cows than either gai or tort cakes, though the butter is said to be softer than that obtained where mustard- or cotton-seed cake has been given to the cows. Basu speaks of the straw of linseed being reduced to bhusa and given to cattle in mixtures with the bhusa of wheat, barley, gram, lentils, etc. It is considered as heating, and therefore seldom given to animals by itself. The crop is sometimes barren and thus becomes a dead loss to the cultivators.

Trade in Bengal (see p. 728).—In the Annual Report on the Maritime Trade of Bengal (1904-5, 24) it is stated that the quantity shipped rose by 26·7 per cent. and was the highest on record, the year 1898-9 coming next, but the value advanced by 6·6 per cent. only. In May, 1903, the price of linseed in Calcutta was Rs. 5·0-6·6 per maund; while in May, 1904, it was Rs. 3·10. The world's production in the year 1904 was enormous and in April the home price fell to 29s. per quarter, a figure not approached since July, 1896, when the price was 28s. 6d.
BENGAL AND CENTRAL PROVINCES

The average price for 1904 was 33s. as compared with 39s. in 1903. There was an extremely large crop in Argentina, and the United Kingdom imported even more from that country than from British India. The United Kingdom took 55.5 per cent. of the quantity shipped from Calcutta, and Germany 33.7 per cent. Exports to the United States, which did not exist in the previous year, totalled 60,047 cwt. "In the United Provinces the outturn of pure linseed during the year was 26.3 per cent. better than the season before, and in Bengal the improvement was 5.7 per cent., or 41.4 per cent. above the ten years' average." [Cf. Basu, Agri. Lohardaga, 1890, pt. ii., 35; Banerjei, Agri. Cuttack, 1893, 89.]

2. CENTRAL PROVINCES AND BERAR.—Judged by the area devoted to the crop, these provinces are undoubtedly the second most important centres of production, and are usually just under the Bengal area. In 1905-6 the Central Provinces had 812,068 acres devoted to linseed and Berar had 90,703, or close on a million acres between them. A slight increase of these areas would have to be made to cover the mixed cultivations of linseed and wheat or linseed and gram, etc., which expressed as pure linseed usually represents a cultivation of say 30,000 acres. The districts enumerated in sequence of these acreage were in the Central Provinces:—Raipur, 181,699; Bilsapur, 109,993; Nagpur, 66,980; Wardha, 61,912; Bhandara, 68,950; Chanda, 82,533; Jabalpur, 43,913; Balaghat, 28,358; Sangor, 23,970; and Damoh, 22,082. In Berar:—Wun, 46,129; Buldana, 19,563; Akola, 15,097; and Amraoti, 11,317. The balance in both instances on the total areas given is made up by districts with smaller acreages than those shown.

Sir J. B. Fuller, in a Report on the Outturn of Crops (1894, 20-2), furnishes many useful particulars regarding linseed. "Thirty years ago," he says, "the production of linseed was relatively very small. It is now one of the principal of agricultural resources of the Provinces, and crop statistics indicate that the area is still extending. But there is reason to believe that the land rapidly becomes linseed-sick, when it requires a long period of rotation." "By far the most important producing tracts are the Nagpur and Chattisgarh plains. In the former it is almost entirely a single crop. In the latter it is of most importance as an after crop, though its growth as a single crop is by no means insignificant." "The crop would be exceedingly profitable were it not very precarious. In a good year it gives a larger return than wheat with a far smaller outlay on seed and cultivation. But the plants are very sensitive to damp when in flower, and a few days' cloudy weather at this time will prevent the seed from setting and bring a promising crop to a disappointing harvest. Rust also causes great damage." The late Dr. Barclay (Agri. L. 1895, No. 20, 267-70, 351-2) devoted much attention to the study of that fungal parasite. While by no means confined to the Central Provinces and Berar, it has been specially studied in connection with these provinces, and a reference to the available information may therefore be given in this place.

The methods of cultivation and all other details are precisely similar in the Central Provinces to those already described under Bengal and Bombay, and need not therefore be here repeated. Subsequent years to those discussed by Sir James Fuller have manifested an even greater expansion, though severe fluctuations and heavy losses through failure of crops were also recorded. About 5 per cent. of the total cropped area in the Central Provinces is ordinarily under linseed. It cannot be grown more frequently than once in five or six years but it has this advantage, that when wheat and gram give bad returns, linseed, in such seasons, is usually successful, and thus may save the cultivator's position. When cotton or jwar fail, the land may be suddenly thrown under linseed and a good crop obtained. When grown as a sole crop, linseed is ordinarily sown earlier than wheat, and this is sometimes in its favour. But a large part of the linseed produced is sown as a second crop following rice, and is thus much later. An early cessation of the monsoon would thus injuriously affect the late crop.

Trade in Central Provinces.—The bulk of the production in these provinces is conveyed by train to Bombay, but a fair amount is imported from Rajputana and Central India.

3. UNITED PROVINCES.—The two provinces of Agra and Oudh viewed together undoubtedly take the third position in the Indian production of linseed. During 1905-6 the area in the former came to 185,034 acres and in the latter to 60,886 acres, or a total of 245,914 acres. And to indicate the distribution the following figures of the district areas may be recorded. In Agra Province:—

To Bombay.
THE LINSEED PLANT

Linseed

Chief Districts.

Gorakhpur, 60,331; Basti, 22,144; Allahabad, 8,803; Mirzapur, 22,581; Hamirpur, 40,990; Banda, 2,457; Jalaun, 6,379; all other districts with lesser areas. In Oudh Province—Gonda, 33,175; Bahraich, 17,120; Sitapur, 3,907; and Kheri, 2,299; all others much smaller areas.

The system of cultivation pursued in these provinces, and the results obtained, have been so fully dealt with in the Field and Garden Crops and in the Dictionary, that it is hardly desirable to republish a general statement. The remarks that follow may therefore be regarded as useful particulars gleaned from various sources with a view to supplement what has already been said. In the Gazetteer for Barcolly, linseed is described as one of the minor staples that is always sown broadcast, and nearly always as the second (dosahi) crop of the year. Of Moradabad it is said that when the rice is cut, advantage is taken of any moisture left in the soil to scratch the ground hastily with the plough and throw a mixture of gram, linseed and barley into it and leave these to take their chance. These are, however, rather exceptional than typical districts in linseed production. Mr. W. H. Moreland, the Director of Agriculture, in his annual forecasts and final reports of the linseed and rape crops of these provinces has for some years past furnished a most useful review of the facts of interest and value. In the report for 1903-4, he observes that linseed is generally sown after the autumn crop. Excessive moisture at the sowing season would appear to be injurious, but rain in December and January is necessary, and if delayed till February the crop is not much benefited.

Trade. Trade with the United Provinces.—The exports shown in the rail and river-borne traffic of these provinces go almost exclusively to the port of Calcutta. These, in fact, constitute about one-third of the total Calcutta supply, the remaining two-thirds coming almost entirely from Bengal. The total amount of linseed shown in the returns of internal trade of India came in 1904-5 to 12,051,507 cwt., of which Calcutta took 6,915,008 and Bombay 4,561,085 cwt. Hence the two towns named drain practically the entire amount of linseed that is annually produced and in the proportions shown. But in 1906-7 the quantity produced fell to 4,859,773, of which Calcutta took 2,666,604 and Bombay 1,936,053 cwt.

Bombay. 4. BOMBAY AND SIND.—In the Western Presidency linseed can hardly be regarded as a very important crop. It, in fact, has hitherto held the fourth, if not the fifth, position among the Indian provinces, with, in 1904-5, 523,968, and in 1905-6, 130,623. That area was distributed as follows in 1905-6:—

Chief Districts.

Nasik, 24,115; Bijapur, 44,662; Khandesh, 16,333; Solapur, 21,727; Dharwar, 14,013; and Ahmednagar, 12,645; all others with less than 5,000 acres. But the figures for the years 1903-4 and 1904-5 were in nearly every instance double what might be called the normal area in the districts named. The total for the Presidency, owing to an expansion on the area during 1902-3 of 108 per cent., and on that of five years previously of 149. Mollison (Textbook Ind. Agr., iii, 94-8) furnishes an account of a practical nature regarding this crop in Western India. The following may be given as an abstract of his views:—When grown for linseed (as in India), the seed rate is much lower than when grown (as in Europe) for fibre. In India, a mature crop stands 18 to 24 inches high. The stems rise from the ground some distance, and then branch freely. A linseed crop in flower is, during December—January, a noticeable feature of the black-soil districts, particularly in Khandesh—the common variety with a rich mahogany-brown coloured seed; but a creamy-white variety is sparingly grown in the Bombay Presidency, and to a considerable extent in the Central Provinces. The dry crop rabi areas under linseed, wheat, gram and jwar are more or less interchangeable, depending on the character of the monsoon season, and particularly on the late rainfall.

From the district areas given above, it will be seen that the Bombay linseed supply comes mainly from the Deccan and Karnátak, very little being grown in Gujarat and none at all in the Konkan. It is raised in the rabi season only, and on deep moisture-holding black soil, and on such land is rotated chiefly with wheat, gram or safflower, and sometimes rabi jwar. The best linseed soil is probably the deep black-soil belt on each side of the Tapti in Khandesh. Linseed is the sole crop of its year. The tillage should be completed by the end of September, and the seed drilled in October at the rate of 10 to 12 lb. to the acre, in rows a foot apart. But the land should be so thoroughly harrowed that weeding may not be necessary, since interculture is usually harmful. The
crop is in good seasons ripe by February, and is reaped with a sickle near the ground or uprooted. It is then carried to the threshing-floor and dried, when the seeds readily separate, and are winnowed in the usual way. A full crop may be 500 lbs. to the acre, but it is precarious, and often may yield much less. Linseed may therefore be considered a delicate crop, which in favourable seasons only is of particular success.

**Trade in Bombay.**—The port town of Bombay drains its supplies from the Nizam’s Territory, Bombay, the Central Provinces and Berar, Rajputana and Central India, the United Provinces of Agra and Oudh, the Panjáb, and Madras. In the returns of traffic carried by rail and river, it is shown that the town of Bombay received in 1904–5, 4,561,058 cwt.; in 1905–6, 2,580,494 cwt.; and in 1906–7, 1,936,053 cwt. The most important contributing single centre is the Nizam’s Territory. From these supplies are, of course, drawn the Bombay exports to foreign countries, and it is thus instructive to note that one-half comes from the Nizam’s Territory—a region very different from that from which Calcutta drains its supplies.

5. **Panjáb.**—Since the time that Baden-Powell wrote his *Panjab Products* (i.e., 497–500, 522–5) and Stewart published his *Panjab Plants*, a considerable expansion of the area of linseed seems to have taken place. Still, the total area in 1905–6 was only 31,293 acres, the bulk being in Kangra, 12,680 acres; Gurdaspur, 4,039; Sialkot, 3,624; Ambala, 1,575; Hoshiarpur, 1,927; Gujrat, 1,579; and Jhelum, 1,309. In Kashmir there is also a fair area, the plant being cultivated up to 6,000 feet above the sea (Lawrence, *Assess. Rept.*, 1890, 1910). The imports into the Panjáb of linseed obtained from Kashmir is an important item in the Trans-frontier trade, and one of increasing value. In 1898–9, these imports were 20,423 cwt., valued at Rs. 88,932; in 1901–2, they had become 223,642 cwt., valued at Rs. 15,52,993; and in 1903–4 stood at 50,602 cwt., valued at Rs. 3,55,136; but in 1906–7 fell to 6,083 cwt., Rs. 41,189. In 1906–3 a company carried out fairly extensive experiments at Sialkot in order to ascertain if flax could be there produced; they were apparently unsuccessful, for the plant presently grown in this district is entirely for linseed. In Kangra the seed is thrown among the stubble after cutting the rice and sprung up without any special cultivation; it is thus a second or supplementary crop.

6. **Hyderabad, Central India and Rajputana.**—It is unfortunate that particulars cannot be ascertained regarding the production in the Native States, since one or two of these, more especially Hyderabad, are important centres of production. The only sort of conception that can be obtained regarding this, is by a study of the railborne traffic. During the year 1904–5 the Nizam’s Territory exported 1,226,202 cwt., and in 1906–7, 850,037 cwt.; Rajputana and Central India, 951,460 and 182,170 cwt. in the same years; these amounts, going to Bombay, constituted fully one-half of the Bombay supply.

7. **Madras, Assam and Burma.**—These provinces take so small a share in the Indian linseed traffic that they can be neglected without serious consequences. The reports from the province of Eastern Bengal and Assam were in 1904–5, 85,746 cwt., and in 1906–7 only 45,893 cwt.; of Madras still less, namely 50,171 and 31,269 cwt.

**Indian Trade in Linseed and Linseed Oil.**—In the provincial paragraphs above, mention will be found to have been made of the extent of cultivation and the supply of linseed obtained from the chief producing provinces. It is not necessary to repeat these statements, but a good starting-point in a study of the total linseed trade of India is naturally to be had in the figures of Foreign Trade.

**British Gift to Indian Cultivators.**—**Foreign Exports.**—Royle informs us that the first mention of the Exports of linseed from India occurs in 1832, when 3 cwt. were recorded. The very next year the exports were 1,583 cwt.; in 1839, 120,922 cwt.; and in 1850, 560,452 cwt. In 1860–1 the exports from India were 550,700 cwt., valued at Rs. 1,25,57,790; in 1880–1, 5,997,172 cwt., valued at Rs. 3,69,81,265; in 1900–1, 5,060,189 cwt., valued at Rs. 4,45,60,096; in 1903–4, 8,616,356 cwt., valued at Rs. 5,74,41,762; and in 1904–5 they

attained their highest record, namely 11,182,009 cwt., valued at Rs. 6,328,872,565, but sank in 1905–6 to 5,788,860 cwt., valued at Rs. 4,115,539,835, and in 1906–7 still further to 4,378,826 cwt., valued at Rs. 3,259,837,765. The linseed consumed in India represents only about 5 per cent. of the production, hence it is not far from correct when it is affirmed that the traffic as known to us to-day is entirely a consequence of the British administration—a gift to the agriculture of India which covers an area of land, profitably utilised, of approximately four million acres, and gives a production of half a million tons of oil-seeds, which represents a contribution to the earnings of the farmers of three and a half million pounds sterling. Moreover, it is a crop that may be used as a safety-valve, and be increased or decreased according to the owner's advantage. In other words, land is thereby profitably cultivated, in excess of ordinary food necessities, which may be thrown under food crops as occasion arises. But for these very reasons, the traffic is subject to the greatest possible variations. Production depends greatly on local necessities of food, the prices ruling in Europe for linseed, and the relative values of linseed and cotton for the time being. The Argentine Republic has within recent years become India's most formidable rival.

Out of the total exports in 1904–5, India's record year (total 11,182,009 cwt.), 3,885,776 cwt. were consigned to Great Britain; 2,746,965 cwt. to Germany; 1,889,846 cwt. to France; 1,173,647 cwt. to Holland; and 673,874 cwt. to Italy.

Linseed, like wheat, is very readily influenced by the vicissitudes of bad seasons, caused either by drought or blight. But so important a position has the Indian supply secured in the markets of the world, that when the quantity decreases the price, as a rule, rises, thus compensating the producer. But perhaps the most instructive lesson to be learned from the study of the areas of production of linseed, in relation to the returns of foreign exports, is the circumstance that while linseed holds the third position in area, the value and quantity of the seed exported from India are usually very nearly the values and quantities of all the other oil-seeds taken together. And from this standpoint alone, therefore, is derived a fairly tangible conception of the consumption of oils and oil-seeds within India itself, and full confirmation obtained of the statement already made that linseed is grown primarily for the purpose of export: it is a rent-paying crop.

Internal Trade.—The returns published officially regarding the movements of linseed by road, rail and river afford the only really definite conception of production and sale that can be learned. The traffic registered as carried by these routes during the five years ending 1906–7 were, 1902–3, 5,922,967 cwt.; 1903–4, 8,884,004 cwt.; 1904–5, 12,051,507 cwt.; 1905–6, 5,278,659 cwt.; and 1906–7, 4,859,773 cwt. Analysing the record year (1904–5), the total shown under foreign exports (disregarding for the moment the traffic in the oil) came to 11,182,009 cwt., or say half a million cwt. less than the deliveries registered by the railways at the port towns—and that surplus may, therefore, be taken as the amount used up by the local mills or carried forward into next year's stock. A certain discrepancy has, however, to be accepted, due to imperfections in the returns and unavoidable duplications. Still, it can fairly be said that the figures compiled by one department (Railways) provide the exact quantity shown by another (Foreign Exports), and a third line of reasoning might...
be used to confirm both, namely the area of cultivation expressed to the accepted average yield. Viewed from any and every standpoint, we learn that the linseed of India is grown purely and simply in obedience to a foreign demand. As already mentioned, the exports from Calcutta are drawn from the province of Bengal (two-thirds) and from the United Provinces (the remainder); Assam and the Central Provinces contributing between them only about 120,000 cwt., out of a total Calcutta supply of close on 7,000,000 cwt. The exports from Bombay, on the other hand, are drawn from the Nizam’s Territory, Rajputana and Central India, the Central Provinces and Berar, and lastly the Bombay Presidency itself, and in the order named. Of the producing provinces (judged of from the railway returns), Bengal heads the list, and is followed by the United Provinces (a good second); by the Nizam’s Territory (an indifferent third); by the Central Provinces and Berar (a very poor fourth); then Rajputana and Central India; Bombay; next Assam; and, last of all, Madras. Karachi exports a small amount of Panjáb linsee. Seeing that the Central Provinces have so large an area under the crop, their position as fourth in exports is a little difficult to understand. The explanation is perhaps that the area is shown larger than it should be owing to mixed cultivation being estimated as pure.

Linseed Oil and Oil Mills. — It cannot be ascertained how many of the 99 oil mills, reported to be at work in India, are concerned in the linseed traffic proper. Only one appears to deal exclusively in linseed, namely the Gourepore Company, Ltd., near Calcutta. Their oils and oilcakes are noted all over India. The mill, moreover, produces both boiled and unboiled oils. The exports of linseed oil from India are not very important, nor do they appear to be increasing; in fact, judged of by the returns from 1899–1000 to 1906–7, they have, if anything, been decreasing. In 1899–1000 they were 248,479 gallons, valued at Rs.4,20,167; in 1903–4, 137,952 gallons, valued at Rs.3,61,654; in 1905–6, 186,682 gallons, valued at Rs.4,57,983; and in 1906–7, 114,205 gallons, valued at Rs.2,18,926. Nearly the whole of these exports go from Bengal, and thus to a large extent doubtless embrace the Gourepore Company’s transactions. It is also noteworthy that the major portion of the cake is valued as an article of cattle food when not adulterated with mustard (see pp. 184, 770, 817).

LIVE STOCK OF INDIA. — This very large and important subject may be discussed under the following sections: Oxen and Buffaloes; Sheep and Goats; Horses, Donkeys, Mules, Camels; and Pigs.

An analysis of the returns of Live Stock in India during 1905–6 manifests the existence of approximately 198 million head of cattle (cows, bulls, bullocks, buffaloes, sheep, goats, horses, mules, donkeys, camels, etc.). The actual figures are 30 million bulls and bullocks, 22 million cows; 13 million buffaloes; 26 million young stock; 18 million sheep; 25 million goats; 2½ million horses; donkeys; mules; and 393,308 camels. The

<table>
<thead>
<tr>
<th>Estimate for Bengal.</th>
<th>Live stock of Bengal is not recorded, but, since its population is twice that of Madras, it may be assumed to possess double the returned live stock of all sorts met with in the Southern Presidency, viz. 61 million. This gives the 198 millions (above mentioned) as the total live stock, in place of the officinal figure of 137 millions (exclusive of Bengal). But to that total has also to be added the 15 millions shown as owned by the Native States. In fact 30 millions would not over-state the live stock of these States, making a grand total for India of over 228 million cattle of all kinds. Some such estimate seems essential to allow of comparison with the trade returns, which include Bengal and the Native States. Thus, for example, the term &quot;hides&quot; may be taken to mean undressed skins of full-grown bovine animals, and &quot;skins&quot; those of calves, sheep and goats. For the five years ending 1903-4 the average number of hides (raw and dressed) exported from India came to 124 millions, and of skins 37 millions; these collectively would, therefore, show 23 per cent. on the estimated total live stock of all India for the period in question. But the exports by themselves take no cognisance of the numbers of hides and skins used up by the indigenous leather industries of India itself, nor of the numbers of animals that die or are killed and the skins, for various reasons, entirely lost. Were a figure to be given for the annual death-rate (from all causes) of the cattle, sheep and goats of India, it is probable that it would be something nearer 70 to 80 rather than the 50 millions indicated by the returns of foreign trade specially dealt with above. For further particulars see the article Hides and Skins (pp. 632-9).</th>

<td>Skins.</td>
<td><strong>Bos indicus</strong>, Linn.; Blanford, Pa. Br. Ind. (Mammalia), 483-4; Mollison, Textbook Ind. Agr., 1901, ii., 63-139; Meagher and Vaughan, Dairy Farming in India, 1904, 41-7. The Zebu or Humped Ox, bai, gai, gau, dhur (cattle), dhur danger (horned cattle), dhudhar (milch cow), etc. The Indian animal differs from the tame ox of Europe and North Asia in structure, general coloration, voice and habit. Its origin is unknown, but according to Blyth it was probably African. No ancestral form has as yet been discovered among the Indian fossil bovines. Humped cattle have, however, often been reported to have run wild in India. All the breeds of the Indian ox are held sacred by the Hindus and are, therefore, neither killed nor their flesh eaten by a large portion of the people. On the other hand, the tending on cattle is regarded as a highly honourable position, and hence also milk, butter, cheese, etc., are largely consumed by all classes of the community. Below will be found a brief sketch of some of the leading breeds of oxen.</td>

The Buffalo, arna, meng, main, bhains, bir biar, gera crumi, moe, silo, misip, iroi, kowai, pana, karbo, etc. Tame buffaloes are found all over the plains and lower hills of India. They are repeatedly mentioned in the Institutes of Manu (xi., 69), so that they have been known from the earliest historic times. They are semi-aquatic animals, and accordingly most abundant in humid localities. Are large, massive, and clumsy creatures, with exceptionally short thick legs and conspicuous hoofs. The horns are thick, flat, curved or straight, and marked with rings indicative of age. The muzzle is large, remarkably square, and the head carried very low. A truly wild buffalo is fairly abundant in India (except in the Southern and Western Provinces), especially in low-lying swampy land covered with tall grass. Few domestic animals have, in fact, changed less than the buffalo. While it will not breed with the ox, the tame buffalo-cow will pair readily with the wild buffalo-bull, the stock being thereby improved,</td>

They are powerful draught animals, and the milk is exceptionally rich in butter-fat.

**B. grunniens**, Linnaeus; Blanford, l.c. 490; Turner, Acc. Emb. to Tibet, 1800, 186, t. x. (from a picture belonging to Warren Hastings); Vigne, Travels, etc., 1842, ii., 277; Hoffmeister, Travels in Cont. Ind., 1848, 362, 374. The Yak or Grunting Ox, dong, bronng-dong, ban-chower (the wild): yak, pegu, chour-gau, kotass (the domestic animal).

In its wild state it inhabits the coldest and most desolate tracts of the Himalaya—being found at a greater elevation than any other mammal. It is dark brown, almost black, with the exception of the muzzle, head and neck, which are often grey. In domestication it becomes smaller and variable in colour, being often pure white or piebald. Mention is made of the qatas or "Tibetan yak" in the Ain-i-Akhari (1500, Jarrett, transl., iii., 121). It is kept by the Tibetans and various other tribes that inhabit the higher regions, on account of its being a sure-footed pack animal. The flesh is said to be rich, juicy and delicately flavoured. The milk is exceptionally rich (considerably richer than that of the cow), and much of the food of the people consists of curd either fresh or dried and powdered into a kind of meal. The white tails constitute the chowris (fly-flaps) sold all over India. The hair is woven into cloth and ropes. The horns are made into cups and other objects of domestic use and ornament. But the yak breeds freely with domestic cattle. One was sent to England by Warren Hastings, which lived for some years and became the sire of many cross-bred calves, only one of which lived and was successfully crossbred by an Indian bull. A cross is common on the North-West Himalaya and is known as the dzo, zoba, etc.; it is fertile and in some localities preferred to the pure yak.

**Other Species.**—Three other animals belonging to this genus may be here mentioned, but, as scarcely of economic value, need only be exhibited very briefly:—

(a) **B. frontalis**, Lamb; Blanford, l.c. 487-9; the Mithan or Gayal of Assam, Manipur, Naga hills, Chittagong and Burma. Said to be partly domesticated by the Kukis.

(b) **B. gaurus**, Hume; Blanford, l.c. 484-7; the Gaur or Indian Bison of the hilly forests of the Indian Peninsula, Assam, Burma and the Malay Peninsula, ascending to altitudes of about 6,000 feet. It has occasionally been tamed by the people on the hill tracts between Assam and Burma, but has never, strictly speaking, been domesticated. The horns are in great demand for ornamental work. (See Horn, p. 646.)

(c) **B. sassalus**, Müller & Schley; Blanford, l.c. 489-90. The Banting, found in Burma and the Malay Peninsula, Borneo, Java and Bali. It has been more or less domesticated in Java and perhaps elsewhere.

**CATTLE AND CATTLE-BREEDING.**—In Europe cattle may be said to be reared for milk and meat, but in India their chief value is as beasts of burden. Horses are all but unknown in Indian agriculture, the bullock being very nearly exclusively used for tillage and transport. Occasionally camels are so employed and buffaloes are highly valued for their milk, though they are too slow to be much in demand for agricultural operations.

There are many breeds of indigenous cattle. Nearly all the pure stocks are of one colour—white or grey. In areas where little attention is paid to the subject, mixed colours or piebald cattle are not infrequent. Except in the north-east of Madras, all Indian cattle are horned. The hump is prominent, and more highly developed in some breeds. Bullocks which are suited for slow and heavy work have usually massive heads, long pendulous ears, thick short necks, coarse leg-bones, big feet, much loose skin on the neck, dewlap and sheath, and no particular droop in the hind quarters. Those best suited for quick work have clean heads, fiery tempers, short erect ears, thin necks, compact rounded bodies, small hard feet, a very decided droop in the hind quarters, and little or no loose skin on the neck, dewlap and sheath. Indian oxen, it may thus be observed, are distinguished collectively from the breeds of
THE OXEN AND BUFFALOES

Hump.

Europe by the hump on the shoulders, by the deep undulating dewlap, and by the short grunt in place of the ringing bellow of the European ox (Imp. Gaz., iii., 77–89). Many European travellers in India allude to the "hump" as a special feature of the provisions (beef) procurable in India. Thus Terry (Voy. E. Ind., 1622 (ed. 1777), 89–90) says the "beeves" differ from ours in being smaller and in having "each of them a great bunch of grisly flesh which grows upon the meeting of their shoulders." He then adds that the flesh is very sweet and tender.

There are few subjects in which India is so very backward as those of Cattle-breeding and Dairy Farming, hence the available literature is comparatively insignificant and defective when judged of in the light of their importance. This is the more surprising since, with a large proportion of the people of India, the cow is the most sacred of all animals. In the Ain-i-Akbari (1590) special mention is made of the veneration in which it is held. Linschoten (Voy. E. Ind., 1598, i, 257, 300), Bernier (Travels, 1656–68, in Constable, Or. Misc., i, 326–7), Tavernier (Travels Ind., 1676 (ed. Ball), ii, 217), and many other European travellers in India, dwell on the sacred character of the Indian cow. It might naturally, therefore, have been expected that the cow, and some at least of the products it affords, would have existed in even a higher or more fully developed condition than is the case in most other countries.

While there are certain Indian breeds of cattle that compare favourably with those of other parts of the world, most are inferior in size and strength as well as in quantity of meat and milk which they provide. The breeds vary directly with the soil, climate and food of the countries in which they live. For example, in deltaic tracts the oxen are inferior but the buffaloes superior. Meagher and Vaughan very rightly observe:—"The great variations in the Indian climate largely affect the milk yield of cattle imported from foreign districts. Hansi-Hissar cows will not prove as satisfactory say in Jabalpur, as they will in Delhi or Meerut, and this should be borne in mind before condemning the Hansi-Hissar breed. It appears to be a fact that the further they travel east or south (i.e. the damper the climate becomes), the more certain is the decrease in the yield." Climate, soil and available food in fact influence so rapidly the breeds of cattle that it becomes undesirable to extend schemes of improvement very much beyond selection from existing stock within each area. Indeed for the plains of Lower India, crosses of foreign strains, more especially from Europe, have proved highly unsatisfactory. The chief difficulty is to overcome the opposition that exists in transferring, without loss of special merit, the stocks even of one part of India to another. If the intention be to improve, as heavy draught animals, the breeds of the Panjáb, Gujarat and Mysore afford ample material: if the desire be for swiftness, the trotting bullocks of the Central Provinces and of South India (gainis) are unsurpassed anywhere: and, if milch-cows be sought, there are several famed breeds, such as the Nellore or Ongole and the Gir of Kathiawar and the Hansi-Hissar of the Panjáb. In the Ain-i-Akbari (Blochmann, transl., 149) special mention is made of the Gujarāt breed of cattle and of the small swift-footed gainis. This is curiously confirmed by Ralph Fitch (in Purchas' Pilgrimes, 1625, ii., 1733), who, while telling of his visit to the Emperor Akbar in 1585, specially mentions the carved and gilded carts of Agra and Fatehpur drawn by "two little bulls..."
GOVERNMENT FARMS

BUFFALOES

about the bignesse of our great Dogs in England.” [Cf. Tavernier, l.c. 44; Terry, l.c. 144–5, 187.]

But, excepting at the homesteads of the wealthy or at the experimental farms owned by Government, special selection of stock or the rearing of healthy, well-formed bulls for service purposes is practically unknown from one end of India to the other. The story told by Abul Fazl of the “Cow Stalls” kept by the Emperor Akbar reads more like a proclamation of the pageant of the all-wise and good Emperor than a statement of his efforts towards the improvement of the cattle of India. The Amrit Mahal breed is said to have been introduced into Mysore and specially developed by Haider Ali for military purposes. But history tells of no Hindu Prince who devoted anything like the attention Akbar bestowed on this most important subject.

Indian agriculture has for centuries been and is to-day essentially a peasant industry. It is in the hands of persons who have the traditional knowledge of their ancestors to guide them, but absolutely no capital beyond that absorbed in daily necessities. Each person, as a rule, keeps but two or three cows, and cannot afford to keep a bull. And moreover, since the male offspring are not generally emasculated until they are three years old, the cows are served by immature and as often as not diseased, degenerated or otherwise undesirable males. Improvement of the breed under these conditions is naturally very difficult. For some years past, however, the Government of India have recognised the obligation of initiating a reform, and with this in view have had superior bulls reared at special farms (such as those of Hissar, Charodi, Pusa, etc.) and presented to districts where it was desired to improve the local breed of cattle. Voelcker alludes approvingly to this action, and urges that the satisfactory results attained should be pushed forward until the remotest corners of the Empire have been reached. So also the Government have aided very greatly by encouraging local fairs and cattle shows, by awarding special prizes on the verdict of high expert officials who have been deputed to visit the shows for that purpose. But it is well known that half-bred cattle contract rinderpest and other common diseases in a most virulent form and rarely recover under treatment, while many indigenous breeds are comparatively immune. This has accordingly led to belief that the best results are likely to be obtained by breeding strictly within carefully selected and special local stocks, not promiscuous inter-breeding of all races.

(A) Chief Breeds of Indian Buffaloes.—The breeds of buffaloes have not as yet been critically studied. Until this has been done, little more can be accomplished here than to indicate those most frequently spoken of. Terry gives a curious reference (Voy. E. Ind., 1622 (abrid. ed. Havers), 1665, 359) to “a very large beast having a smooth thick skin without hair called a buffalo which gives good milk; the flesh of them is like beef but neither so toothsome nor wholesome.”

In rice-growing tracts buffaloes are extensively used for tillage and cartage work. But although they thrive well in wet climates, the best breeds are met with in localities of moderate rainfall and under the conditions best suited for cattle-breeding. But buffaloes must have access to water, and require to be bathed once or twice a day if they are to be kept in health. It is also customary to clip off their sparse coat of hair once or twice a year. Buffaloes vary in colour, but the majority have black, shining

skins. Some have white markings and a few are grey, light dun or white. Their lowing differs from that of kine and they have no hump. Most writers allude to the fact that it is difficult to get a good buffalo-bull, owing to its being less valuable than the buffalo-cow. The bulls are not often reared, but are either purposely starved or killed. They attain maturity at 3½ years and are used for stud purposes for not more than 7 or 8 years. "It is just as essential when starting a dairy, to get a good bull as to get good cows, for many authorities now hold that it is from the sire, and not so much from the dam, that a heifer inherits her milking powers." Middleton, who has kindly perused this review of Indian information, observes that the milking properties may be transmitted by either sex equally, but in England bulls are usually more carefully bred than cows and may so transmit properties with greater certainty.

Considerable commercial interest is taken in the shape of the buffalo-horn, the straight forms being of greater value than the curved. From the standpoint of the dairy farm, the breeds with curved horns are apparently the most highly appreciated. The following are mentioned by authors as the characteristics by which the chief breeds of buffaloes may be classified:—those with horns approaching a circle (the *spirocerus* of Hodgson), and those with the horns long, straight, the tips only arching forward (the *macrocerus* of Hodgson).

1. Delhi.—The breeds of the United Provinces, the Púnjáb and Sind are often collectively designated "Delhi Buffaloes." The horns are short, thick at the base, sharply angled, and rise from the head in a backward and upward course, then become completely curled up like the horns of a ram. According to Meagher and Vaughan (loc. cit. 47-8) the best buffaloes of this kind are the *murrah*, procured in Hansi-Hissár, Rohtak, Jhind and Nabha. The name given to them is derived from *murna* (= to turn), and is an allusion to the form of the horns. They are sometimes also called *kundi*, and cross-breeds with this and the inferior village buffalo (with straight horns) are called *dogla*. [Pease, *Agri. Ledg.*, 1895, No. 22, 408; Hadi, *Agri. Ledg.*, 1895, No. 12, 206-8.]

2. Surat and Deccan.—The buffaloes of Surat and the Deccan are very different. They both have what are called straight horns. That is to say, in the Surat animal they extend along the side of the neck, then turn up near the shoulder with an inward graceful curve; and in the Deccan breed are even straighter, and extend backwards to the shoulders before becoming arched.

3. Jafferabad.—In the Jafferabad (Kathiawar) buffalo the horn is very massive and coarse. It is flat and broad below, developed at first downwards and backwards, then curved forwards, thus forming three-quartors of a circle, placed on either side of the head. But there is still another peculiarity. The frontal bone becomes greatly developed until it causes the horns to appear united across the forehead. This is a very large, clumsy animal with unusually long legs and large spreading feet.

4. Dun-coloured Buffaloes.—Here and there all over India, more especially in hilly districts, remote from swampy country, a dun-coloured buffalo is met with that seems very distinct from the other breeds. This has by zoologists been regarded as possibly a distinct variety, and has received the name of *B. bubalis, var. fulvus*. Meagher and Vaughan say these dun or brown buffaloes generally start well but bad end badly. They are not as a rule heavy milkers for any length of time.

5. Burma and Assam.—Varthéma (*Travels*, 1510 (ed. Hakl. Soc.), 200-1) speaks of the breeds of Tenasserim as very "misshapen." Many subsequent writers have incidentally mentioned the buffaloes of Burma, but no one apparently has studied them comparatively with the breeds of India. Evans (*Agri. Ledg.*, 1895, No. 10, 165-72; 1896, No. 10) gives, however, many particulars of the Burmese breeds. They would seem to have long, so-called straight horns, like those of Surat. They give very little milk. The buffaloes of Assam have been discussed in some detail by Darrah (*Agri. Ledg.*, 1894, No. 14). He tells us that though the stock is regularly imported from Bengal, the animals soon improve on the rich pastures of the Brahmaputra valley.
(B) Chief Breeds of Indian Cattle.—Very little strictly speaking of a scientific nature has as yet been published on this subject. Wallace and Voelecker have each given the results of their rapid tours of inspection through India, and numerous local writers have extolled the merits of certain breeds with which they were familiar. No one has as yet critically and comparatively examined all the breeds of India. Little more, therefore, can be here attempted than to amplify the particulars of the chief breeds (given in the Dictionary) in the light of the additional information brought out by the various writers in The Agricultural Ledger, and by Mollison in his Handbook and by Majors Meagher and Vaughan in their Dairy Farming in India, etc.

1. Gujarat.—These are the indigenous breeds of the plains, Ahmedabad, Kaira and Baroda, also the hill districts of Palanpur and Deesa, where a large breed of very superior animals exists. They are, in fact, the finest cattle of India for general agricultural purposes. In the more southern portions of the province, however, a mixed and inferior breed occurs which in many respects resembles the Deccani cattle. The larger and superior race is in colour from white to bluish-grey, the head, neck and limbs often being of a darker tint than the body. The horns are somewhat bowed and curve outwards as they leave the skull, then upwards, and lastly inwards. The animals are tall and somewhat leggy, but very powerful, and for draught purposes, especially when crossed with Mysore, are very valuable. [Cf. Ovington, Voy. to Suratt, 1689, 253-5, 273-85.]

2. Gir or Kathiawar.—This breed is specially noted for its milk-giving powers. It is extensively reared in herds in the Gir forests and hills of South Kathiawar. They are coloured animals, often speckled or "roan," in various shades of red and brown. The long, pendent lop-ears and short crumpled horns are striking peculiarities. In Bombay they are generally called "Surties," because brought via Surat.

3. Sind and Aden.—This small-sized animal is powerful though lazy, but the cows are remarkably good milkers. The horns are short, thick, blunt-pointed, and project outwards and upwards. The best are bred within a radius of 30 or 40 miles from Karachi, and chiefly on the lower hills, where good grazing is to be had. The breed may, however, be met with through Rajputana and the Southern Punjab. [Mollison, The Montgomery and Sind Breeds of Cattle, in Agri. Journ. Ind., 1907, ii., pt. iii., 292-6.]

4. Deccan, Khandesh and Southern Maratha Country.—It cannot be said that the regions indicated have developed any very special breeds of their own. Large portions of the country are subject to periodical scarcity and occasional famine, and the animals have become hardened and thus acquired their chief characteristic. The dewlap is inconspicuous, the forehead narrow and the muzzle large, while the horns spring in an upward direction, then bow abruptly outwards and ultimately inwards. The cows are poor milkers, and the bullocks, though small, are extremely active and have great powers of endurance, if not given too heavy a task. They are accordingly much used in light carts or as trotting bullocks. So long ago as 1503, Vertomannus (in Halkl. Voy., 1811, iv., 577), speaking of the Deccan, said, "It hath innumerable kyne of shynyng yelowe."

5. Mysore and Coorg.—The cattle of this region are celebrated both for their swiftness and for their spirit and powers of endurance. If cattle-breeding could anywhere in India be viewed as having attained the position of a recognised principle of agriculture, to Mysore would have to be assigned that honour. Two descriptions exist side by side, each serving its own particular purpose. The first and by far the most numerous is the nadudana of the villages. This is the agricultural stock and main source of the dairy produce of the State. The second is the dodudana or big cattle. This embraces the following special breeds:—Amrit Mahal, Hallikar, Chittaldurag, Mahadeshwar, Betta, etc. The first mentioned—the Royal Amrit Mahal—is the most highly prized, but is neither the largest nor the most powerful. These splendid animals are capable of performing quick journeys of long distances with a light and moderate load. They are large and powerful animals, chiefly kept by the well-to-do. The finer breeds are pure coloured, the inferior often mottled. There is no extra development of the dewlap to interfere with their trotting action. Their eyes are deep-set, the forehead bulges above the eyes and slopes backward. The ears are short and pointed,
and the horns, which spring close together, take a backward sweep, gradually diverge, and near the extremity curve gracefully upwards and forwards. They are all, even the nuddana breeds, powerful draught cattle but poor milkers. [Cf. Buchanan-Hamilton, *Journ. Mysore*, etc., 1897, i. (many passages); Kristnamangar and Pease, *Cattle of Mysore*, in *Agri. Ledg.*, 1895, No. 24; Kristnamangar, *Diseases of Mysore Cattle*, *Agri. Ledg.*, 1896, No. 28.]

6. Madras, Nellore, Kistna (Ongole), etc., Cattle.—The Ongole breed of cattle is reared chiefly in the districts of Nellore and Kistna. From early times it has enjoyed a well-earned reputation of being one of the best milking breeds of India. Most writers agree, however, in saying that they degenerate rapidly when removed to other localities. The valleys of the Kistna and its tributaries have a rich, soft, deep black soil, and naturally therefore the cattle of such a country are not well suited for hard roads, unless carefully and regularly shod. They are collectively heavily built animals, docile and of a mild and gentle disposition—essential qualities for milch-cattle—but sluggish in action. The head is erect on a short, stout neck. The horns are short and stumpy, somewhat resembling those of Sind cattle, and longer in the cows than in the bulls. They give to the head a curious and characteristic appearance, the bulging forehead forming a very obtuse angle. The prevailing and true colour is white with grey or black points, and frequently the bulls are black about the neck and shoulders—broken colours indicate impurity. In point of size they are inferior to the Gujarat and Nagar cattle. Other Madras breeds are the Alambadi of Salem and Coimbatore; the Baragar of the hills of Coimbatore; the Kangayam of Madura; the Palikolam (Jellicut) cattle of Madura; the small Trichengodi cattle of Salem; the artificially spotted cattle of Tanjore; and the Punganur cattle of North Arcot. [Cf. Pease, in *Agri. Ledg.*, 1895, No. 7; Sabba Rao, in *Agri. Ledg.*, 1890, No. 12; Holmes, *Hair-markings on Horses and Cattle*, *Dept. Land Rec. and Agric. Med. Bull.*, 1900, No. 42; also Notes on Cattle of Madras Pres., *Bull.* No. 44; Gunn, *The Nellore Breed of Cattle*, in *Agric. Journ. Ind.*, 1906, i., pt. iii., 237-42.]

7. Burma.—Very little has been written regarding the cattle of Burma, so that it is not possible to assimilate them with the Indian breeds. Red is the dominant colour. The horns, when not interfered with, take an upward and forward direction and grow to a length of 10 to 18 inches. The neck is short and powerful and the dewlap not much developed. The Burmans are most considerate of their cattle, never overworking them, and grooming them carefully on the close of the day's task. The animals are also well-fed, so that they are naturally much superior to the imported cattle from India. But as milk-producers the Burman cows occupy a very low place, owing to the prejudice entertained by the Burmans against the use of milk. [Cf. Frost, *Note on Cattle of Burma*, 1889; also *Quart. Journ. Vet. Sc.*, *Ind.*, 1890, Evans, in *Agri. Ledg.*, 1895, No. 10; *Rept. Rev. Adv.*, 1889-90, 17-8, *Dept. Rept.* (natives only), *Agri. Ann. Repts.*, etc.]

8. Bengal and Assam. The very valley cattle of these provinces ought practically to be spoken of as the most inferior in India. They are small over-worked and half-starved animals of which little more can be said than that they are suited to the climatic conditions and soils of the countries in which they live. In certain localities, such as Bihar and Tirhut, considerably better breeds exist, most probably a consequence of the continual importation and crossing of fresh stock. In Gaya, for example, it is not uncommon to find an animal supposed to have been derived originally by crossing the Indian cow with an English "short-horn" bull imported in 1857. "Bihar is overrun with *pols* (bulls dedicated to the gods). These are very fat, and comparatively useless for stock purposes, but do much harm in eating and trampling the growing crops." [Cf. Buchanan-Hamilton, *Stat. Acc. Dinaj.*, 221-8; also in Montgomery Martin, *Hist.*, etc. (many passages); Banerji, *Bankipur Cross-bred Cattle*, in *Agri. Ledg.*, 1895, No. 25; Darrah, *Cattle of Assam*, *Agri. Ledg.*, 1894, No. 14; Mukerji, *Bengal Cattle, Handbook Ind.*, 1901, 578-93; *Imp. Gaz.*, iii., 77-89.]

9. Central Provinces.—The stock is often very mixed. In Nimar, red and brown coloured animals prevail, and in other districts white predominates. The Nimar is, however, generally held to be the best breed. It is a medium-sized animal. Mollison says that it may be recognised by two peculiarities in the colour of the skin and shape of the horns. They are red or brown mottled, but the red is always light, sometimes almost yellowish, and the white markings are never pure white. The horns are thick at the base, blunt, flattened and curved over the head like those of the Delhi buffalo. They are chiefly valued for agricultural work and as draught bullocks. The Arvi cattle of these provinces closely
BREED

BEST MILKING BREED

LIVE STOCK

Oxen

resemble those of Nellore. The bullocks are strong, but not active. [Cf. Repts. Land Rev. Settl. (many districts); Trydell in Apri. Legd., 1898, No. 18; Ann. Repts. Dept. Agrt.; Exper. Farm. Repts., etc.]

10. United Provinces of Agra and Oudh.—Throughout Oudh, the nampadra breed ranks high. But there is a sub-breed known as the risia, which is smaller in size, more leggy and quicker tempered than the nampadra. The horns in both are elegant, thick below, and tapering to a fine point. One important feature is a slight but distinct depression on the forehead which makes it easy to distinguish the Bahrai, from the Doab and Mathura (the kost) cattle. The cows of Kosi and Chhata are celebrated for their milking qualities, and the bullocks have the reputation of being good draught animals (see No. 13 below). The breeds of Kheri are, however, far superior to those of Bahrai, and much resemble the Malvi of Central India and Rajputana. In fact Kheri occupies the most prominent position amongst all the districts of Oudh, being famed for its so-called parchar cattle, sometimes spoken of as bangar. White is considered the best colour and black the worst. The bullocks are fast walkers, have a highly irritable temper, but possess great powers of endurance. Other breeds may be named:—Bhur, Khasirgarh, Majhra-Singahi and Dhaurahra. [Cf. Sayyed Mohammed Hadi, Bahrai, and Kheri Cattle, in Apri. Legd., 1895, No. 12; also Mathura, No. 19; Leather, Barabanki Cattle, Agri. Legd., 1895, No. 17; Ann. Repts. Civil Vet. Dept., 1902, 2, et seq.; Prov. Gaz., 1903-4 (many district accounts).]

11. Panjab. — “It may safely be said that the best milch-cows of Upper India are obtained from the Hansi-Hissar district, and they are commonly termed Hansi cows. With these words Meagher and Vaughan open their chapters on the “Best Milking Breeds.” Speaking of the Harriana cattle, Pease describes the region in which they are produced as “the green country which comprises about 292 villages of the Hissar district chiefly in the Hissar and Hansi Tahsil and the greater part of the Rohtak district.” The region in question has a good soil, passing into clay-loam in one direction and into sand in the other. The average rainfall is 16 inches, and the climate, therefore, is dry and well suited to cattle. But the increase of cultivation within recent years has curtailed the pasture lands and lessened the interest in cattle-rearing. Still the country indicated produces a large surplus of cattle regularly exported, as also a very important supply of ghi traded in all over India. The Hansi-Hissar cattle are uniform in colour; brown colours are seldom, if ever, met with. The skin is usually dark coloured and the hair white or grey, but darker at the shoulders and neck, and on the flanks sometimes almost black or blue. Red-coloured examples are rare and usually inferior. The horns are short, set wide apart and arch outwards, upwards and then inwards, but only slightly forwards. Meagher and Vaughan, while apparently accepting the Hansi as the best breed for Upper India, give several illustrations of the Sanhiwal sub-breeds, which would appear to be frequently broken coloured—red or mixed colours—white being rare. According to many writers, the Montgomery cattle are powerful rivals of the Hansi for the claim of first position as a milk-yielding stock. They are small, shapely and short-legged animals with exceptionally long tails. The Director of Agriculture, in July 1903, drew up a statement of the breeds of cattle in the Panjab, in which he adds to the above the Kuchi or Chenab breed: the cattle of the Jhang district; the Dera Ghazi Khan breeds; the Dhami cattle of the Salt Range; and the Maja cattle of the uplands between the Sutlej and the Ravi. [Cf. Pease, Cattle of Harriana and Sirdar, Apri. Legd., 1895, No. 22; Meagher and Vaughan, Dairy Farming in India, 41-59; Repts. Civil Vet. Dept., 1895-1900.]

12. Rajputana, Central India, Berar and Hyderabad. — The animals of a large portion of the tracts of country indicated naturally approximate very closely to the Hansi breed already briefly indicated. The characteristic cattle of Rajputana and Central India are invariably pure white, though grey or silver-grey specimens are occasionally seen, but broken and mixed colours are unknown. As in other large areas, there may be said to be two sub-races—a large animal specially selected and used by the well-to-do as trotting or fast walking animals, and the ordinary village or agricultural breed. Mollison calls these collectively Malei (or Malvi) cattle, and Major Kemp speaks of the high-class animal as the Nagore (or Nagar) and the agricultural the Rinda (small) breed. It would seem that throughout the country indicated local names are often given which, like “Nagore,” originated from the name of a village or locality specially noted for the superiority of its cattle. Mollison observes that “the head is short, the eyes
are dark, prominent and have a docile appearance. The ears are short with little or no tendency to droop. The horns are very characteristic. They are moderately thick at the base, of fair length and are sharply pointed and invariably spring in a forward and upward direction from the head with a graceful outward bend.” Prof. Wallace describes the horns as resembling two arcs of a circle set on the crest of the head with the concavity inwards. They are much prized as heavy draught animals, and are accordingly frequently seen all over Central and Western India. They are very strong, but not swift; being reared on stony ground, have hard feet and do not require shoeing even when worked on metalled roads (Col. Gerard). They are very largely bred in the territories of H.H. the Maharaja Holkar and H.H. the Maharaja Sindia and the cows are often not milked at all, and in consequence when used as milch-cows are a very inferior stock.

The Khiliari cattle of the Satpura hills (in Holkar’s territory extending to North Khandesh), according to Mollison, were derived originally from Mysore and should be spoken of as the Amrit Mahal breed. Mollison adds, “The fact that Khiliari are now bred true to a particular type in a district where Malvi cattle are also extensively reared is a clear indication that the breeders know the advantage of keeping a good strain as pure as possible.” Mr. Ali Abdoola describes four breeds, met with in H.H. the Nizam’s Dominions, that take their names after the towns in which reared. Commenting on these, Vet. Major W. R. Hagger observes that from the description of the prevailing colours “some seem to have a strong strain of Mysore in them, some show a Deccani cross, while others seem to resemble the Malvi breed.” [Cf. Kemp, Powlett, Reynolds, Hendley and Hagger, in Agri. Ledg., 1900, No. 21; Gerard and Abdoola, in Agri. Ledg., 1900, No. 22; Gaz. Raiputana (Ajmir), 1904, i., A., 49–50.]

13. Hill Cattle.—The cattle seen on the higher cultivated Himalaya are small sturdy animals with short, thick legs. They are admirably suited to the regions in which they are reared, and are very active and wild. They are mostly black in colour, though occasionally dun or mottled examples are met with. They are well protected from the severity of the winter by a thick, shaggy coat. The hump and dewlap are hardly if at all present, and, as pointed out by Walker, they much resemble the Kerry-Dexter cattle of Great Britain and Ireland. The cattle of the lower tracts, being annually taken to the grazing lands of the Bhaber country, have been crossed with the breeds of the adjacent plains. In the higher tracts the pure hill breeds are met with, and these are spoken of by names denoting regions or special sub-breeds. The males are used for ploughing, but their working qualities are poor and many refuse to work at all, while the cows are poor milkers. In a further paragraph will be found particulars of the traffic from Nepal to the plains of India in live stock. [Cf. Walker, Kumaon Cattle, in Agri. Ledg., 1899, No. 7; Lawrence, Valley of Kashmir, 358–60.]

**CATTLE FOOD AND FODDER.**—There may be said to be two conditions of cattle-rearing in India—(a) village or agricultural, and (b) prairie or nomadic. The latter consists of large herds fed on fertile non-cultivated lands, the former small herds or solitary animals reared at the homesteads, thus mostly on cultivated lands. It is generally said, moreover, that the advances of cultivation are rapidly curtailing the areas of nomadic production and thereby cutting off the sources of supply of

Conditions of Rearing.
superior breeds. Hay-making is not practised by the Indian cultivators, and the surplus of naturally produced grass is thus left to waste. Moreover, the cost and difficulty of transport preclude the equalisation of supplies, hence in seasons of drought the greatest hardships have to be endured, and the first indication of famine is the increasing death-rate of the cattle. For example, during the famine years of 1899–1900 something like 70 to 80 per cent. of the cattle perished in certain districts of Bombay, notwithstanding the large imports of fodder made by Government, for the railways were unable to cope with the burden thrown on their resources in conveying food and fodder to the famine-stricken districts.

It has sometimes been upheld that cattle represent the raiyats' capital. They certainly provide the labour for ploughing and carting, as well as very largely supply the manure and fuel used by their owners. In return the animals get what they can pick up (after the crops are off the fields) and what they can discover on the waysides and waste lands. Nevertheless they often become the cultivator's greatest source of poverty and danger. They increase beyond the needs of the neighbourhood, and thus rapidly change the character of the vegetation: noxious weeds survive and nutritious plants are gradually exterminated. Thus are the village cattle themselves not only depraved and starved, but the natural fertility and humidity of the soil lowered to such an extent that any untoward climatic disturbance only too frequently means famine. Of few localities can it be said that special food or fodder is grown for the cattle, but where this is done, as, for example, the cultivation of the cluster-bean, Cyamopsis psoralioides (p. 449), and of fodder crops of Sorghum vulgare (of which the races known as sundhia, dudhia, nilva, etc., may be mentioned, p. 1039) in Gujarat and Jhang, etc., etc., the superiority of the cattle in these regions has been frequently attributed to that circumstance. It is of course customary to give rich foods (including several kinds of oil-cake) to milch-cows and to bullocks in daily work. Mollison reviews the opinions that prevail in India regarding linseed, til, niger, safflower, ground-nut, cocoanut, and cotton-seed cake. [Cf. Leather, *Agri. Ledg.*, 1897, No. 8.] It is somewhat remarkable, but true, that a very large percentage of the draught bullocks of India are fed exclusively on dry food. It is of course very generally believed that green food is not suited to working cattle. This is, however, a very different question from that of the conditions of life and the food-stuffs essential to systematic breeding, where the improvement of stock is a distinct feature. The contrast between the bullocks belonging to the European planters in Tirhut and those of the Bihar peasants, or between the bullocks owned by the Burmans and those possessed by the Hindustani residents in Burma, abundantly exemplify the difference between carefully reared and properly tended cattle and those brought up under a system of indifference and neglect.

In the *Dictionary* will be found a complete enumeration of the trees, shrubs, herbs and grasses known to be of value as cattle food and fodder. Excellent pasturage exists in most provinces, especially on the lower hills and great Himalayan range. Open stretches of grass-land (maidans) often extend from the upper limits of the forests towards the snow-line. On these uplands vast herds of sheep and goats are to be found, the latter affording the much prized *pashm* wool (hair). But on the lower Himalaya the cattle are largely fed on the leaves of four species of oak and a few other trees. The grass that exists abundantly in these tracts is as a rule

Cut and dried as hay in order to be exported to the plains. The extent to which leaves are utilised as cattle fodder is a speciality of India. In the deltaic tracts and rice lands generally, the cattle are miserably poor. Grazing lands are limited, or totally wanting, and the only fodder available in any quantity is rice straw, which provides scant nourishment. Moreover, it may be said that little or no concentrated food is given even to the work cattle in busy seasons. In peninsular India, good grass is not found where the average annual rainfall much exceeds 40 inches. In some parts of that vast area, therefore, the cattle are extensively fed by hand on the produce of arable tracts (Imp. Gaz., iii., 86). The grazing lands of India and the grazing rights of the people are highly controversial questions. Voelcker (Improv. Ind. Agri., 169-97) discusses these very freely, and his views have on the whole been upheld by subsequent experience. But the almost complete absence of special fields of cattle food is perhaps the aspect of Indian farming that strikes the visitor as most significant. The possession of immense herds, reared on waste lands, accounts very largely for the qhi, which is so much traded in all over India; but one of the surest signs of the devastation caused through failure of the rains is the sudden rise in the exports from India of cheap hides—a melancholy consequence of the starvation of these unprovided-for herds.

[cf. Benson, Ind. Fodder Grasses, in Agri. Ledg., 1892, No. 1; Watt, Ground-nut as Cattle Food and Fodder, 1893, No. 15, 87 et seq.; Leather, Silage-making in India, i.e., 1894, No. 2; Feeding Exper., New York Agri. Exper. Agri., 1901, ii., 11-41, 48-52; Mukerji, Handbook Ind. Agri., 632-42; Meagher and Vaughan, Dairy Farming in Ind., 1904, 1-14; Settl. Repts., especially those of Burma, deal fully with the fodder supplies and grazing rights.]

DISEASES OF CATTLE.—The Agricultural Ledgers enumerated below contain many valuable papers on the diseases of cattle. The more serious and special diseases are briefly:

1. Rinderpest—the bossonto, güté, kalawah, pitchinow, peya, kyauk-pauk, etc. 2. Anthrax—the golafula, gutherewan, goli, suth, odro, thalorinova, daunghan, etc. 3. Foot and Mouth Disease—the khural, aosa, khurpakka, mohona, mupaving, sha-na-kwalna, etc. And 4. Pleuro-pneumonia—the phipri, asok-yau-ga, etc. In a special Veterinary Series of The Agricultural Ledger have been published numerous papers on the above and other diseases which the reader, desirous of such information, should consult. Two papers may, however, be specially indicated, namely, Dr. K. Mcleod’s Measures, Legal and Sanitary, adopted by European Countries to oppose the introduction and spread of cattle plague (1896, No. 20), and Prof. Koch’s Method of Immunising Cattle against Rinderpest and the Resolution of Government of India on the same, together with the Opinions of Indian Veterinary Authorities (1898, No. 5). But for practical dairying operations, particulars of all the ordinary ailments of cattle will be found in the chapter on diseases of horned cattle and their treatment given by Meagher and Vaughan, in their work on Dairy Farming in India (1904, 113-143, 147). These authors conclude with the following recommendations, strict attention to which they consider calculated to avert serious loss and inconvenience:

“(a) Proximity of grazing grounds to the cattle-yard, enabling the
cattle to go out and back without possible contact with outside cattle or their tracks; (b) Complete separation between the dry stock and cattle in milk; (c) Frequent inspection of all home cattle, and immediate isolation of animals from any disorder, however simple; and the prompt disinfection of all ropes, standings, troughs, etc.; (d) Perfect sanitation in and about the cattle-yard, standings, stalls, etc.; (e) Tramway lines for the conveyance of grain, fodder, etc., to the cattle-yard and the rigid exclusion of all outside draught-cattle bringing in these supplies; (f) The allotment to sick cattle of special attendants, who must not be permitted to approach the healthy animals, or associate with the staff working in the cattle-yard; (g) The best and most wholesome fodder, grain, cake, etc., only fed to the cattle; and (h) Complete segregation at as great a distance as possible from the infected enclosure; and, as calves are the principal medium, not more than sixteen calves should be housed together.”

Poisoning.—Among the important causes of cattle-death has unfortunately to be given criminal poisoning. The chumara are the chief criminals, and their method of accomplishing their nefarious purpose is by the use of the sui (see Abrus, p. 1).

[ Cf. Voelecker, Improv. Ind. Agr., 1893, 213-5; Peace, Cattle Plague, in Agr. Ledg., 1896, No. 8; also Kristnasumyengar, Cattle Disease of Mysore, 1896, No. 28.]

II. THE GOATS AND SHEEP OF INDIA.

In addition to the oxen (discussed above) the family of the Bovidae includes the goats and the sheep:—

THE WILD GOATS.—The following are the species recognised by zoologists:—

Capra aegagrus, Gmelin: Blanford, Fa. Br. Ind. (Mammalia), 502–3: Masson, Journ. to Kalat, 1843, 445–6; the pasang (male), bəz (female), borz, kayik, thar, sair, sarah, chank, etc. A wild goat found throughout Asia Minor, Persia, Afghanistan, Baluchistan and Sind.

This remarkably interesting goat inhabits barren rocky hills in herds of varying numbers, but always keeps much to the cliffs and crevices. Capt. Hutton, who, while Resident at Kandahar, devoted much careful study to C. aegagrus in domestication, and cross-bred it with the common goat, arrived at an emphatic opinion, opposed to that advanced by Hodgson and others, namely, that the Persian and Afghan goats at all events were not derived from C. aegagrus. The late Dr. Blanford, the most recent author, however, says “there can be no doubt that C. aegagrus is one of the species, and probably the principal from which tame goats are derived.” The flesh of this wild goat is highly prized. The skins are valued as water and flour bags. The horns are carried by mendicants, and trumpet-horns made of them. The bezoar-stones are found in the stomach (see Bezoar, p. 131).

C. falconeri, Hugel; Blanford, l.c. 505–8; Vigne, Travels, etc., 1842, ii., 279; the markhor (snake-eater), ròche (the great horn), tush-ra (water goat), rezkuk, rūsh, pachin, etc.

A magnificent animal which inhabits the Himalayan tracts west of the Beas to Kashmir, Ladakh, Baltistan, Afghanistan, Baluchistan, etc. It frequents high ranges, especially where concealment is afforded by shrubs or broken rocks, and is then met with in large herds. There are several well-marked local varieties that differ from each other mainly in the length, shape and degree of twisting and curving of the horns. It is much sought after by sportsmen, and is said to be in appearance by far the grandest of all the wild goats. Has repeatedly been bred in confinement and crossed with the domestic goat. It is generally believed, in fact, that some of the races of domestic goats with spiral horns have descend from this species. There are two important points that should be borne in mind: the direction of the spiral of the horns is outward, not inwards (as in most domestic goats), and the markhor does not possess the under-fur or pashm (pam) of the alpine domestic breeds.

C. sibirica, Meyer; Blanford, l.c. 503–5; the Himalayan Ibex, the skin or sakin, dabmo or dammo, kail, tangrol, buz, skiul, etc.
THE GOATS AND SHEEP

LIVE STOCK

Goats

Ibex.

This ibex may be said, so far as India is concerned, to extend from the eastern limits of the last-mentioned species east to Nepal. On the north of the Himalaya, however, it is very plentiful and passes considerably to west of its more strictly speaking Indian area, so that in Central Asia it can be spoken of as distributed from the Altai to the Himalaya. It frequents the most precipitous cliffs at elevations close to the limits of perpetual snow. Is able to withstand the extreme cold through its possessing a thick under-fur (pashm or porm). This interesting animal is, in fact, much sought after on account of its under-fur, which in Kashmir is called asali tás. Shawls, stockings and gloves are lined with it and the wool is also woven into the remarkably fine cloth called tísí or into the famous ibex shawls. Cooper speaks of two specially fine qualities of pashm, a white and a grey, both obtained in Tibet from a small species of wild goat called thosh. It is said that no wool is so rich or so soft. The hair or upper-coating, on the other hand, is made into ropes or woven into coarse cloth—pattu—and used for coats, tents, etc. In Ladakh large numbers of this goat are annually killed in winter, when forced to descend into the valleys. In consequence a fairly extensive supply of wild pashm is regularly obtainable. No one has, however, recorded the existence of the ibex in domestication, nor of its having been crossed with the tame goats. Still it is sometimes upheld that the pashm-yielding domestic goats of the alpine tracts must have been derived from this or some closely allied extinct species.

BREEDS OF DOMESTIC GOATS.—Very little is known of the origin of the Indian domestic goats. As just stated, C. aegagrus is believed to have given an important strain to a large percentage of the breeds. C. falconeri is viewed as having similarly contributed in building up the peculiarities of some of the breeds with spiral horns. Fossil remains of a closely allied goat have been found in the rocks of the Siwaliks and of possibly another species in Tibet. Crosses between the wild goat of Western Sind and Quetta with the markhor have not only been produced but found naturally and shot by sportsmen. The powers of endurance possessed by these animals may be inferred from the circumstance that C. aegagrus is found near the sea-level in Sind and Baluchistan and at 13,000 feet in Persia. According to Henderson, C. sibirica bears so strong a resemblance to certain breeds of tame goats, met with on the alpine Himalaya and Tibet, that it may be safely assumed to have given to these their undercoat of pashm.

Thus, then, the authors whose opinions are of most value admit the possibility of the Asiatic goats having been derived from more than one species, and the advisability of such a conclusion (apart from the diversified form, stature, colour, habits, etc., of the tame races) receives countenance from the admitted existence of fertile hybrids between the wild species themselves, as also between these and the domestic animals. The progression in characteristics from the typical village goat of the plains and the düqü goat of the lower Himalaya to the Alpine pashm-yielding animal may, therefore, mark the stages of adaptation and crossing of different species, with the nearer approach in the extremes to the specific types. If there be any plausibility in this suggestion, the difficulty which the early writers foresaw in any attempt to breed the true pashm goat on the southern slopes of the Himalaya would at once assume a distinct position. Lawrence (Valley of Kashmir, 364), speaking on this subject, says, “An attempt was made to introduce the shawi-goat into Kashmir, but if failed, as the climate is not sufficiently severe to induce the undergrowth of wool which nature provides in Tarfân for the protection of goats and other animals from the keen winds of that country.” It would thus seem certain that the closer the effort at improvement is kept within special areas and with existing stocks the better. To cross the pashm goats with the non-pashm breeds

744
of Angora blood, has as been suggested, would obviously be to court failure. It might, however, be possible to cross the alpine breeds of Sind, Baluchistan and Hazara with the Angora goat, if foreign blood be considered essential.

Many years ago the proposal was made to establish sheep and goat runs on the southern slopes of the Himalaya with a view to improve and extend the Indian supplies of wool and hair. This has never been definitely tried, though much has been written on the growing necessity for better and more certain supplies of these staples. Falconer seemed to think that the pashm goat might be acclimatised on the southern slopes of the Himalaya, but it must not be forgotten that the down of the ibex and of the pashm domesticated goat seems to be directly the result of the drier and ever so much colder nature of the northern as compared with the southern slopes. Indeed the pashm goat may be said to actually exist at Spiti, and according to Hodgson the chädpǔ is the acclimatised form of the Tibetan chängrä. If this be so, the goat, even if successfully reared on a more extended scale than at present on the southern slopes, would probably yield a far inferior pashm than the northern stock, if indeed it did not degenerate into a form of the pat-yielding (not pashm) goat. It may, however, be safely said that for present European commerce a pashm goat is not an indispensable necessity of success.

Speaking of the plains, sheep and goats are most successfully reared in areas that receive a moderate rainfall. Upland well-drained soils with sparse jungle growth and a considerable variety of herbage are necessary. In peninsular India the shepherds possess large flocks, with which they wander from place to place when arable land is usually clear of crops. The sheep and goats graze during the day and are folded at night on land where it is desired to obtain the manure of their droppings. This is paid for by the cultivators whose lands are thus benefited. Goats are valued for their meat and milk, and on the Himalaya for their hair.

CHIEF BREEDS.—With the exception of Mr. B. H. Hodgson's valuable paper on the sheep and goats of the Himalaya and Tibet, and of Capt. T. Hutton's paper on the sheep and goats of Afghanistan, the subject has never been systematically treated, and little can be added to the particulars given already in the Dictionary. I am, therefore, unable to do more than mention by name some of the better known breeds of Indian goats:

1. South Indian Goat.—These are gaunt in appearance and badly proportioned, but hardy and active and can exist on almost any kind of vegetation.
2. North Indian Goat.—A much finer animal than that found in the south. The ears are large and perfectly pendent. This is possibly the jamnāpari of Hodgson. [Cf. Hoey, Monog. Trade and Manuf. N. Ind., 1880, 90, 105-6; Pirn, Monog. Woollen Fabrics U. Pem., 1898, 2-3; Note on Indig. Sheep and Goats of the Pb. in Land Res. and Agri., 1903.]
3. Surat and Gujarat Goats.—These are small short-legged animals that are much valued as milkers.
4. Nepal Goat.—The best-known breed; has long flapping ears and rounded nose.
5. Bengal Goat.—This is smaller even than the Madras animal, and is usually quite black and destitute of horns. Hodgson identifies it with the dīgu of the Himalaya. [Cf. Basu, Agri. Lāhardaga, 1880, i., 92; ii., 44-5; Banerjei, Monog. Woollen Fab. Beng., 1899, 1-3, 33-6.]
6. The Hill Goats of the Deccan, Sind, Rajputana and Baluchistan.—The hair of these animals is more abundant and woolly than the plains goat, and the horns

745
are often large but only exceptionally spiral. These are the hair-yielding species of India.

7. Syrian Goat.—Hybrids of this breed, commonly designated "Aden goats," are well known in India, wither they are imported by the Arab traders and passed off under the names Angora or Kashmir. They have long, flapping, pendent ears and slender limbs. Their horns are usually erect and spiral.

8. Himalayan Goats.—Hodgson's paper (Journ. As. Soc. Beng., 1847, xvi., pt. 2, 1003-12), as already stated, practically gives all information regarding those known to exist. He refers them to the following special breeds:—

(a) Chângrá—the common domestic goat of Tibet, which hardly deviates from the wild goat (C. aegagrus) except in the large and pendent ears. Hutton, on the other hand, holds that so far as the Persian and Afghan goats are concerned, they could not be regarded as derived from the wild goat just-named.

(b) Chápu or Chhyápú—the goat of the Sub-Himalaya (especially the Cis-Himalaya). It is much smaller than the chângrá and has long hair and fine sub-fleece.

(c) Sinul or Singál—an inhabitant of the more northern parts of the Sub-Himalaya from Kumaon to Nepal, where it is probably indigenous. The surcoat and fine sub-fleece, though inferior to those of the chângrá and châyápú, are yet capable of being applied to the manufacture of ropes, blankets, serges, etc. It is less patient of change than the chângrá or châhyápú, but the mutton is good, especially that of the kids.

(d) Dûghâ—a goat of the Central Sub-Himalaya and lower warmer tracts. It is characterised by the absence of the long hair and the nearly as frequent absence of the interdigital pits of the other breeds. The male is much larger than the female, and often almost shaggy. There is no sub-fleece, the hair is coarse and next to useless. [Cf. Barnes and Lyall, Settl. Rept. Kangra, 1889, 38-43; Diak, Settl. Rept. Kangra, 1898, 36-68; Drew, Jummo and Kashmir, 1875, 288; Lawrence, Valley of Kashmir, 1895, 360-4.]

THE WILD SHEEP.—It has, however, been known from the most ancient times that wild sheep and goats exist in India. Älian (compiling from Megasthenes, 300 B.C.) speaks of the wild sheep and goats on the mountains of India. If considerable uncertainty exists as to the origin of the Indian goats, a far greater obscurity enshrouds the sheep. The structural difference between the members of the genus Capra—the goats—and that of Ovis—the sheep—is very small indeed, and one species—Ovis nahuara—is practically intermediate. The origin of the Indian tame sheep is unknown. Continuing the example above, the following are the wild species:—

Ovis hodgsoni, Byth (O. Ammon, Hors.); Blanford, Fa. Br. Ind. (Mammalia), 494-5; the Great Sheep of Tibet, the nyam, nyand, hyam, niar, etc. This magnificent sheep, probably the largest of the genus, does not usually occur on the Indian side of the Himalaya. It is the shyest and wildest of all animals, and is very hard to kill. It has never been domesticated, but wild hybrids between it and O. vignei have been shot.

O. nahuara, gray; Blanford, l.c. 499-501; the Bharal or Blue Wild Sheep, the bharal, bharut, na, wa, nervati, nai, etc. This sheep is met with in the alpine tracts (between the limits of forest and snow) from Bhutan to Ladakh and Western Tibet.

O. poli, Byth; Blanford, l.c. 496-7; the Great Sheep of the Pamirs: Marco Polo's sheep is the kuchkár, ras, rish, kulja, arkar, etc. This remarkable sheep only occurs within the Indian area at Hunza, north of Gilgit. [Cf. Marco Polo, Travels (Yule, transl.), i., 163-9.]

O. vignei, Byth.; Blanford, l.c. 497-9; the Ural or Sha—the Bearded Sheep, known to the Natives as the kuch, koch, guch, gad, mish, sha, ural, uriar, etc. It is the wild sheep of the Salt Range in the Panjáb and of the Suliman Range of Hazara and Afghanistan, etc. The varieties most generally recognised are the ural, which occurs between 800 and 5,000 feet, and that called the sha at much higher altitudes—10,000 to 14,000 feet.

It has been bred freely with tame sheep, and wild hybrids (as already noted) between it and O. hodgsoni have been shot. If, therefore, any of the preceding
animals have contributed to the breeds of Indian sheep, \textit{o. signeri} seems to have done so. It apparently affords a small proportion of the \textit{pashm} known as \textit{thosh}, and from the lacrimal sinus a thick gummy substance is obtained that is much valued in greasing metal locks. Mr. Drummond informs me that pure or half-breed \textit{dumba} have been crossed with this wild sheep and that the progeny exhibit, while young, an under-fleece similar to \textit{pashm}. But according to local belief this cross is only attained if \textit{dumba} stock be employed.

**Breeds of Domestic Sheep.**—Sheep are met with throughout the plains and lower hills of India and up the Himalaya to the sub-arctic zones. The breeds of Indian sheep are quite as extensive and diversified as those of Europe. Some are tropical, thriving in swampy regions or on dry, arid tracts, others warm temperate, still others temperate or even arctic. There has, however, been even less of an authoritative character written of the Indian sheep than of the goats. Most writers have discussed the Patna, Dumba, Meywar, Madras, Mysore, etc., breeds without having considered it necessary to detail their characteristic features. Shortt (\textit{Manual of Indian Cattle and Sheep}), if his illustrations can be viewed seriously, would seem to establish for South India certain well-marked breeds, and doubtless extensive diversities exist among the sheep of other provinces. But, speaking generally, it may be said of perhaps more than half the breeds found on the plains of India, that they afford a kind of hair rather than a wool. They are reared chiefly on account of mutton, their fleece, like the hair of the village goat, being, comparatively speaking, valueless.

But although many of the sheep of India yield a fleece of hair rather than of wool, certain breeds give fairly good wool. Of this class may be mentioned the black-headed sheep of Coimbatore, the woolly sheep of Mysore, the sheep of large portions of the Deccan, of Rajputana, of the Panjáb, and, in Bengal and the United Provinces, the so-called Patna sheep. Although there are possibly several very distinct breeds of large fat-tailed sheep (all designated \textit{dumba}), these should be classed as wool-yielding breeds. They have been crossed with the Patna, the Merino and other imported sheep, and apparently with satisfactory results, though the improvement effected cannot be said to have been lasting. Some of the fine wools imported from Afghanistan and Persia are obtained from breeds of \textit{dumba} sheep, and this fact having been ascertained many years ago, effort was put forth to secure stock for breeding purposes. So far the result, however, has been unsatisfactory, for when conveyed to the moister tracts of India, the fat tail has proved a source of danger. It is liable to disease, so that unless a breed could be produced, in the natural habitat of this animal, that would preserve its merit as a wool-producer during successive crosses in which it was gradually developed into a condition suitable to the plains of India generally, it is not likely to be of much value to future breeders. It may, in fact, be said in conclusion that, so far as past experience goes, the breeds of most value, as Indian stock for improvement, are the Coimbatore, Mysore, Rajputana and Patna. But it may be added that perhaps the majority of persons who have given this subject anything like careful consideration seem to incline to the view that except in certain tracts, there is very little hope of India as a whole becoming of much greater moment than at present as a country of wool-supply. Interest is far more keenly directed towards facilitating importation from the mountainous countries bordering on India, than in any material improvement of the wools of the
THE GOATS AND SHEEP

LIVE STOCK
Sheep

The following may be mentioned as the better known breeds of sheep in India:

1. Rajputana (Meywar) Sheep. These are the finest and largest sheep in India. They are sometimes called Delhi-Hansi or Tuttgyhar sheep. They have poor wool, but the mutton is large though somewhat coarse. [Cf. Ann. Rept. Civil Vet. Dept., 1893-4, 14-6.]

2. Bengal and Patna Sheep. The former is very inferior but the latter one of the best breeds in India. They yield good wool and fatten readily. In 1836 an effort was made to improve the Patna sheep by crossing them with Southdown rams. So also a similar effort was made with Bhagalpur sheep.

3. Madras Sheep. The best are those of Chingleput, Kistna, Godavari, Ganjam, Arcot, Salem, Trichinopoly, Tanjore, Madura and Tinnevelly. They are coated with a coarse brown wool or hair of little value. An experiment was for some years prosecuted at Herangallhi to improve these sheep by crossing them with Merino rams imported from Australia. This was abandoned in 1893.

4. Nellore Sheep. A large breed, examples of which have been known to scale 80 to 100 lb. They are tall, leggy, and white or light brown in colour.

5. Coimbatore Sheep. This is known as the kurumba breed. It is a wool-producing sheep, small in size, the prevailing colours being black with white heads. They fatten well, and the mutton of gram-fed animals is rich and well-tasted.

6. Mysore. This is a woolly breed. The colour is light to a very dark grey or black. It furnishes the best fighting rams of the plains. [Cf. Buchanan-Hamilton, Journ. Mysore, etc., 1807, i, 119-21; ii, 276-8; iii, 354-5.]

7. Bombay Sheep. Dr. Hove, in 1787, speaks of the sheep in the Deccan as being the finest he had seen in India and as having superior wool. So long ago as 1835 Col. Jervis conducted extensive experiments with a view to improving the Bombay sheep. Subsequently Col. Pottinger, Sir A. Burns and others brought sheep from Kabul, the districts of the Upper Indus, Persia, the Cape of Good Hope and England. A farm was established at Ahmednagar, and for some years vigorous experiments at stock improvement were prosecuted. This was reported on by Sir George Arthur in 1843, who recommended that fresh Merino rams should be continuously imported for some years to come. The subject seems, however, to have been suddenly forgotten and the farm abandoned, for nothing of any importance was subsequently published regarding it. Mollison (Textbook Ind. Agrî., ii, 59) says nothing of these experiments nor of the fate of the farm. He offers, however, many useful and practical suggestions based chiefly on experience gained in Bombay. Sheep and goats, he says, are most successfully bred in districts with moderate or light rainfall and light, naturally well-drained soils. Neither sheep nor goats thrive during the monsoon in heavy-soil districts. In the breeding districts large flocks do not thrive unless they are continuously grazed on clean ground. Large flocks of sheep and goats are brought in the fair season by professional shepherds from Kashiswar into the plains of Northern Gujarat, and also from the upland comparatively dry waste grazing lands east and north of Khandesh, to the black-soil tracts and arable plains of the Deccan. A few goats among the sheep are decidedly advantageous. They lead the flock and keep the sheep moving and thus grazing. [Cf. Morgan, Sheep-Breeding in the Deccan, in Agrî. Ledg., 1896, No. 18.]

8. Nepal Sheep. Of these there are two kinds—the village ghorapalla and the forest ran baria. The last is a small and almost semi-wild animal that lives in large flocks on the wooded hill slopes.

9. Kashmir Sheep. Lawrence (Valley of Kashmir, 360-4) gives many interesting particulars regarding the sheep and wool of Kashmir, but says nothing of the breeds met with except that some are as good as the Southdowns. Mr. Drummond informs me that in Kashmir it is the custom to wash the sheep in the river before being shorn, a circumstance that would point to the wool being valued more highly than is commonly believed. Baldrey (Agrî. Journ. Ind., 1906, i, pt. iii, 201-4) urges the “Benefits of Sheep-dipping” in India.

10. Himalayan and Tibetan Sheep. Hodgson mentions some five breeds with, under some of these, several sub-breeds. Space cannot be afforded to do much more than enumerate the principal examples of these by name:

(a) Hümä of Western and Hálik of Eastern Tibet. A tall, graceful animal,
the universal beast of burden on the higher snowy ranges—is docile and sure-footed. Hodgson compares this with the great wild sheep (O. hodgsoni). It cannot endure the ranks pasture or high temperature of the Sub-Himalaya. Mutton and fleece are both excellent.

(b) Silingia or Siling sheep or Pelik of the Eastern Himalaya. According to Hodgson, the Siling country corresponds to the Serica regio of the classics. The animal is smaller than the hümā. In colour it is white tinged with fawn.

(c) Báráíal or Barwal is a Cis-Himalayan breed and the ordinary sheep of the Cachar or northern regions of the Sub-Himalaya between the Jümula and the Kirant. Hodgson, in fact, says this breed practically extends from Kumaon to Sikkim. It is the great fighting ram of the hill tribes. It is remarkable for its massive horns entirely covering the top of the head. The flesh and the fleece are both abundant but coarse. By far the largest number of the ráhria or coarse blankets and serges manufactured in these hills, and which are extensively exported therefrom, are made of báráíal wool. Coarse as this wool is, it is, however, superior to the wool of the plains.

(d) Cágéa—This is the characteristic breed of the central region of the Sub-Himalaya. It is reared rather by householders than shepherds, and for its flesh rather than its wool. It is a handsome animal, but its head is too large, though the legs are short.

(e) The Teraí Sheep. This is practically identical with the sheep of the plains.

It may in conclusion be pointed out that Hodgson’s Trans-Himalayan sheep (the hümā and the silingia) are, like his Trans-Himalayan goats (chángrá and chápi,) far superior to his Cis-Himalayan breeds. If, therefore, India cannot acclimatise and develop new breeds on the southern slopes of the Himalaya, attention should be given not only to increased facilities of transport and more friendly intercourse with the Trans-frontier tribes for increased supplies of superior wool.

11. Hira and Dumba Sheep.—Some at least of the breed are natives of Afghanistan and Persia, and others of Africa. They are frequently imported into India, and are large sheep characterised by the immense development of masses of fat placed on either side of the tail, forming stores of nourishment which are drawn upon during the winter months, when fodder is scanty. Hutton tells us that in some parts of the country the tail grows, in fact, to such a size that a small wheeled carriage has often to be constructed to carry its weight. Hodgson calls them puchia (tailed) sheep. The wool is of good quality, and on that account they have often been crossed with Indian plains sheep. Mollison says dumba sheep have proved exceptionally suitable for crossing with the Deccani stock. The wool of these half-breeds, like that of the pure dumba, is of fine quality and long. The mutton is said to be coarse, though the tail is sometimes spoken of as of great value.

Ælian (De Nat. Hist. Anim., 250 A.D., iv., 32) speaks of the tails of the Indian sheep reaching to their feet and as being cut open by the shepherds, the tallow removed, and the tails sewn up again. Marco Polo, in the 13th century, and Varèthema, in the 16th, describe the dumba or Ethiopian sheep as seen by them on the east coast of Africa. Marco Polo says the tail often weighs 30 lb., but Varèthema puts it at a lower figure, 15 to 16 lb. Terry (Voy. E. Ind., 1622 (ed. 1777), 90) observes that “their sheep differ from ours by their great fleshy bob-tails which severed from their bodies are very ponderous. Their wool is generally coarse but their flesh is not so.” There would thus seem no doubt that this particular sheep has existed in India from fairly remote times. The head and neck are quite black and the body otherwise white. In the Cairo Museum, among the ornaments found in the mummy-pits, there is a little figure of one of these sheep, so that it may safely be said they have been known from ancient times and beyond the limits of India. [Cf. Cordemoy, Le Prod. Colon. d’Origine Animale, Paris, 1903, 126-38.]

III. HORSES,ASSES, AND MULES OF INDIA.

The horse has been a domesticated animal since prehistoric times. Ælian, compiling doubtless from Megasthenes, 300 b.c. (De Nat. Hist. Anim., xvi., 2–22), says, “In India there are herds of wild horses and also of wild asses.” No aboriginal or truly wild horse is known to exist to-day, though wild representatives of the ass are well known. [Cf. Blanford, Fa. Br. Ind. (Mammalia), 470-1.] There seems, however, little doubt that
all the existing races and breeds of horses have descended from one common stock, which Darwin believed was dun-coloured and more or less striped. In Neolithic times a wild horse would appear to have existed in Europe, but the animals of the present time have probably not been developed from these, but from animals which it is well known were imported from Asia into Greece and Italy. But even these Asiatic ancestors were doubtless only a consequence of a still earlier long-continued selection from a stock or stocks that to some extent may be indicated by the fossil remains discovered. The artificial selection conducted by man has been toward specific purposes. The English thoroughbred may be mentioned as the final manifestation in speed; the English draught-horse in working capacity; and the Shetland pony in sure-footedness and suitability for mountainous regions. What may be true of England can be shown as equally applicable to all countries wherever the horse has been appreciated in agricultural, industrial and political life. The most ancient histories and traditions of India point to a specialisation in warfare. Aelian describes the King's stables; the use of the bit and bridle in making the horses move at a measured pace; the breaking in of the animals by forcing them to gallop round and round in a ring; and when on the march, we are told the war chariots were drawn by oxen and the horses led on a halter so that their legs might not be galled nor their spirits damped by drawing the chariot to the battle-field. None of the early writers would seem to make even the most distant allusion to the Indian horse being used for agricultural purposes or for transport; adaptation, therefore, to riding and swiftness were the directions of early Hindu influence on the horse. The establishment of the rule of peace under British supremacy of necessity meant the overthrow of martial power and the loss of the races of fiery chargers that doubtless previously existed in India.

**Principal Indian Breeds.**—There seems at all events little doubt that the Native breeds of horses have diminished and deteriorated since the establishment of British rule in India. The suppression of the predatory system lessened the demand, and the superior Lakhi and Cutch breeds which for centuries had been famous became almost, if not altogether, extinct. It is probable also that the requirements of modern warfare for larger and more powerful animals than India naturally produced, led to a system of artificial breeding, in which size was the object mainly aimed at, an object that might easily have resulted in the deterioration of the original small, hardy and swift breeds and the production of badly formed and weedy animals. Within recent years the Government of India have adopted, in the Civil Veterinary Department, a policy of supplying specially selected stallions to each important centre. These have been chosen in consideration of the most hopeful directions of improvement of existing stock, and their services are placed at the disposal of horse-breeders free of charge, provided the mares have been examined, approved and branded, by a representative of the Department. According to universal repute this has had a most beneficial effect. The following are some of the better known indigenous breeds:

1. **Kathiawar and Rajputana.**—The Chiefs in these States still continue to give attention to horse-breeding and many of them keep up very large stables, in which the most careful selection is observed. The original breed—known as the Kathi—was noted for its great powers of endurance. The peculiarities of the animal are that it is generally under-sized and small-boned and has a distinctive mark, a black cross down the back and black bars on the legs, the colour of the
cost varying in every shade of dun. It is supposed to possess a strong strain of Arab blood, an opinion supported by the known frequent intercourse between the two countries. The mares are most esteemed, as the horses are noted screamers. The Bhavnagar and Palitana Princes take the greatest possible interest in the preservation and improvement of this peculiar and special breed. The horses of Kach and Sind do not materially differ from those of Kathiawar. They are usually a little over fourteen hands, are well-made, spirited, showy in action, with clean limbs, good bone, thin long neck, large head, outstanding ram-like brow, and small ears. Their great defect is their bad temper. But there may be said to be three other types in the Presidency in the hardy Maratha pony, the little Gujarati, and the Bimthadi of the Deccan. The last mentioned is one of the best breeds in India.

3. Waziri and Baluchi.—A fine breed of hardy and active animals. They have good shoulders, very deep and moderately broad chests and angular drooping quarters, very broad across the hips. They make excellent troopers on account of their speed and endurance, and, crossed with Arabs and thoroughbred English horses, become good cavalry remounts.

4. Panjáb.—There are many special races, such as those reared about Rawalpindi, Jhelam, Gujrat, Gugaira and Lahore. In the Sikh times the greatest care was bestowed on them, and stallions from Kathiawar, Kach, Baluchistan and Afghanistan were regularly imported and used to improve the stock. The average Panjábi country-bred to-day is small, but possesses great powers of endurance. It used to be a by no means uncommon occurrence to hear of an ekka pony dragging a cart and three passengers from Simla to Kalka, thus covering 58 miles in one day, without, as the saying goes, "turning a hair." This is representative of the hardy little animals found on the plains adjoining the North-West Himalaya. In former times the Sikh cavalry were horse from Dhanni, north of the Salt Range, and even now large numbers of remounts are drawn from that country.

5. Burma and Manipur.—The ponies of Burma, which are small, hardy and exceedingly tractable, are said to be all importations from the Shan States and Manipur. Their characteristic pace is an unbroken run, in which the shoulders seem to roll from side to side. The pure Manipur is generally considered the best of all Indian ponies. It is well under thirteen hands, is mostly dun-coloured, and is possessed of wonderful powers of endurance and weight-carrying capabilities.

6. Himalayan Ponies.—The Ghunt or Khand breed is met with in Lahoul and Spiti, and is employed almost entirely for saddle purposes. It is never over twelve hands, is strongly built, exceptionally surefooted and hardy, but is often very hard-mouthed and stubborn. A similar animal is the Bhtia pony, which often attains a height of fourteen hands. A larger and more valuable breed is that known as the Yábí of Afghanistan; has a short round body, deep chest, full quarters, and thick limbs—a miniature English cart-horse. It is an admirable pack-horse, and insured to heavy loads. It moves at about five miles an hour, and if allowed to preserve that pace has great powers of endurance. Closely allied is the pack and riding pony of Baltistan and Kashmir.

7. Asses and Mules.—The ass exists in all parts of India and is largely used as a beast of burden, especially by the dhobis or washermen, potters, tinkers, etc. As a rule it is badly cared for, its only redeeming feature being its cheapness. In Kathiawar there is a specially good breed of donkeys, of which the Halar or Jalavad white variety is especially deserving of notice. The people of the interior Himalaya have also a peculiar breed—a very small black animal with long shaggy hair. This they bring with them when they come down in the winter months to seek work at Simla and other outer hill stations. Mules seem to have been known from the most ancient times in India. Allian says that the mares are often covered by the wild asses, red-coloured mules being the result. These are very fleet and impatient of the yoke. They are caught with foot-traps, and when only two years old may be tamed and domesticated. They are then taken to the King of Persia. Blanford gives full particulars of the Asiatic Wild Ass. It is found throughout Central and Western Asia, a few being occasionally seen in Baluchistan, the Panjáb frontier, and even east of the Indus in Bikánir and the Rann of Kach.

For many years past the Government of India have made strenuous efforts to improve the breed of the plains donkeys, and to secure the rearing of a good quality of mules. They have accordingly supplied donkey stallions and offered
Pigs

THE PIGS AND BOARS

IV. THE DOMESTICATED PIGS AND WILD BOARS OF INDIA.

Pig or Hog is the name applied to different animals of the family Susidae, the only representative in India of the sub-division of the Ungulates known as Susina. Blanford enumerates the following species:—

**Sus cristatus**, Wagner: Blanford, Pa. Br. Ind. (Mammalia), 560-2; **Indian Wild Boar**, sur, bad janvar, varaha, paddy, dukkar, pandi handi, tan-wet, etc. This is the only species of any interest or importance economically. It is found throughout India, from the sea-level to an altitude of about 12,000 feet, wherever there is sufficient shelter, either of long grass, low jungle or forest. When abundant it does great damage to crops. The tame pig of India is probably derived from the wild animal, and in some places is said to breed with the latter. Several races of domesticated pigs are met with in India, where religious and caste beliefs allow of their being kept. In the article on **Lard** (pp. 701-2) it will be seen that two chief classes of pigs are spoken of, namely the "China pig" and "the Country pig."

**S. andamanensis**, Blyth: Blanford, Lc. 562-3. The Andaman Pig. A small animal, some 20 inches high, occurring in the forests of the Andaman Islands.

**S. salvarius**, Hodg.: Blanford, Lc. 563. The Pigmy Hog. In the forests at the base of the Himalaya in Nepal, Sikkim and Bhutan. Its habits are very similar to those of **S. cristatus**. It is found chiefly in high jungle grass, in herds of five to twenty. They are rarely seen, as they leave the forests at night only, but may be traced to their lairs by the mud coatings of the lower vegetation left behind them. In Manipur I found this species to form coverings over their lairs by breaking and throwing down the spiny bamboo.

The pig affords various economic products, the chief of which are Bristles, Lard, Meat (Pork, Ham, etc.) and Skin. **Lard** is separately dealt with under that heading (pp. 701-3). Pig-skin forms, when tanned, a leather which is principally valued for saddlery. That of the wild boar is much thicker than that of the domesticated animal, and consequently offers more difficulty in the process of tanning and preparation. It is also used in the manufacture of many small articles of leather-ware, such as purses, coverings of pocket-books, etc.

**Bristles** are employed chiefly in the manufacture of brushes, and the export trade in bristles and other brush fibres in recent years is very considerable. For the period 1900-7, the following were the **Exports** of bristles and fibres for broom and brush manufacture:—1900-1, 49,682 cwt., valued at Rs. 14,93,685; 1901-2, 48,488 cwt., Rs. 13,65,600; 1902-3, 70,917 cwt., Rs. 15,79,002; 1903-4, 83,258 cwt., Rs. 20,76,331; 1904-5, 81,290 cwt., Rs. 18,39,854; 1905-6, 93,873 cwt., Rs. 21,51,028; 1906-7, 88,158 cwt., Rs. 17,68,930. Of the total for 1905-6, Madras exported 89,978 cwt. and Bengal 3,604 cwt., and the countries to which the largest quantities went were—the United Kingdom, 30,485 cwt.; Germany, 27,874 cwt.; Belgium, 24,463, cwt.; Ceylon, 5,536 cwt. The **Imports** are compara-
TRADE IN LIVE STOCK

Bacon and Ham

India annually imports large quantities, and the exports are small. The Imports for 1900–7 were as follows:—1900–1, 1,144,716 lb., valued at Rs. 7,61,782; 1901–2, 1,136,959 lb., Rs. 7,47,093; 1902–3, 1,231,934 lb., Rs. 8,16,613; 1903–4, 1,267,724 lb., Rs. 8,18,228; 1904–5, 1,373,474 lb., Rs. 8,09,678; 1905–6, 1,600,898 lb., Rs. 9,40,140; 1906–7, 1,487,729 lb., Rs. 9,52,715. Almost the whole comes from the United Kingdom, viz. 1,575,838 lb. in 1905–6, while small quantities are drawn from Hongkong, Australia, the Straits Settlements, Germany, and Sweden. The Exports of Indian hams amounted in 1904–5 to 672 lb., valued at Rs. 150, and in 1906–7 to 259 lb., valued at Rs. 150. The re-exports in 1904–5 were 7,323 lb., valued at Rs. 4,358, but in 1906–7 only 537 lb. Thus, adding together all the available returns of the products derived from the pig, the exports in 1905–6 were Rs. 21,69,778 and the imports Rs. 10,17,138; and in 1906–7, exports Rs. 17,84,827 and imports Rs. 10,70,304. The decline in the exports of lard and increase in the imports point to a serious defect, and the large demand for foreign ham and bacon is significant. There are thus great possibilities in the future.

TRADE IN INDIAN LIVE STOCK.

Of the estimated number of animals of all sorts (220 million in 1904–5), about 23 per cent. are annually exported in the form of hides and skins.

But India imports and exports live stock, and by sea as well as across her land frontiers. Hence the returns under these headings have to be taken into account. It may be desirable to set forth the Trans-frontier trade before exhibiting the foreign. In the official statistics the imports are referred to the following groups—(a) Horses, Ponies, Mules: (b) Cattle: (c) Sheep and Goats: and (d) Other Kinds. The totals for the year 1904–5 were 665,024 animals, valued at Rs. 74,74,928; for 1905–6, 685,732 animals, Rs. 65,30,041; for 1906–7, 714,368 animals, Rs. 70,12,607. The most important are the cattle, 105,726, valued at Rs. 44,04,266 in 1906–7: the sheep and goats, 166,653, valued at Rs. 6,12,062; and other kinds of animals 434,704, valued at Rs. 13,14,543. The chief countries of supply of cattle are Nepal, North Siam, and the Southern Shan States. For sheep and goats, Northern and Eastern Afghanistan, Nepal and Kashmir. Of the other kinds, Nepal, South Siam and North Siam. The Trans-frontier exports from British India are less important and need hardly be reviewed. The totals in 1906–7 were 92,644 animals, valued at Rs. 11,78,866. Perhaps the most remarkable feature of the trade recorded as carried by rail and river is the fact that Bengal is the chief exporting province and the United Provinces the principal importing area. The next most important receiving centres are Calcutta and Bombay.

Turning now to the transactions by sea, the Imports are most valuable under the heading of horses. The total imports in 1903–4 were valued at Rs. 53,62,833, of which Rs. 52,48,590 represented the horses brought mostly from Australia into Bombay and Calcutta; in 1904–5, Rs. 59,27,625 (horses, Rs. 55,47,939); in 1905–6, Rs. 49,41,452 (horses, Rs. 46,76,055); in 1906–7, Rs. 46,55,792 (horses, Rs. 44,88,933). Of the Exports it may be said the position is reversed, the traffic in horses being the least important. The total for 1903–4 was returned at
LUFFA, *Acutangula*

**Trade in Live Stock**

Rs. 22,27,523, of which Rs. 21,23,214 represented cattle, sheep and goats, etc.; 1904-5, Rs. 19,40,129 (Rs. 18,98,380 cattle, sheep, etc.); 1905-6, Rs. 19,33,828 (Rs. 19,07,228 cattle, sheep, etc.) and 1906-7, Rs. 22,63,176 (Rs. 22,21,416 cattle, sheep, etc. The horses go mainly from Bengal and Bombay to Ceylon and Mauritius, and of the others Madras practically conducts the entire trade, sending the animals to Ceylon and the Straits Settlements.

**Fodder.**

**Cattle Food and Fodder.—Exports.**—It is somewhat surprising to discover in the published returns of the foreign trade of India, a heading “Fodder, Bran, and Cattle Food, including Hay and Straw.” This is referred to three groups, as follows—Oil-cake: Rice bran: Other sorts. The total exports under these three headings were in 1900-1 valued at Rs. 70,13,826; in 1902-3, Rs. 85,73,627; in 1904-5, Rs. 97,21,116; in 1905-6, Rs. 1,18,15,434; and in 1906-7 at Rs. 93,99,644 (£626,642). Of the large amount for 1905-6, Rs. 51,99,194 represented the value of oil-cake, and Rs. 55,41,825 that of rice bran. Practically the whole of the Rice Bran goes from Burma and the Oil-cake very largely from Madras, with a fair amount from Calcutta and the balance, very nearly, from Bombay. Fully a third of these articles of cattle food is consigned to the United Kingdom; another third to Ceylon, the Straits Settlements and Germany in approximately equal quantities. The balance goes to Java, the Philippines and East Africa, followed by France, Aden, Hongkong, Belgium, etc.

**Exports.**

**Rice Bran.**

**Beef and Mutton.**

**Prices of Beef and Mutton.**—Particulars are given in *Prices and Wages in India* (1904) of beef and mutton in certain localities of Western India since 1855. During that time they have practically remained stationary: if anything, cheapened. Taking the average of the quinquennial period 1871-5 as a standard, the price in the Presidency for beef was 25 rupees a seer (=2 lb.); in Sind 17; in Rajputana and Central India 16. For mutton, Bombay 31; Sind 18; Central India and Rajputana 21. Taking these as 100, beef in Bombay was (in 1903) 80; in Sind 118, and in Central India and Rajputana 50; mutton similarly was 100 (during 1871-5) in Bombay, and in 1903 it was 97; in Sind 144, and in Central India and Rajputana 95. These results are doubtless fairly expressive of India as a whole; but no other returns are available, so that particulars of the other provinces cannot be furnished.

For trade in Lard and Tallow, see the separate article (pp. 701-3); Hides and Skins (pp. 632-40); and Oils (pp. 813-4, 819).

**D.E.P., vi., pt. ii., 549-83.**

**D.E.P., v., 84-7.**

**Luffa, Cav.; Fl. Br. Ind., ii., 614-6; Duthie, Fl. Upper Ganq. Plain, 1903, 367; Cooke, Fl. Pres. Bomb., 1903, i., 531-3; Prain, Beng. Plants, 1903, i., 519-20; Cucurbitaceae.** A genus of climbing plants, native of the warmer regions of the Old World and one indigenous in America. Four or five are wild in India.

pikunkai, etc. A little branched climber, met with in North-West India, Sikkim, Assam and Eastern Bengal.

Is cultivated in most parts of India for its fruit. Rich soil should be selected, and the seed sown from March to June in lines 5 feet apart. When the young plants are about 4 inches high, supports are required. Until the rains begin, the first sowings have to be regularly watered. The fruit is highly esteemed by Natives and eaten either in curries or dressed with clarified butter. When fully developed it is about a foot long, but if allowed to grow longer than 4 inches it rapidly deteriorates. The seeds possess emetic and purgative properties and also yield an oil. The fibrous texture of the fruit forms, like that of L. amygdalina, a cheap and efficient flesh-brush. [Cf. Gollan, Ind. Veg. Gard., 1892, 117–8; Banerjei, Agri. Cuttack, 1893, 117–8; Woodrow, Gard. in Ind., 1899, 333–4; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 108.]

Var. amara; L. amara, Roxb.; Prain, l.c.; Rec. Bot. Surv. Ind., iii., 216: karui-taroi, ghosha-latá, tita-jhingú, rüntarai, kadu-siroda, adavi-bira, etc. Met with all over India, especially on the western side. The fruit is largely used in Native medicine. The juice of the roasted fruit is applied to the temples to cure headache, and the ripe seeds are generally said to be a sure and safe emetic. [Cf. Pharmacog. Ind., 1891, ii. 80–1.]

L. amygdalina, will.; Duthie and Fuller, l.c. 61, l. xxiii.; Rec. Bot. Surv. Ind., iii., 60, 216. The ghia-taroi, dhundul, bhod, bhaiada, dilpasand, gosháti, gutti bira, etc. A large climber common everywhere and often cultivated, especially in the plains. The fruit is edible, and when dried forms a structure of interlacing fibres, used as a flesh-brush in the Turkish bath or as a substitute for the bath sponge, and has more recently been made into boot-socks. The seeds are emetic and cathartic and yield an oil. [Cf. Dodge, Useful Fibre Plants of the World, 1897, 229; Woodrow, l.c. 333–4.]

L. echinata, roxb.; bindaal, janthori, kukod-vel, etc. A small climber, native of Gujarat, Sind and Bengal (Purnah and Dacca). The fruits ripen in the cold weather and are medicinal, as is also the stem. It is a bitter tonic and powerful diuretic. [Cf. Pharmacog. Ind., 1891, ii, 81–6; Sen, Orig. Res. in Treatment of Trop. Diseases, 1902, 95–6.]

An erect annual, native of West Tropical Africa and of Tropical America; introduced into India and now plentiful throughout the hotter damp tracts from the United Provinces to the Karnatak. It yields an excellent fibre, 8 to 9 feet long, which experts have decided is little if at all inferior to jute. It was at one time hoped that Bombay through the cultivation of this plant might secure a good and profitable substitute for Bengal Jute. These expectations have never been realised, but the plant in some parts of the Presidency has become so abundant as to be often viewed as indigenous. [Cf. Offic. Correspond. on Exper. Cult. in Bomb., 1878–82; Agri. Ledg., 1896, No. 6, 30; Dodge, Useful Fibre Plants of the World, 233; Woodrow, Gard. in Ind., 1899, 184; Imp. Inst. Tech. Repts., 1903, 69.]

MALLOTUS PHILIPPINENSIS, Muell. Arg.; Fl. Br. Ind., v., 442; Gamble, Man. Ind. Timbs., 1902, 619–20; Talbot, List Trees, etc., 1902, 316; Hooper, Agri. Ledg., 1905, No. 4; also Rept. Labor. Ind. Mus. (Indust. Sec.), 1905–6, 30, 33–4; Rec. Bot. Surv. Ind., iii., 101; Brandis, Ind. Trees, 1906, 590; Euphorbiacæ. The kamela, kamala, kamblá, ruín, rori, sinduri, shendri, pûnay, tâng, gangai, rolí, puroa, kapli, kümkuma, kuru, tavethidin, etc. A small tree, usually with a buttressed trunk, occurring along the foot of the Himalaya from Kashmir eastwards (rising to 4,500 feet in altitude); also in Bengal, Central, Western and Southern India; Burma; the Andaman Islands and Ceylon.
Dye.—The most important product of this tree is the kamela powder—a
dye formed of the red glands found on the surface of the capsule. It is used
chiefly for imparting to silk a bright orange or flame colour. A full account of
the history of this dye is given in the Dictionary. In collecting the powder, the
ripe fruits are placed in a cloth or sack, and beaten until the glandular pubescence
is removed. In some districts the fruits are simply rubbed between the palms
of the hands, or are kneaded with the feet on the ground. The powder thus
obtained is then sifted to free it from the fruits and broken pieces, and in this
condition it is ready for market. Through careless collection or fraudulent
admixture, the commercial article, however, is often met with in a very impure
state, and this may partly account for its neglect by the Native dyers and the
decrease in its consumption.

The following abstract of the available information regarding the chief
localities and collecting areas may be given here:—

Bengal.—The tree is fairly abundant in the forests of Puri and Singhbum,
but is scarce in other localities. In the Puri Division it is said to occur in abun-
dance in the southern tracts. It grows wild in the forests, but attains greatest
perfection in open situations. Flowers and fruits heavily on lands leased to
the Khonds, who clear away all other tree growth, and carefully prune the trees
every year. In the thick forests it bears few flowers and fruits. The flowering
season is in December, and the fruits mature in January to February. The
fruit of the Bengal plant is larger than that of the United Provinces, and
doubtless yields a more abundant and better colouring matter. The dye was
formerly procurable in large quantities from Raman Lall Das of Elam bazar,
Birbhum, at Rs. 13 to 14 per maund.

Panjáb.—Very abundant in the Nurpur forests, Kangra. About 30 manndas
are annually exported from Nurpur, where it is sold at the rate of 4 seers per
rupee. The cost of 100 lb. would thus be Rs. 12–8, or, delivered at the nearest
station, Patankot, would come to Rs. 16. At Amritsar it is said to fetch Rs. 20
a maund. Kamela is imported into Kowalpindi from the Hoshiarpur district at
the latter price. The tree grows in abundance in the Simla forests, but the
dye is not gathered.

Bombay.—The Belgaum district is the principal collecting ground for Western
India. About 4,000 lb. are sold locally every year at 4 to 5 annas per lb. The
price of 100 lb. delivered at Belgaum railway station is Rs. 12–8.

Madras.—Widely distributed in the Gamsur taluk of the Ganjam district,
the annual output varying from 30,000 to 35,000 lb. The cost price at Madras,
including transport and delivery, is Rs. 20 to Rs. 40 per 100 lb. In Madras City
there is no local demand for kamela, and the dye from Ganjam is all shipped to
England and the Continent.

Burma.—More common in Upper than in Lower Burma. The dye collected
is estimated to cost at least double what it does in North India. There
do not appear to be any regular market rates, but the prepared powder can
be obtained in the jungles at Rs. 5 per viss.

Indian Methods of Dyeing.—Hooper gives the following account of the
method of dyeing pursued in Belgaum:—"Two lb. of silk and 1 lb. of carbonate
of soda are placed in a vessel of water and boiled for a short time. As soon
as the silk softens, it is removed. In the same water are then placed 20 tolas of
kamela powder, 2½ tolas of jinjili (Sesamum) oil, ½ lb. of alum, 1 lb. of carbonate
of soda (in addition to the 1 lb. previously used). This mixture is boiled for
a quarter of an hour, and then the silk is replaced in the vessel and taken out
after another quarter of an hour's boiling. The colour is deep yellow." In the
Central Provinces, in dyeing tasar silk, the powder is first mixed with the ash
of the myrobalan (Terminalia Arjuna) and then put in water and allowed to
stand till the sediment subsides. The water is then decanted into another
vessel in which is placed finely powdered lodh (Strychnos Racemosa) bark. The
tasar silk is next soaked for six hours in the preparation; then taken out and
dried, put back in the fluid, dried and again submerged till the fabric obtains
the desired shade.

756
MALT LIQUORS and Indian Brewing.—The manufacture of BEER embraces two distinct operations—MALTING and BREWING. In the time of Herodotus (450 B.C., bk. ii., ch. 77) there was no separate name for beer; he accordingly speaks of the Egyptians as making wine from barley. Dioscorides, Galen and others condemn beer as prejudicial to the head and nerves.

History.—The Hindus, as well as most of the aboriginal tribes of India, have been acquainted with both distilled and fermented beverages from very ancient times. But it is curious that while full particulars exist regarding the more advanced art, viz. that of distillation, the rationale of malting as a distinct stage in the production of fermented beverages does not appear to have been understood. Indeed it has been contended that, even in England, malting as a separate operation was not known until the time of Henry VIII., when the use of hops was also discovered. A fermented but non-distilled liquor may be said to have been prepared all over India, the materials varying according to the region or people, but in no instance has malting as a distinct and necessary stage been recorded. And what is perhaps even more striking, a fermented beverage made from grain would seem, so far as India is concerned, to have been more closely associated with the Mongolian than with the Aryan races. With the latter branch of the human family sweet liquids, such as honey and water, cane-juice and water, or the sap of various palms, were fermented into beverages that would more closely correspond with the ancient mead of England or the ales subsequently in favour, than with the beer of modern trade. It would be thus easy to understand why the art of malting was not known, since unnecessary, indeed almost impossible, under these circumstances. The most general Indian name for fermented sweet liquors is possibly tārī, though sendhī is sometimes used almost synonymously, while pachwāi (or handı and maru) denote malted and fermented beverages made from grain, mostly rice, though barley and millet are also utilised (see p. 840).

The English word "beer" came through the Anglo-Saxon beor and the German bier—words which indicate the grain used in the fabrication of the beverage. The Asiatic word which in meaning most closely approaches "beer" seems to be buzah or buza, a Turkish word adopted into Persian and ultimately into many languages in India and Africa. It is, however, the name more used by the well-informed, pachwāi being the every-day word for beer or malted liquor made from grain. Shaw (Travels, etc., 1757, 407) speaks of the Egyptians making a fermented and intoxicating liquor, known as bouzah, from barley. Moorcroft (Travels, 1819-25, i., 102), while describing Ladakh, says that the inhabitants make "a sort of beer called buzah from barley, the grain of which is parched and ground, and the flour mixed with rice which has been softened by steeping in water. The powder of the root of some bitter and aromatic plant that grows higher up in the mountains is added to the mixture, and the whole is put into a press to squeeze out the water, and dried. When required for use a piece of the dry cake is thrown into a vessel of water, and in
the course of three or four days fermentation takes place and the liquor is ready for drinking." In another passage, Moorcroft remarks, "The Tibetans never drink plain water if they can avoid it. The wealthier drink grape-juice and water, or sherberts; the poorer, a beverage called buza by the Kashmiris, and chang by the Tibetans, which is made from barley. The grain is boiled until it is soft, and then dried; to about 10 lb. of this softened grain, three ounces of the dough used for wheaten cakes, but dried and pounded, are added, and the mixture is put into a bag and kept in a warm place until it ferments, which it does usually in two or three days. Equal measures of the prepared barley and cold water are put together in an earthen vessel. After standing for two days the fluid is strained off; a similar quantity of water is again added, and treated in the same manner, and the beverage is the liquor called chang." "The grains remaining after infusion are dried, and ground into flour." The above passages bring to mind the account of buzeh as given by the Emperor Baber in his Memoirs (1625, 283, 294), speaking of Sewad and Bajour (practically the same country), and thus three hundred years before Moorcroft's time. The passage has already been quoted under Eleusine (p. 520), and there would seem little doubt that the substance called kim, which was "round like a loaf," was the softened grain (whether barley or marua), with its ferment and bitter flavouring ingredient, taken from the cloth in which squeezed to deprive it of its moisture, and thus compressed into what might easily be described as a sort of loaf.

Aitchison (Fl. Lahul, Journ. Linn. Soc., 1869, x., 76) says that "from barley, as well as from rice ('daii,' "daii") a kind of beer is made, called chang." In making chang, a ferment is used, called pab, imported from Ladakh in the form of dry yeast. "The Lahulies admit their ignorance as to its nature and their non-ability to make chang without it." In the Hemp Drugs Commission's Report (1894, i., 157) mention is made of a liquid preparation used in Sholapur, Bombay, under the name boyic, which consists of a gluclus made of jufur (Sorgum, p. 1046) flavoured with hemp and a little Nux vomica.

The practice of making buza or beer from barley is thus quite as ancient in India, very possibly, as in Europe. In passing it may be added that the great conquering Emperor Baber tells us he did not like "buzeh" because of its bitter flavour—the Indian objection to-day to European beer. (See Cannabis sativa, p. 257.)

Under Coix (p. 396) particulars will be found of the Naga hills beer, known as dau. This is, undoubtedly, a fermented beverage made either from coix or rice or both mixed, the one fermented and the other not. Grain is placed in a large wooden trough and hot water poured over it. It is then left to malt, and, when this stage is complete, a further quantity of boiling water is added. In three days' time the liquor is in prime condition, and by the fourth or fifth day it becomes intoxicating. It has already been pointed out that the dispersion of coix grain over India and Burma accompanied the Mongolian invaders, and further that the name kosi or kasai or some obvious derivative from that word was conveyed to remote countries and into diverse tongues.

**Ferments.**—Bergtheil (The Study of Fermentation as Applied to Agriculture, in Agri. Journ. Ind., i., pt. i., 68-75; pt. iii., 230-6) reviews some of the more interesting modern opinions regarding Fermentation. Among all races and in every age, he says, we find a knowledge of some means for the production of alcohol, all fundamentally depending on the fermentation of sugar. In many instances the initial action is the conversion of starch into sugar by an enzyme action,—the "malting" of barley. The grains are placed under conditions favourable for germination, and when the production of a soluble, easily assimilable food for the infant plant has been accomplished, the grains are killed. The further stage, namely, the fermentation of the sugary fluid into alcohol, is ordinarily accomplished by a fungus, known as yeast. "In Western countries," writes Bergtheil, "yeasts and their actions have been carefully studied, and pure cultures of special yeasts, which have been found most suitable for the production of the particular type of fermentation desired, are deliberately introduced and their growth most carefully regulated and guarded; in other cases, such as those we are familiar with

758
HOPS AND HOP SUBSTITUTES

in India, wild yeasts are allowed to gain access from the air and grow in the liquid to be fermented, but under all circumstances a yeast or closely allied organism is necessary to the process."

From the facts already briefly reviewed, it may be inferred that this art of fermentation is fairly understood in India. In most Excise Reports of Bengal mention is made of a ferment known as bakhar—a compound prepared from the roots and leaves of several plants (names unknown, but innocuous) (see Spirits, p. 1047). In most cases the yeast used is conveyed from one brew to another. The bakers of the lower provinces of India, for example, regularly purchase their supply from the palm-wine (turi) manufacturers. In Upper India numerous ferments are known. For example, while travelling in Kullu and Ladakh my attention was drawn to the ferments employed by the people in these countries. I found that in Kullu the brewers of sur (grain beer) sent, just as Moorcroft tells us, up country for the root of a herb which they employed in brewing. In Kullu this is known as mathosan, and seems to be a species of Ligusticum. The root is reduced to powder and mixed with damp barley flour. Fermentation is soon set up, and the mixture is then baked into cakes and dried. These are sold under the name dheti, and are said to preserve the fermentative germ for an almost indefinite period, and may be used either by the baker or the brewer as desired. In Ladakh I was unable to discover the plant employed, but the cakes are there known by the name paps (see above, pab). [Cf. Ann. Rept. Ind. Mus., 1894-5, 35.]

In Manipur I discovered that the powdered stems of a leguminous plant (possibly a species of Millettia) were employed as the fermenting material, and Mr. C. B. Clarke says that in the Khasia hills the people procure fermentation from the flowering spikes of a Rhynchospora. [Cf. D.E.P., v., 131-6; Lawrence, Valley of Kashmir, 1895, 82.]

Hops and Substitutes.—On more than one occasion the effort has been made to cultivate hops (Humulus Lupulus) in India, but with indifferent results. The amount required by the brewers in India is annually imported. Hooper (Rept. Labor. Ind. Mus. (Indst. Sec.), 1906-7, 12) gives the results of his chemical examination of a sample of hops grown in Kashmir. By way of comparison, he exhibits the amounts of resin (ascertained by Cöez's benzol method) in certain trade samples:—California, 21-0; East Kent, 18-7; Kent, 17-8; Bohemian, 15-6; North French, 14-8; Kashmir, 13-2; and other Indian samples, 12-9. Thus Kashmir is not far behind French hops.

By the Indian makers of liquors, various substances are used as substitutes for hops, the most general being the distiller's bark (see Acacia leucophloea, p. 15), but in this connection it may be of interest to invite attention to the suggestion that the soma of the ancient classical writers may have been the astringent stems of Ephedra (D.E.P., iii., 247-51) employed in place of hops, and not as itself the source of the liquor of which so much has been written.

Barley.—All forms of barley (p. 643) are not equally suitable for brewing any more than all forms of coix are suited (see p. 396). The best Indian barley comes from Northern India (United Provinces and South Panjâb). Plumpness of grain and uniformity in weight are desirable. The finest Indian samples weigh 56 lb. per bushel. The grain must also be bright in colour and not "steely"—the condition of most of the samples from the plains. But above all, it must be living and capable
of active germination during malting, and must not have germinated before reaching the brewery. Damaged grain will rot during malting, and thus lower very greatly the value of the material. [Of D.E.P., v., 128.]

The grain must be thoroughly screened and winnowed before it is placed in the steeping-vats. It is now conveyed to the malting-floor, where it softens and germinates. Simultaneous and uniform malting is essential. When malting is completed, the grain is again screened to remove the rootlets, then crushed, infused with water and hops added. The infusion is next fermented, and shortly after the liquor is ready for bottling and casking.

**Indian Indigenous Brewing.**—No one has hitherto attempted to produce a definite statement of the art of brewing and of the beverages produced for the whole of India. In the Excise Reports issued annually by the various Provincial Governments, brief paragraphs now and again deal with what appear to be beverages akin to beer and ale. As already explained, pachuwa is made from fermented grain, mostly rice; it is thus a form of beer, but when distilled it becomes a kind of spirit or whisky, and in that case is called phatika or maadira. On the other hand, toddy or tari (palm juice) fermented, but not distilled, corresponds very closely with the theoretic definition of ale, and when distilled becomes the spirit generally called arak. But palm juice is often drunk without being fermented, and is then spoken of as "pachuwa." For this purpose the law requires that a private person tapping his own trees must wash the interior of the collecting vessels with lime-water so as to prevent fermentation taking place. Similarly a sweet drink or fermented ale is often prepared from mahua flowers.

In the Excise Reports for both Bengal and Assam, pachuwa and tari are mentioned. (See Oryza (Revenue), p. 840.) The licenses granted for home-brewing of pachuwa are explained: these are issued (mostly to hill tribes) without limit as to quantity, but at a fixed annual fee. The beverage cannot, however, be sold. In the Central Provinces the revenue from tari consists of license fees paid for the right to manufacture and to vend. But pachuwa and sagda are in these provinces spoken of as "Native Beer." (Of Hooper, Rept. Labor. Ind. Mus. (Indist. Sec.), 1903-4, 35.) In the reports of the United Provinces reference is given to tari (the juice of Borassus), to sendhi (the juice of Phoenix), to boza, a fermented liquor made from rice, and to darbakra, a fermented beverage from various herbs (not known). Of Madras, mention is made of both sweet and fermented "toddy" collected from the cocoanut, sago, palmyra and date palms, also from a palm not previously recorded as affording the juice, namely the dadasal or dadasel (Arenga Wightii). Of Bombay toddy, it is said the revenue in 1903-4 came to Rs. 15,52,000. This was raised both by a tree tax and a vendor's license. The chief trees tapped are the date palm, the brab (Palmyra) and the cocoanut. The total number of trees tapped in 1903-4 was 231,245. Unlike Madras, tree-tapping for sweet toddy is not permitted, as fermentation is said to be set up immediately the juice is drawn from the stem. In a special experiment separately reported, thirty-two brab trees yielded in Salsette during the month—February 16 to March 15, 1904—a total of 176 gallons of toddy. The Burmese reports speak of "fermented" liquors under two headings—(a) other than tari, and (b) tari. The consumption of fresh tari is allowed without being subject to a tax, and the owners of trees may sell the juice obtained from their trees to professional tari makers without paying any fees. Of the non-tari beverages, mention is made of kaung, seinge, hawza and seye. These are said to be manufactured from rice, fermentation being procured by yeast. It would seem that a mistake may have been made regarding both the grain and the ferment. Coix is certainly largely employed by the hill tribes, but the ferment need not be yeast as understood in Europe. (See Bassia, pp. 118-9; Borassus, pp. 170-1; Caryota, p. 286; Coos, pp. 361-2; Phoenix, p. 886; Setaria, p. 988; Spirits, p. 1047.)

** Anglo-Indians.**

**European Beer.**—Turning now to Indian beer brewed after the European method. In the writings of the early European visitors to that country, frequent mention is made of "beer" or of "country ale," but whether these were malted beers or merely the various sweet-liquor beverages already indicated, under the name toddy or tari, it would be difficult to say. The English word "toddy" comes, of course, from the Indian tari, and was originally, and in India is to-day,
BREWRIES

the fermented sap of the tar palm. Friar Jordanus (1328 A.D.) speaks of the tree that gives all year round a white liquor, pleasant to drink, which tree is called tari. Sidi Ali Reis refers to the wine obtained in Gujarat from the tari tree. On the other hand, Mandelso (Travels, in Olearius, Hist. Musceoy, etc. Davies, transl.), 14; also Hobson-Jobson (ed. Crooke), 738 mentions that the captain of the ship in which he journeyed to Surat had excellent good sack, English beer, French wines, arak, and that they prepared from the latter good punch (palepunsen). Ovington (Voy. to Surat, 1689, 238, 395) says "no Malt drink is made in India"; and again, "Europe Wines and English Beer," though expensive, were "yet purchased and drank with pleasure." Tavernier (Travels, 1676 ed. Ball), ii., 368 tells us that the President gave him a large cask of "English beer" to take with him to Batavia, where none could be had. Birdwood and Foster (E.I.C. First Letter Book (Introduction), xxii.) describe the "Cock Ale" in use in the 17th century. It consisted of a bruised cock (the older the better) with 3 lb. of raisins, mace, cloves, etc., two quarts of sack and ten gallons of ale, the whole being left to ripen as with other ales. Punch was another special Indian preparation, and "milk punch" has survived to the present day—the last of a long list of Anglo-Indian preparations—a sort of home-brewed or concocted liquor. [For further particulars see the articles on Opium, pp. 845-61, Tobacco, p. 796, and Spirits, pp. 1043-8.]

Indian Breweries.—Within recent years "Country Beer" has come to mean beer brewed in India after the European system. The first European brewery in India was started in 1825 by a Mr. Henry Bohle at Meerut and Mussourie, but in time the business was taken over by Mr. John Mackinnon. It was not, however, until 1870 that the enterprise became successful. In the meantime, between 1850 and 1860, several breweries were started on hill stations. The official statistics of the larger establishments show that in 1880 there were seventeen breweries in India producing 1,974,578 gallons of beer made after the European system; in 1890, 22 breweries producing 5,192,572 gallons; in 1900, 26 breweries producing 4,947,841 gallons; and in 1904 there were 27 breweries producing 6,219,761 gallons, of which the Commissariat Department purchased 2,839,177 gallons, or a little under half the production. These figures abundantly demonstrate the rapidity with which brewing had developed, and its present position. The breweries and shares of production in 1904-5 are as follows:—Panjáb, 8 breweries and 2,233,955 gallons; United Provinces, 6, and 1,451,796 gallons; Madras, 4, and 416,852 gallons; Mysore, 3, and 700,281 gallons; Bombay, 1, and 558,767 gallons; Baluchistan (Quetta), 1, and 388,580 gallons; Burma (Mandalay), 1, and 306,396 gallons; Central Provinces (Jabbalpur), 1, and 130,194 gallons; Bengal (Sonada), 1, and 82,940 gallons.

Consumption of country-brewed (English) beer and ale by the Natives of India is not important, though in some provinces it is more extensive than in others. In Madras these beverages are fairly popular, especially in the hill districts, and in the Panjáb mention is made in the Exeise Reports of the demand being on the increase.

External Trade Returns.—The rise and fall in the popularity of imported ale, beer and porter may be said to mark the steady progress of European opinion against the use of strong drinks, and of large quantities of liquors of any kind in tropical countries. The first importation of beer from London recorded in modern commerce may be said to have been consigned from Hodgson’s brewery in 1816. This was ultimately known as "Hodgson’s Pale Ale." By 1825 the beers made by Bass, Allsopp, Ind and Smith, etc., had found their way to India. It is within the recollection of those still living that a guest was supplied with a basket of four or six bottles of beer and was supposed somehow
MANGANESE

CHIEF ORES

TRADE IN ALE AND BEER

to get through that supply during the repast. For many years this practice has died out, and the demand been steadily made for a higher grade, lighter beer. This was first met by the Indian brewers. But in time there appeared on the Indian markets not only new firms with light ales and beers, but all the older ones had to respond to the popular desire, and in consequence of this keen competition the Indian breweries lost temporarily some portion of the position they had attained.

Imports.—To contrast with the Indian production, already given, the following figures of the import trade may now be recorded. In 1900-1 India received of ale, beer and porter, 3,226,534 gallons, valued at Rs. 46,82,648; in 1902-3, 3,820,938 gallons, valued at Rs. 51,66,378; and in 1904-5, 4,607,530 gallons, valued at Rs. 60,41,973 (£402,798), or say, on an average, two-thirds the quantity brewed in India. In subsequent years the imports were: 1905-6, 5,002,448 gallons, valued at Rs. 62,95,616; and in 1906-7, 4,916,294 gallons, valued at Rs. 60,27,011. Of these foreign imports by far the major portion comes from the United Kingdom. Out of the totals mentioned, for example, the United Kingdom supplied in 1900-1, 3,014,064 gallons; in 1902-3, 3,581,544 gallons; and in 1906-7, 4,506,145 gallons, the only other important country being Germany, with an average of over 200,000 gallons for each of the past five years. The receiving ports are Bombay—the chief emporium for the large military towns of Northern India—followed by Burma, Bengal, Sind and Madras, in the order of importance named. It seems, however, that some of the beers imported from England may be of German origin, though it is perfectly true that Pilsener and Lager are now merely trade names for certain qualities of light beers, and do not necessarily denote German manufacture.

MANGANESE; Ball, Man. Econ. Geol. Ind., iii., 326-32; Bose, Manganese-iron and Ores of Jhabalpur, in Rec. Geol. Surv. Ind., 1888, xxii., pt. 3, 71-89; 1889, xxii., pt. 4, 216-26; 1904, xxxii., pt. 1, 47-8; pt. 4, 235-6; Holland, Rev. Min. Prod., in Rec. Geol. Surv. Ind., 1905, xxxii., pt. 1, 13, 55-63; 1906, xxxiii., pt. 2, 94-100; Fermor, Trans. Min. Geol. Inst. Ind., 1906, i., 69-131. In India the commonest ores are psilomelane, a complex manganate; braunite, a sesquioxide and silicate combined; and pyrotusite, or the black peroxide. The peroxide has the following names, kola-ka-pathar, inganî, nîjîn, iddali kalu, etc.

Output.

Production.—In 1906 India took the first place among the manganese-producing countries of the world. In 1903 the output was 171,806 tons; in 1904, 150,297 tons; and in 1905, 253,896 tons. The most important deposits occur in the Central Provinces, Madras, Central India and Mysore. In 1905 the production of the Central Provinces was 159,950 tons; in Madras, 63,695; and in Central India, 30,251. Investigations into the manganese-ore deposits of India were started in 1903-4 by the Geological Survey, and a summary of the results is given by Fermor. It has been shown that the deposits can be classified into (a) braunite, psilomelane and pyrotusite, associated with and derived from manganese-bearing silicates in the Archaean schists and gneisses. Examples occur in Narukot.
CENTRES OF PRODUCTION

MANGANESE

Trade

in Bombay; Jhābua in Central India; Bālaghāt, Bhandāra, Chhindwāra and Nagpur in the Central Provinces; Ganjam and Vizagapatam in Madras. (b) Psilomelan and pyrolusite, in part superficially formed on outcrops of rocks of Dharwar age, with which the ores are also embedded. These occur in Singhbhum in Bengal; Dharwar and Panch Mahals in Bombay; Jabalpur in the Central Provinces; Sandur hills in Madras. (c) Psilomelan and pyrolusite, associated with or contained in laterite. These occur in Belgaum and Satara in Bombay; Jabalpur in the Central Provinces.

Chief Centres.—Panch Mahals in Bombay; Jhābua in Central India; Bālaghāt, Bhandāra, Chhindwāra and Nagpur in the Central Provinces; Vizagapatam and the Sandur hills in Madras; and Shimoga district, Mysore, are the localities in which economically important deposits are located and worked.

Uses.—The uses to which the ores of manganese are put are somewhat varied. The peroxide is extensively employed in glass-making, to destroy the green colour. The same oxide is used in porcelain painting and glazing for the fine brown colour it yields, while violet colours are got from the carbonate (Ind. Art at Delhi, 1903, 22). The ores are now mainly employed in the manufacture of ferro-manganese for use in the manufacture of mild steel. For use in steel-making, manganese ores should not contain more than 0·25 per cent. phosphorus, nor more than 10 per cent. silica. Under conditions laid down by the Carnegie Steel Company, ores containing less than 40 per cent. manganese and more than 0·27 per cent. phosphorus or 12 per cent. silica may be rejected at the option of the buyer. Holland deplores the exports, since “the whole industry is at present equivalent to a heavy loss to the country.” The ore exported is worth perhaps Rs. 30 a ton; whereas India gets merely the margin left after paying the heavy freight charges, and possibly Rs. 15 a ton can be regarded as the profit divided between the railways, the miners and the owners. He then concludes: “If a flourishing steel-manufacturing industry existed in the country, much of the manganese would be retained in India, and the lower-grade ores would be economically developed. As it is, our manganese-ore is being exported to the three great steel-producing countries—England, United States and Germany.”

Trade.—As regards foreign trade, the EXPORTS have in recent years shown a considerable increase, especially in 1905–6. In 1900–1, they amounted to 2,613,394 cwt., valued at Rs. 12,51,639; in 1904–5, to 3,618,909 cwt., valued at Rs. 24,07,681; and in 1906–7, 9,859,855 cwt., valued at Rs. 70,88,280. The largest quantity goes to the United Kingdom, viz. in 1906–7, 4,392,130 cwt. Then follow the United States, 2,786,400 cwt.; Belgium, 1,971,614 cwt.; France, 669,710 cwt.; Holland, 40,000 cwt. In the same year the share of Bombay in the exports was 7,010,863 cwt.; Madras, 2,130,701 cwt.; Bengal, 718,291 cwt. Tables showing the variation in the price of manganese ore at the United Kingdom ports since 1890 are given by Holland. In 1903 the price for ore carrying over 50 per cent. of the metal, delivered at United Kingdom ports or at New York, ranged between 9 and 10 pence per unit, or in other words, an ore containing 52 per cent. manganese would be valued at 39 shillings a ton. These prices have considerably risen since, and during 1906 reached 16 pence per unit, the higher rates having greatly stimulated production in India.
MANGIFERA
INDICA

MANGIFERA INDICA, Linn.; Fl. Br. Ind., ii., 13; Talbot, List Trees, etc., 1902, 113; Gamble, Man. Ind. Timbs., 1902, 211-3; Duthie, Fl. Upper Gang. Plain, 1903, 189; Cooke, Fl. Pres. Bomb., 1903, i., 273-4; Brandis, Ind. Trees, 1906, 206; Anacardiaceae. The Mango Tree, 'am, uli, jegachu, qharidam, tsaratpang, marka, mawashki, mad, mangos, mamadi, marina, thayet, etc. A large evergreen tree of the Tropical Himalaya, at 1,000 to 3,000 feet, from Kumaon to Bhutan, the Khasia hills, Burma, Oudh, lower hills of Bihar, and in the Western Peninsula from Khandesh southwards. According to De Candolle it is a native of the south of Asia or of the Malay Archipelago. The mango has been known and cultivated all over India from a very remote epoch. It is closely connected with Sanskrit mythology, and finds a place in old Hindu tales and folklore. Mention is made of it by Friar Jordanus, who wrote about 1328, and by most of the early Indian travellers. Vartehma in 1510 describes it under the name of amb, and Baber, in 1528, speaks of the excellence of the fruit. Again Garcia de Orta, in 1563, writes that those of Hormuz are so good, when in season, that no other fruit can be sold; he then describes the various kinds known.

Cultivation.—Mangoes can be grown from seed, but it is the general belief that seedlings rarely produce fruit equal to the parents, and the usual method of propagation is by inarching. According to Maries, the best place to plant the mango is on a raised, well-drained piece of land with a good depth of soil. The nature of the soil does not appear to interfere much with the growth of the tree. In Bengal it succeeds equally well on a rich, deep river deposit, on clayey or on sandy soil; and in Gwalior, Maries wrote that fine trees were grown on kankar, i.e. soil with a large proportion of lime nodules.

Inarching.—The "stones" are usually sown at the time the fruit is in season, and the plants raised from them are potted to be grafted by inarching with desirable plants. This is accomplished during the setting-in of the rains in the second year of the growth of the seedling. At the close of the rains the union is usually complete. The essential points in this method of grafting are to bring the cambium of the stock and scion together before the graft is completely severed, the parts being bound together so as to exclude air and water and keep the plants healthy during a short growing season. Care should be taken that the scion be of the same thickness as the stock.

Planting Out.—The best season for planting out the young grafts is the monsoon. The following is a brief account of the method recommended by Woodrow (The Mango, Cult. and Varieties, 1904, 11). Having selected the plot of ground, holes should be dug about 3 feet in dimension. The centre of the holes should be about 20 feet distant from each other. About 20 lb. of fresh bone manure should be placed in the bottom of each. The soil on the margin should then be drawn in to a depth of about 9 inches, and the surface soil, mixed with manure, placed on the top. The holes are now ready to receive the grafts. The soil that is left over is put round the margin as a ridge, or tala, to form a dam which causes the water given to the young graft to sink
near the root. Firm stakes and shade are desirable during the following six months, and the intervening land may be cultivated with moderately irrigated and richly manured crops till the trees have attained flowering size. In five years the plants should be fit to bear a considerable quantity of fruit. When fruiting age is attained, there is no necessity for irrigation from the time the rain ceases in September till the young fruits appear; thereafter, irrigation about once in fifteen days is desirable while the fruits are increasing in size, but may be discontinued when ripening approaches. The surface soil should be kept in a loose, friable state to cause the water to pass downwards. The general flowering season is from January to March, and ripening from May to August, but varieties flower and ripen at all seasons.

Fruit. — The cultivated kinds of mango are very numerous, but the reader need only be referred to the list given by Maries in the Dictionary, and to the accounts by Firminger (Man. Gard. Ind. (ed. Cameron), 1904, 256–61) and by Woodrow (l.c. 23–32). An interesting paper by Maries in the Journal of the Royal Horticultural Society may also be consulted. The two principal localities in India where the finest fruits are said to be produced are Mazagon at Bombay and Malda in Bengal. On the other hand, the fruit ripens so badly and is so much diseased in Assam that it is hardly ever seen to be cultivated, except as a shade-tree. Maxwell-Lefroy gives an account of the Mango Weevil (Agri. Journ. Ind., i., pt. ii., 164–5) which is so very destructive to the fruit. Besides being eaten as a ripe fruit, numerous preparations are made of it. When green it is cut into slices, and, after extraction of the stone, is put into curries, or made into pickles with other ingredients or into preserves and jellies. When young and green it is boiled, strained, mixed with milk and sugar, and thus prepared as the custard known as mango-phul, or dried and made into the Native ambçhûr. When very young it may be cut into small pieces and eaten in salad. So again, the ripe fruit is used in curries and salads, and the expressed juice when spread on plates and allowed to dry is formed into the thin cakes known as ambseth. Attempts to bring the fresh mango on the London market, at a paying price, have hitherto been unsuccessful, but if it could be conveyed cheaply to England, a trade that would rival the fruit of the West Indies might be immediately anticipated. In times of famine the kernels are eaten. Preserves, chutneys and pickles made from mango fruit are largely exported to England and elsewhere. In Medicine, the ripe fruit is considered invigorating, fattening, laxative and diuretic, but the fibrous rind, as well as the unripe fruit, are astringent and acid.

Timber. — According to Gamble, the Wood is used for planking, door and window-frames, in Calcutta for packing-cases, and in Bihar for opium and indigo boxes. Canoes and masûla boats are also made of it, and in Dehra Dun and some other tea districts it is in large demand for tea-boxes. Hooper (Rept. Labor. Ind. Mus (Indust. Sec.), 1906–7, 8) says that samples of the resinous substance procured from the tree were found to contain 79 per cent. of resin and 15 per cent. gum. Some samples also contained an insoluble gum like tragacanth. The bark and leaves yield a yellow Dye of which little use is made; one of the curiosities of the industrial uses of the tree is the peori (or Indian yellow) made from the urine of cattle fed on the leaves. (See Coal Tar Dyes, pp. 345, 707.)

MANIHOT UTILISSIMA, Pohi; Fl. Br. Ind., v., 239; Gamble, Man. Ind. Timbs., 589; Prain, Beng. Plants, 1903, ii., 940; M. palmata,
Muel.; Kew Mus. Guide, 1907, 187; EUPHORBIAE. Cassava, Tapioca,
Manioc, Mandioca, maravuli, marachini, simla-alu, simul-alu, pulu pinan
myouk, etc. According to De Candolle, this is a native of America, but
cultivated for so long that the wild parent is no longer recognisable. At
the present day there are many widely different races. Some botanists,
moreover, regard M. palmata as a separate species, others only as a variety of
M. utilissima, from which it differs chiefly in the absence of the acrid taste and poisonous principle of the latter. On
this account M. palmata is known as the sweet, while the other form
is the bitter cassava (see p. 444).

Cassava is cultivated in most of the provinces of India, and in view of the
fact that it is a drought-resisting plant, requiring only about 14 to 16 inches
of rain per annum, there has been considerable discussion as to whether its cul-
tivation should not be more widely extended, in view of its value in times of famine.
The soil should be rich and light. Propagation is carried on by cuttings from the
stem, 4 to 8 inches long, which are half buried in the soil at an angle of 45°
and placed in rows 4 feet apart. Planting can be done during the whole year,
but the best time is at the close of the cold season. Irrigation is employed in
some parts, chiefly about Pondicherry and Travancore, but hardly elsewhere.
During the first two months the young plants require a moderate supply of
water. After the crop is planted, no special cultivation is necessary except to
keep the soil free from weeds.

The time the crop takes to mature depends on the particular race grown.
Most require about twelve months, though some only six and others as many
as eighteen. The yield per acre is very variously stated. In all cases it is large,
running from about 2,500 lb. to as much as 30,000 lb. or more (Agri. Ledg.,
1904, No. 10, 144–5).

Crop.

From the roots, various preparations are made. The preliminary operations
are the same. The roots are scraped, carefully washed, and then reduced to
pulp by being passed through rollers. Subsequent stages vary according to
the product required, the most important of which are cassava
meal, Brazilian arrowroot and tapioca. Couac is a coarse meal obtained from
the pulp by expressing the juice and then pounding and drying the remaining
particles. Cassava meal is simply couac of a greater degree of fineness. Brazilian
arrowroot is the starch washed out of the root, and tapioca is the same slightly
pared. In Cuddalore and Pondicherry the roots are sold after having been
part boiled (Agri. Ledg., i., 125). The juice of the tubers of the bitter variety
can be converted by boiling into a valuable product widely known as cassareep.
It is a wonderful antiseptic, will preserve fresh meat for considerable periods,
and is also the chief ingredient in many sauces.

It was formerly supposed that the root consisted chiefly of starch with a
varying quantity of prussic acid, which latter in the case of the “sweet” cassava
was confined to the bark, but in the “bitter” occurred throughout the root.
To this prussic acid the numerous cases of cassava-poisoning which have at various
times occurred were said to be due. Leather, however (Cyanogenesis in Plants,
Agri. Journ. Ind., 1906, i. pt. iii., 223–4), states that a number of varieties were

766
examine him at Poona in January 1904, and that none were found to contain any prussic acid as such, but that all manifested a cyanogenetic glucoside "associated with an enzyme which has the property of causing the splitting up of the glucoside, and the consequent formation of prussic acid." In exemplification of this he gives particulars regarding the glucoside thurin in the leaves of the JUAR (Sorghum vulgare, see p. 1040) and of the glucoside in the present plant. "I was able," he adds, "to establish three facts: firstly, none of the varieties contained any prussic acid as such; secondly, all the varieties, irrespective of the colour of the petiole or other botanical features, contained a cyanogenetic glucoside, which varied much in amount; thirdly, this glucoside is associated with an enzyme which has the property of causing the splitting up of the glucoside, and the consequent formation of prussic acid. As in the case of Juar leaves, it is only necessary to crush tapioca root with water in order to bring about this change. The amount of prussic acid varied very much; from some roots 15 grains of prussic acid per pound of root was obtained, from others only one-tenth as much." "Boiling the root is quite sufficient not only to destroy the enzyme, but also to allow the glucoside to pass out into the water, for the root splits up freely." Dunstan and Henry (Pois. Prop. Beams of Phascolus lunatus, in Journ. Board Agri., 1908, iv., 730) are of opinion that the application of enough heat to destroy the activity of the enzyme present should render such food material harmless. (See Phascolus lunatus,ore. 880.) In Medicine tapioca has the same properties and uses as starch. Hanausek (Micro. Tech. Prod. (Winton and Barber, transl.) 1907, 45) gives interesting details of his microscopical examinations of the grain. (Cf. Shortt, Man. Ind. Agri., 1885-7, 307-10; Nicholls, Textbook Trop. Agri., 1892, 247-8; Pharmacog. Ind., iii., 203-5, app.; Sawyer, Tapioca Cult. in Travancore, in Proc. and Journ. Agri.- Hort. Soc. Ind., April to June, 1897, xi., 666-74; Agri. MANURES AND FERTILISERS.—The most general vernacular names in India for manures are:—khad, khau, pous, khadar, sar or sarra, kollar, etc.; pousa, Sansk.; and zibl, Arab.

Speaking of India as a whole, it may be said that systematic manuring is almost entirely neglected by the Natives. From the most ancient times they have been accustomed to observe a casual system of manuring, namely the collection of such substances as are inexpensive and easily obtainable. Moreover, by the very general employment of dried cow-dung as fuel and the utter neglect, through insufficient litter, to conserve cattle urine, they have been deprived of the most important source of all fertilisers and the one readiest to hand, namely farm-yard manure. Caste prejudices, moreover, have to a great extent forbidden the employment of many manures such as bone, animal refuse, night-soil, etc. Still, here and there the value of manure is fully understood (as, for example, in some parts of the Western Presidency); and in the treatment of special crops (such as sugar-cane) manuring is regularly practised. But neither example nor precept have, as yet, succeeded in arousing the average Native cultivator to a sense of the benefits likely to accrue from an extended use of manure beyond that pursued by his ancestors. But in all fairness it must be added that in the majority of cases this apathy proceeds far less from ignorance than from inability to purchase soil-fertilisers. The most urgent necessity of agricultural progression in India is, therefore, a system of fuel and fodder reserves calculated to release the supply of farm-yard manure for its more legitimate purpose, that of a soil-fertiliser.
Voelcker (Improv. Ind. Agri., 131) has very properly said: "Whilst a few soils, such as those of silt-renewed tracts, the black cotton-soil, and newly reclaimed or virgin land, may not require manure, it may be said of the greater part of India that the necessity for using manure is enormous, and the supply of it is notoriously inadequate. Water and manure are interdependent, and, just as the former has been, and is still being provided for, so must attention be given to the supply of manure. These two factors, water and manure, constitute the raiyat's great needs, and in their supply consists, very largely, the Improvement of Indian Agriculture."

In dealing with Manures and Fertilisers it may be convenient to assort them under three main groups, namely Animal, Vegetable and Mineral Manures:

I. Animal Manures.—These may be referred to the following (a) Farm-yard Manure; (b) Town Refuse and Night-soil (Poudrette); (c) Bones; and (d) Guano.

Farm-yard Manure.—It would be impossible to review here the very large amount of interesting new information that has accumulated during the past decade or so regarding Indian farm-yard manure and its uses. The chief contributors in this direction have been Benson, Leather, Lehmann, Mehta and Mollison. Leather, in his Final Report, points to the fact that throughout the greater part of Gujarat, farm-yard manure is extensively utilised as a manure, not as a fuel, and with much skill and intelligence is stored in specially prepared pits. Benson deals with a somewhat similar state of affairs in Coimbatore and Salem. But what is more to the point, the people who do so find no difficulty in growing for themselves, in the form of hedges and otherwise, the fuel that they require for domestic purposes, and thus disprove the oft-affirmed opinion that, having no other fuel, the people of India are driven to burn their manure. In many parts of India even the surplus cow-dung—the proportion that is not required for fuel—is rarely appreciated to the full extent as manure. It is all too often thrown into waste hollows or on the roadsides or on the bank of the village tank, in most cases becoming a source of danger in place of an advantage. Very rarely indeed is any effort made to preserve and utilise the cattle urine. This is a most unfortunate state of affairs seeing that it has been shown in Europe and America most conclusively that farm-yard manure is, perhaps, the best and certainly the most economical of all manures. It contains all the constituents of plant food; is a most valuable and convenient source of nitric acid; its nitrification is most active at the very period of greatest growth; as a manure it is less liable to be washed out of the soil than most artificial nitrogenous fertilisers; it permanently enriches the soil; and acts under all climates, on all soils and with all crops.

Leather says that Indian experiments show that when an application of 6 tons to the acre is given, an increase of 300 to 400 lb. of wheat may be the result. After ascertaining that such an allowance would not be beyond the capabilities of the cultivator, he adds, "consequently these experiments really illustrate what the value of the cattle manure is in terms of food-grains." Moreover he confirms the opinion, advanced originally by Voelcker, that "Indian dung is not poorer than English." [Cf. Leather, Note on Value of Ind. Cattle-dung, in Nagpur Exp. Farm Rept., Annex. F, 1893-4, 1-10; Econ. Util. of Cow-dung and Rab. in Bomb., in Ind. For., 1886, xii., 541-5; Benson, Care and Manage. Farm Man. in South India, Bull. 1894, No. 31; Watt and Mann, The Pests and Blights of the Tea Plant, 130-4; Clouston, Cattle Manure, in Agri. Journ. Ind., 1907, ii., pt. iii., 261-9.]

Town Refuse, Night-soil and Sewage.—The question of the disposal of night-soil and its utilisation for manurial purposes is one which has been, of late years, earnestly considered throughout India by all Governments and Municipalities. In large towns night-soil and street refuse are removed at the expense of the local authorities, but the question arises as to its disposal. The most general practice is to trench it into fields and by its means to reclaim waste land. For this purpose, in some cases deep, in others shallow trenches are employed. Leather remarks, "It is at Allahabad Grass Farm that I have found the most perfect methods employed. The night-soil is

here usually trenched, but instead of the trenches being narrow and deep, about 1 foot by 1 foot, they are really shallow beds, about 14 by 5 feet and only 3 inches deep. A cart-load of night-soil is thrown on, and the excavated 3 inches of earth put back upon it. I have several times, when at Allahabad, dug up these "beds" in which the night-soil had been placed only a few days previously, and found no objectionable odour." "In deeper trenches the decomposition takes naturally longer, but at Meerut I found that a fortnight had been ample for the purpose." In the shallow system the manure is distributed over a larger area, and thus more usefully; with deep trenching as much as 200 tons per acre may be given in the year, whereas one-tenth or one-twentieth would have been ample. In many instances a kind of snow-plough is run over the ground and shallow furrows thus excavated, into which liquefied night-soil is run.

Of the manufacture of poudrette it may be said there are many advantages, and disadvantages. Of the latter, the chief is the fact that the atmosphere of the locality in which the pits are located becomes almost uninhabitable. Still, the poudrette, when prepared, may be carried to great distances and thus utilised over a wide area. The increasing demand for the poudrette of certain towns is indicated by the continuous increase in the price at which it is disposed of. In fact it may be said that the night-soil of many cities has become a source of revenue, so that much progress has taken place. All that is necessary is to extend the demand from the vicinity of the cities to that of the villages, in order to secure a much-needed sanitary reform and great agricultural advances. [Cf. Buck, Employ. City Refuse for Agri. Purposes at Farukhabad, 1872; Moreland, Use of Town Drainage as Manure, in U. Prov. Bull., 1901, No. 18; Ann. Rept. on Working of Sewage Farm, Manjiri, 1902-3; Leather and Mollison, Agri. Value of City Sewage in India, in Agri. Ledg., 1903, No. 2; Joshi, The Util. of Night Soil as Man., C. Prov. Bull., 1901, No. 5.]

Bones (see p. 169).

Guano and Allied Manures.—The excrement of fowls, pigeons, wild birds and bats, etc., may be said to be all forms of the substance known as Guano. It is one of the most highly prized animal manures in European countries, and owes its value to the readily soluble ammonia, phosphates, potash and soda that it contains. A small amount of this substance is annually imported into India, and it has been ascertained to be of special value in protecting sugar-cane cuttings from being attacked by white-ants. Mollison says it is one of the best manures for wheat, 2 to 3 cwt. per acre being sufficient. It acts rapidly and is expended almost entirely on the crop to which applied.

Indian guano is not unknown. It is procured from the caves in Karnul and of the Andaman and Nicobar Islands. The former is possibly mainly the produce of bats, and the latter of the edible swallows (see Birds, p. 138). The imports during the past five years have averaged 2 tons, valued at Rs. 700. [Cf. Encycl. Brit., 1880, xi., 233 et seq.; Spons, Encycl., 1882, i., 358; ii., 1258; Journ. Soc. Chem. Induat., 1887, vi., 228; 1888, vii., 84 et seq.; 1899, xviii., 213 et seq.; Thorpe, Dict. Appl. Chem., 1890, ii., 504 et seq.; U.S. Yearbook, Dept. Agri., 1899, 274 et seq.; Board of Trade Journ., 1901, xxxiii., 72 et seq.; 1902, xxxix., 201-2.]

Fish Manures. (see pp. 543-4).

II. Vegetable Manures.—Many vegetable substances, such as boughs and leaves of bushes and trees, indigo refuse, wood-ashes, weeds of every description (green, dry and burnt), oil-cakes, tank deposits consisting largely of aquatic weeds, etc.,—these and such like are, when obtainable, fairly extensively used as manure here and there all over India. They are usually thrown on the surface of the land and ploughed or hoed into the soil in a fresh state, where they only too frequently become a nidus for insect pests and fungal blights. Except by market gardeners and by tea and coffee planters, pits or heaps are rarely resorted to for the storage and maturation of vegetable manures, and as often as not the stuff casually secured is thrown on the field at the wrong season, and thus becomes next to useless. The following are the chief manures of this class:

Green Manuring and the Assimilation of Nitrogen.—As with the clover in Europe so with several leguminous crops in India, their value as alternating D.E.P., v., 174.
MANURES

Green Manuring.

Leguminous Crops.

Advantages and Requirements.

Jumming.

Burning or Räbing and Jumming.—Burning of weeds in heaps collected all over the fields is less commonly seen in India than in Europe. Aboriginal tribes are fond of cutting down the trees and brushwood and firing these on the surface of the soil—a process of both clearing new land and manuring it with vegetable and mineral matter.

This is known as jumming. A civilised modification of this is pursued in Western (and to some extent also in Southern) India. Seedbeds or even whole fields are manured by what is called räb. This consists in burning the surface soil by means of layers of dried manure, leaves, branches and weeds. After the burning has ceased, the soil and ashes are ploughed in, and thus mixed together. The reader will find much useful information regarding the production of räb soil in Mallison (Textbook Ind. Agri., 1893, 83–5).

Top-dressing of Soil by silt from canals and streams or by the soil from dried-up tanks, bhils, etc., is a subject that has attracted much attention recently. To the tea-planter a dressing of "peat bhil soil" has been proved in some cases profitable, but it is feared soil of comparatively little value has, in many cases, been used in top-dressings, with the result that the cost has far exceeded the value. Much, therefore, depends on the quality of the bhil soil available. What may be called peaty soil is formed by the decay of many generations of rank-growing plants, especially if the decomposition has been accomplished under water. Soil of that nature is most valuable, and has with great advantage been used in many tea estates. [Cf. Pesta and Blights, i.e. 122–30.]

For many other crops silt deposits have been highly commended. For example, of this nature may be mentioned the special cultivation of ground-nuts in South India, manured with tank-soil (see p. 79). [Cf. with Leather, Agri. Ledg., 1897, No. 8, 172–3; Silt of Rivers as Manure, in Journ. Board Agri., 1897, iv., 351.]

Oil-seed Cake.—The Indian cultivators fully recognise the value of oil-seed cake or the refuse of such, both in feeding cattle and as manures of great value. The edible sorts of oil-cake, such as Linseed (see p. 731), Rape and

MANURES AND FERTILISERS

crops or as green manure was appreciated for centuries before their exact action was understood: The chief crops of this nature are Cajanus (see pp. 197–8), Cliser (see p. 298), Crotalaria (p. 433), Dolichos (p. 504), Indigofera (pp. 673, 679), Phaseolus (pp. 225, 879), and Vigna (see p. 1107). It is significant that all these, and a good few others that might be mentioned, belong, like clover, to the special sub-order of leguminous plants that have been shown to possess in the strongest degree the power of producing on their roots, warts that harbour bacterial organisms that have the power of fixing the free nitrogen of the air and thus enriching the soil. Unless, therefore, leguminous crops have been grown so extensively as to render some other plant a desirable rotation, it is preferable in green manuring to select a leguminous crop for that purpose. In that way the advantages of green soilings as well as the supply of nitrogen to the soil may be secured. A green manure should, in fact, be a plant that develops rapidly; should give the largest volume of green vegetation; should be as deep-rooting as possible, thus opening up the soil to a fair depth; should be sufficiently hardy as to flourish under what might be called unfavourable conditions; should occupy the soil and the atmosphere at a season when the crop it is designed to assist is either not on the soil or not growing vigorously at the time; should return more to the land than it has removed; should serve to retain manurial constituents that might otherwise be washed out; and lastly, should be easily rot when hoed into the ground. [Cf. Gilbert, Fixation of Free Nitrogen, Lect. deliv. at Cirencester, July 1890; Lawes and Gilbert, Sources Nitrogen of Legum. Crops, 1892; Warrington, Six Lect. on Rothamsted Exper. Stat., etc., U.S. Dept. Agri. Bull., 1892, No. 8; Frankland, The Chem. and Bacteriology of Ferment. Indust., in Journ. Soc. Arts, 1893; Agri. Ledg., 1893, No. 20, 141–3; 1894, No. 7, 159–200; 1897, No. 10, Nitrogen and Fertilisers in Journ. For., 1897, xxii, 439–52; Green Manuring, in Journ. Board of Agri., 1897, 1–10; Fixation of Atmospheric Nitrogen of Legum. Pl., West Ind. Bull., 1900, i., 396–401; Mallison, Textbook Ind. Agri., 1901, i., 105–7; Allen, Legum. AMMONIUM SULPHATE

MANURES

Mineral

Mustard (p. 184), Safflower (p. 233), Til (p. 986), Cotton (p. 613), Earth-nut (p. 82) and Coconut (p. 360) are much favoured as cattle foods, while the others that may be classed as non-edible are largely used as manure, the most important of this latter class being Caster-oil (see p. 922); but Poppy (p. 806) and Mahua (p. 120) may be added. With highly profitable crops, such as sugar-cane, many of the edible cakes are occasionally employed as manures. Mollison points out that the cultivators in this respect often act against their own interests, since the castor cake very often fetches a higher price than some of the edible cakes which they refuse to use as manure. The advantage to India of the oil-seeds being expressed in the country, instead of being exported, has been repeatedly urged (Voelcker, Lc. 104). Profitable labour would be secured for many persons and a larger percentage of cake retained and to a greater extent than at present, very possibly, returned to the soil. The Annual Reports of the various Agricultural Departments and Experimental Farms of India have for many years past abundantly demonstrated the value of the cakes as special manures. [Cf. Leather, Lc. 157-62; Mollison, Lc. 122-33; Lehmann, Comm. Fertil., in Agri. Journ. Ind., 1906, i., pt. ii., 123-6; also see article Oils and Oil-seeds, p. 818.]

Special Plants as Manures.—Adhatoda (see p. 25); helpful vegetation (see pp. 54, 113-4). Plants with milky sap, such as Calotropis (pp. 53, 206) and Euphorbia (p. 530), are specially preferred; the refuse of Indigo (see, p. 679); and many other such substances are valued as manures and often resorted to by the cultivators. The reputation of Adhatod a, both as a manure and a poison to destructive organisms that appear in the flooded rice-fields, is specially worthy of attention.

III. Mineral Manures.—Though several very valuable manures of this kind exist plentifully in many parts of India, their value and uses are hardly anywhere appreciated. Some of these have already been so fully dealt with in other positions in this work that all that need be necessary is to furnish cross references:—

Lime.—(See p. 712). As a rule lime is present in such abundance in the agricultural tracts as scarcely to require its addition as a manure.

Gypsum.—(See p. 717).

Ammoniacal Liquors and Ammonium Sulphate as Manures.—(See pp. 48, 346.) Sir John Lawes has pointed out that the objection to sulphate of ammonia and all other "highly nitrogenous" manures, is that "they use up certain natural ingredients in the soil, which when exhausted cause the plant to fail." In a further communication he condemned sulphate of ammonia, because it removes lime from the soils. Where the percentage of lime is naturally low, as for example in the tea lands as a whole, it should not be used, or only in exceptional cases. All artificial manures have the further objection that in countries subject to heavy rains, soluble manures are very readily washed out of the soil, so that their action is often only temporary; a fall of rain of only a very few inches may suffice to remove them entirely. For crops that occupy the soil for brief periods only, such as wheat and barley, if given in combination with potash either present in the soil or added as an ingredient of the special manures, these chemical nitrogenous fertilisers may be of special value. [Journ. Soc. Chem. Ind ust., 1899, xviii., 486; Mollison, Lc. 117-8; Watt and Mann, Lc. 154-5.]

Nitrates.—The nitrates of potash and soda are both largely employed as manures. In a crude sort of fashion the Native cultivators of India here and there show that they are aware of the value of crude saltpetre as a manure by the value they place on surface soil collected near the homestead. Certain localities, as for example Bihar, have been noted from time immemorial for the large stores of saltpetre found naturally in the soil, and such localities have accordingly been famed centres for the production of the salt. Saltpetre is specially valued as a manure with tobacco, sugar-cane, and garden crops generally (see Saltpetre, p. 974). [Cf. Mollison, Lc. 119-21; Leather, Calcium Nitrate and Nitric Acid, in Agri. Journ. Ind., 1907, ii., pt. ii., 209-10.]

Potash Manures: Pearl Ash, Kainit, etc.—Saltpetre is valued not only as a source of nitrogen, but on account of its potash. Continuous cultivation and removal of crops must, therefore, gradually lower the stores of this all-important material. With the return to the soil of decomposed vegetable matter or of plant ashes, the potash is to some extent restored. But sooner or later it must

Advantages of Oil Mills.

Production of Cake.

Mineral.

Lime.

Gypsum.

Ammonium Sulphate.

Saltpetre.

Potash.
be added as manure if fertility is to be preserved. To the Natives of India potash may be said to be summed up in Pearl Ash (see p. 49). Plant ashes have been for centuries valued for high-class cultivation. The subject is closely akin to raking and jumming (see above, p. 167). The value of waste bones as manures will be found discussed in many Indian publications, such as the Indian Forester (1879, iv., 284–5). Rice husk, almost worthless as a cattle food, is of great value as a manure, because of the high percentage of potash it contains. So also the refuse skimmings, in the process of sugar manufacture, are much valued, and indigo refuse is also rich in potash. Recently, however, certain natural minerals have come into the market as special potash-yielding manures. Of this nature is kainit, which contains 13 to 14 per cent. of potash. When calcined it is greatly improved, and may be given at from 2 to 4 cwt. to the acre. It is useful on light lands rather than on clay soils. Large beds of this substance have been discovered in Germany.

Phosphates and Phosphatic Manures, Basic Slag, etc.—The phosphoric acid required by plants is one of the soil ingredients liable to be exhausted by continuous cropping, and must be supplied in the form of manure. It is on this account that pastures are liable to get worn out. The principal manures of this class are bones, superphosphates and reduced phosphates. Space cannot be afforded to revert to the subject of bones and the special preparations made from them (see p. 169). But it may be here observed that large fossiliferous deposits have been found in many countries rich in phosphates. Holland (Rev. Min. Prod., in Rec. Geol. Surv. Ind., 1905, xxxii., 112–4) says of India, “One regretful feature” . . . “is the absence, in a country where agriculture is such a prominent industry, of any phosphatic deposits of value, and a further circumstance to be regretted is the continued export of phosphates in the form of bones, due primarily to the fact that, being without means for the manufacture of cheap sulphuric acid, superphosphates are not made in the country, and the little that is used is imported from Europe.” “Amongst the phosphatic deposits of India, the principal and perhaps the only one worth considering is the deposit of phosphatic nodules of the septarian kind, occurring in the cretaceous beds of the Perambular taluk, Trichinopoly district, Madras Presidency. Dr. H. Warth, in 1893, estimated that to a depth of 200 feet the beds contained phosphates to the amount of about 8 million tons, but the nodules are distributed irregularly through clay, varying, in the different deep excavations made, between 27 and 47 lb. per 100 cubic feet, and in some shallow diggings 70 lb. per 100 cubic feet. Analyses of these nodules show them to contain from 56 to 59 per cent. of phosphates, and about 16 per cent. of carbonate of lime, with considerable variations in different nodules. The alumina and oxide of iron vary between 4 and 8 per cent.” Two attempts made to utilise these deposits have proved futile, and it is believed there is no present prospect of mining for export. [Cf. Hooper, Effects of Phos. Man. in Jalap Cult., Pharm. Journ., July 1896; Sly, Min. Fertil. in Ind., Agri. Journ. Ind., 1900, i., pt. iii., 243–6; Leather, Mem. Dept. Agri. Ind., 1907, i., Chem. ser., 45–57.]

Basic Slag. Basic Slag, a by-product in the manufacture of steel, and until recently a waste product, came into use as a phosphate and lime manure. It is ground to a fine powder, and in soil moisture is at once dissolved and rapidly absorbed by the roots. As it contains much iron it is not suited for soils already rich in that substance. [Cf. Hughes, Journ. Soc. Chem. Indust., 1901, xx., 325 et seq.; Hooper, Agri. Ledg., 1898, No. 20.]

Indian Manure Works.—It would, perhaps, be invidious to attempt an enumeration of the bone-mills of India (further than has already been given, p. 169), since these by no means represent all the manure works, nor the firms that trade in indigenous and imported manures.

Trade.—The traffic in manures is not an extensive one, and, when bones are eliminated, is hardly worth mentioning. The total exports in 1904–5 were valued at Rs. 43,77,841, of which Rs. 37,51,480 were bones, and in 1906–7 at Rs. 1,01,54,892, of which Rs. 55,45,241 were bones. But one point is worthy of consideration, viz. while the exports of raw bones have been declining steadily for some years past, the exports under the heading of Others (excluding oil-cakes) have been steadily increasing. In 1900–1 the exports of bones were valued at Rs. 58,41,916,
and the Others at Rs. 71,503; five years later (1904-5) the Others had expanded to Rs. 6,26,361. It is believed this increased traffic may, to some extent, represent the expansion in the manufacture of special manures, the surplus, not required for India, being exported. Lastly, this increase in the exports of manures from India has been chiefly from Madras and Burma. The imports of foreign manures are so unimportant as scarcely to deserve notice. In 1904-5 they were valued at Rs. 50,980, and in 1906-7 at Rs. 55,105, and came almost exclusively from the United Kingdom.

**MARANTA ARUNDINACEA**

**Linn.**; Prain, Beng. Plants, 1903, ii., 1047-8; Sotiamineé. West Indian Arrowroot, tikhar, tarkil, arurut, kiuka neshasteh, kuva mavú, tavaksha, pen-bwa, etc. A native of Tropical America and of the West Indies, cultivated in India. It yields the genuine or West Indian Arrowroot, so called to distinguish it from East Indian, the produce of *Carica angustifolia* (see p. 444), with which it is often confused.

**Cultivation.**—The cultivation of this rhizome is briefly as follows:—Drills are made about 3 or 4 inches deep and 2 feet apart. On these the roots are planted in May, at a distance of a foot and a half apart, and covered over by earth. As the plants grow, they should be earthed up in the same way as potatoes. They require good, rich soil and plenty of water, which should, however, be withheld for a month or two previous to gathering the crop (Firminger, *Man. Gard. Ind.* (ed. Cameron), 143-4). Of Cuttack, Banerjei states that it grows well on rather sandy soil, and of Bombay, Woodrow remarks that as regards soil it is by no means fastidious, “fine sand at Nariad and loam and clay-loam at Poona being equally suitable provided heavily manured and irrigated.” Flowering takes place in August, and in January or February the crop may be taken up. The maturity of the rhizomes may be ascertained by the falling down of the leaves. In digging up the crop it is impossible not to leave behind small portions of the rhizomes, and from those fresh plants spring, so that it is often difficult to eradicate the plant from soils on which it has been once grown. The smaller rhizomes and the pointed ends of the larger ones, on which the “eyes” are situated, should be kept for fresh planting. According to Woodrow, the produce in green tubers is generally 6 to 7 tons per acre, though over 12 tons have been produced at Poona. According to Nicholls the rhizomes contain 20 per cent. or even more of starch, and in Natal as much as a ton of arrowroot has been made from the rhizomes derived from an acre. It is generally said that cultivation should not be attempted in localities remote from a liberal supply of water, since irrigation may not only be required by the crop, but water is essential in the manufacture of the arrowroot.

**Manufacture.**—The method of preparing the arrowroot is simple. The rhizomes after being well washed are scraped with a knife to remove the rind, and at the same time diseased or imperfectly formed portions are picked out and thrown away.
MARSDENIA
Tenacissima

RAJMAHAL HEMP

The rhizomes are then pounded to pulp in a mortar or reduced to that condition on a grater. The pulp is then thrown into a vessel of water, which becomes turbid or milky while a portion of the pulp remains suspended as a fibrous mass. This fibrous portion is lifted out, rinsed, pounded once more and again thrown into water, lifted out a second time, rinsed, and then thrown away. The milky-looking fluid thus obtained from these several washings is now strained through a coarse cloth to remove any particles of the fibre and other impurities, the liquid being thus passed into another vessel, and when the sediment has settled, the water is gently poured off and clean water added. This is again stirred up and strained through a fine cloth, and, on settling, the water is once more carefully and gently drained away. The sediment that remains now consists of pure arrowroot, and is dried on sheets of paper by exposure to the sun, and packed ready for the market. It is a tasteless and colourless powder, which might be spoken of as consisting of pure starch granules. [Cf. Hanousek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 43-4.]

The genuine West Indian arrowroot may be readily distinguished from East Indian by its pure white colour and by its swelling in boiling water. [Cf. Milburn, Or. Comm., 1813, ii., 207; De Candolle, Orig. Cult. Plants. 1882, 81-2; Mason, Burma and Its People (ed. Theobald), 1883, ii., 209; Nicholls, Textbook Trop. Agr., 1892, 278-83; St. Vincent Arrowroot, Kew Bull., 1893, 191; also Bermuda Arrowroot, 1898, 50; Manuf. of Arrowroot in Ceylon, Trop. Agrist., Feb. 1, 1895, xiv., 557; Dodge, Useful Fibre Plants of the World, 1897, 235; Semler, Trop. Agrik., 1900, ii., 747-66; Woodrow, Gard. in Ind., 1903, 480-1; A. W. and M. W. Blyth, Foods, etc., 1903, 141, 144-5; Agri. Ledg., 1904, No. 10, 135; L Agri. Prat. des Pays Chauds, 1904, iii., 757-85.]

M. ROYLE, Wight murukūla, pathor, tar, erti, kurang, kharchu, shengori, etc. A climbing shrub of the Himalaya, from Sikkim westwards, ascending to altitudes of 7,000 feet. It yields a fibre from which fishing-nets, lines and strong ropes are manufactured.

M. tenacissima, Wight & Arn.; Rajmahal Hemp, tongus, jiti (chitti), babal jak, etc. A climbing shrub of the Sub-Himalayan tracts from the Jumna to Oudh, Bihar and Chota Nagpur; Chittagong and Upper Burma.

The bark of the stem yields a valuable fibre, which was said by Royle to be the second best in India. By the hill tribes it is used chiefly for bow-strings and netting. The fibre was examined in 1886 by Cross and Bevan, who reported that it was of excellent quality and in point of fineness and durability ranked next to rhea. More recently a sample was sent to the Imperial Institute for examination. It was found to contain little or no lignocellulose, and to be exceptionally resistant to the action of alkalis. The remarkable quality of the fibre was also shown by the unusually high percentage of cellulose and by the large increase of weight on nitration. The length of the ultimate fibre was found to be 10 to 30 mm. Specimens were also submitted to leading firms of fibre brokers for commercial valuation. One reported that the fibre, though short, was of great strength, and another that it was very strong, but harsh. The sample, of a length of 12 to 15 inches, was valued at £15 to £18 per ton, but it was stated if fibre 30 to 35 inches long could be sent, its value would probably be £35 to £40 per ton. In view of these facts the question arises whether experiments in cultivating the plant might not be undertaken, and whether the fibre could be successfully treated by machinery. [Cf. Royle, Fibrous Pl. Ind., 1855, 304-5; Dodge, Useful Fibre Plants of the World, 1897, 235-6; Dunstan, Rept. on Marsdenia tenacissima, Imp. Inst., July 9, 1903; Agri. Ledg., 1904, No. 8.]

M. tinctoria, S. Br.; rjon, riyong, kål larā, mai-nwai, etc. A large climbing shrub of the Sikkim Himalaya, Assam, the Khasia hills, Northern Burma and the Circars. This species also yields a fibre, but is more especially interesting on account of the indigo dye yielded by the leaves. At the beginning of last century Roxburgh recommended its cultivation, but nothing appears to have been done, nor has the value of the dye been commercially tested. (See Indigo, p. 663.)
MATS AND MATTING

For information regarding woven mats, the reader should consult *Carpets and Rugs* (pp. 271-6), and for the chief matting materials, the list below. The most famous of the so-called mats are the grass-mats—
(a) of *Pálgát* on the Malabar Coast of Tinnevelly, and Ganjam in South India; (b) of Midapur and Calcutta in Bengal; (c) the *sitalpati* mats of Eastern Bengal and Assam (Sylhet); (d) the *coir mats* of South India and Bengal; (e) the *munj* mats of Allahabad, Agra and Delhi in North India; (f) the date and other palm-leaf mats used all over India, more especially in Western and Southern India—in Bombay known as *shaelu* mats; and lastly, (g) ivory mats, woven from strips of ivory so fine that they resemble the strands of *sitalpati* (see *Ivory*, p. 698).

Mats or rather screens (tatties) made of thesweetly scented *khas-khas* are hung in front of doors, etc., to afford shade and to cool, by evaporation, the air which passes through their moistened texture. Bamboo mats are manufactured here and there all over India, and in Bengal more especially *darmá* mats (those constructed of reeds, see *Phragmites* below) are all but universally used in house-construction. The traffic in *darmá* mats must, therefore, be very great, and give employment to a far larger number of persons than can be learned from published statistics. In some of the jails aloe-fibre mats are produced and found a fair market, while cane mats are not uncommon. These are formed by selected canes being placed parallel to each other and bound in position by cross-ties. They are exceptionally strong, and specially valued in public offices where there is much traffic.

The following are the chief matting materials of India:

Agave (see p. 43). In the Panjáb, the fibre of two species is a good deal used in jails for making *darsi* mats and ropes. It is beautifully white and takes dye much better than even *munj* (*Saccharum*), but it is neither so strong nor so durable. The plant is a slow grower and liable to exhaustion. [Gee, *LC. 4.*]

Calamus—Canes and Rattans (see pp. 202-4).

Clinoxyne dichotoma, *Sativ.*; *Fl. Br. Ind.*, vi., 258; *Agri. Ledg.*, 1896, No. 41; *Nisbet, Burma under Brit. Rule and Before*, 1901, i., 383; *Scitamineae*. The *sitalpati*, *mukdá-páta*, *murra*, *thin*, *godúnika*, *bhúdra*, etc. A woody shrub of Eastern Bengal, Assam, Burma and the Malay Peninsula. It thrives on moist ground, which need not be specially prepared, and it can be reproduced by cuttings as well as by transplantation of shoots.

From the stems are prepared the famous *sitalpati* or "cool mats." For the manufacture of the finest mats, the *murra* should be cut when one year old. The split stems as prepared are about 4 feet long, one-twentieth of an inch wide, and as thin as paper. The average size of the mats, when finished, is about that of an ordinary double bed. Owing to their coolness they are much used during the hot weather, both by Europeans and by Natives, being placed beneath the bedding sheets. As a historic fact of some interest it may be here mentioned that formerly the main corridor of the East India House in Leadenhall Street, London, is said to have been fitted with this matting. The quality is judged by glossiness, smoothness and fineness of texture, and it is said that over the smoothest even a serpent cannot glide. The price varies from Rs. 2 for the common sort to as much as Rs. 100 for the best qualities. The chief producing
districts are Faridpur, Bakarganj, Tippera and Chittagong in Eastern Bengal, Sylhet and Cauchar in Assam, and Henzada in Burma. The industry is almost entirely confined to women. It has been suggested more than once that this fibre would make an excellent substitute for the Panama fibre in hat manufacture. The plant also yields a pith, which is discarded by the sitapatti makers, but which might well be employed as a paper material if procurable in sufficient quantity. [Cf. O. W., in Capital, April 25, 1901.]

**Cocos nucifera**, Linn. (see p. 356).

**Corypha umbraculifera**, Linn. (see p. 429).

**Crotalaria juncea**, Linn. (see pp. 435–6).

**Cyperus tegetum**, Roxb. etc. (see pp. 467–8).

*Mats*. The leaves of this plant are made into the sleeping-mats employed by the hill tribes, where the plant is at all plentiful.

**Hibiscus tiliaceus**, Linn.; a large and abundant bush and affords a fibre obtainable by a process much less tedious than with most other fibre-yielding plants—a fibre which would appear well adapted for the manufacture of mats, ropes, and possibly also paper. In the Panjāb it is occasionally employed in the construction of charpais, sides of carts, seats of bullock-wagons and mats. In New Caledonia and Tahiti it is made into fishing-nets (see p. 820).

**Ischemum angustifolium**, Haas. (see pp. 684, 685).

**Juneus effusus**, Linn.; Fl. Br. Ind., vi., 392. This common European rush is found in the Sikkim Himalaya and Khasia hills from 6,000 to 10,000 feet. *J. glaucescens*, Ehrh. Bcltr., which is not unlike the former species, though stiffer and darker, is met with in the Western Himalaya, Nilgiri hills and Ceylon. The European plant is in considerable vogue for the manufacture of baskets, mats and chair-seats, and it is suggested that similar uses might be found for one or both species in India, where they are at present entirely neglected.

**Melocanna bambusoides**, Trin. (see Bambusa, p. 103).

**Nannorrhops Ritchieana**, H. Wendt.; Fl. Br. Ind., vi., 429; Gamble, Man. Ind. Tims., 733; Palmeze. The masrī, patha, kīlu, pīfe, etc. Usually a stemless shrub, but occasionally develops a stem 10 to 14 feet long. It is met with in Sind and the Western Panjāb as well as in the Kuram Valley and in Baluchistan, many acres of country about Harnai being covered with it, and ascending the hills to 5,000 feet above the sea.

In former times it was common all over Kohāt, but railway construction has led to an increased export to the Cis-Indus districts, and the more easily available *masrī* supplies have been exhausted. In 1882 measures were taken to protect the palm. The green leaves are beaten out with a mallet and the fibre obtained is used for matting, fans, baskets, hats, sandalas, nets, etc. Waziri baskets and mats produced at Bannu are famous all over the Western Panjāb. Rope is also made from the stems and leaf-stalks, though apparently it is not very strong. The leaf-bud, young inflorescence and fruit are eaten, and the leaves regarded as a purgative medicine for cattle. The seeds are made into rosaries and exported from Baluchistan (Gwadar) to Mecca. The price of *masrī* matting in Peshawar is about Rs. 8 per 100 sq. yards, and its popularity appears to be increasing.

**Nipa fruticans**, Wurmb.; Fl. Br. Ind., vi., 424; Gamble, Man. Ind. Tims., 729; Palmeze. The gūdga, golphal (fruit), golpatra (leaves), dāni, etc.; a large creeping gregarious palm of the Sundribans, Chittagong, Burma and the Ṭamandas! The old fruits are large, the interior being hard like ivory, but transparent; they are carried to the sea and floated. The leaf-stalks are used to help in floating *sunndri* logs in the Sundribans, also as fishing-floats. The leaves are very largely employed for thatching and in making mats. In the Straits Settlements they are used for covering cigarettes. Toddy is obtained from the spathe (as Linschoten observed in 1598), and the young fruit is edible. Gamble states that the trade in golpatra leaves in the Sundribans amounts yearly to about 135,000 tons, valued at nearly Rs. 60,000.

**Rice**. *Oryza*—Rice Straw (see p. 826). In Kullu and Hazara, mats called *mandrī* and *phindī* as also string, are made of rice-straw.

**Screw-pine**. *Pandanus*, the screw-pines, might be described as a genus of palm-like evergreen trees or shrubs, often scanted and possessed of copious and strong aerial roots. They are met with in the moist tropical regions, chiefly Mascarene and Malayan. Hooker (Fl. Br. Ind., vi., 483–7) describes some seven Indian
species, and mentions many other obscure forms. The only species of economic value may be said to be:—

P. odoratissimus, Linn. f. (P. fascicularia, Lam.); the keura, kea, ketuki, keori, mugaāl, thalay, tulai, kāuida, satthahpu, etc. Common on the sandy coasts of South India, Burma and the Andamans. It forms dense impenetrable thickets in the tidal forests, and is extensively grown as a hedge plant. It is also specially cultivated in gardens in South India on account of the fragrance of its spikes of flowers. These, tied up within the few adjacent leaves, are sold in the market towns, and may be seen in shops and at the railway stations. The women wear the fresh flowers in their hair and use them as offerings at the temples. From them is also prepared keura, perhaps the most characteristic and most widely used perfume of India. The soft floral leaves and pulp of the fruit are also eaten. The leaves afford an excellent fibre which is employed for nets, sacks, brushes, mats, etc. [Cf. Marco Polo, Travels (ed. Yule), ii., 250; Clusius, Ananas silvestris, Exot. Pl., 1605, 285; Ain-i-Akbari, (Jarrett, transl.), ii., 126; Forster, Pl. Esc., 1786, 38-41; Taleef Sherseef (Playfair, transl.), 141; Rept. Ind. Hemp Drugs Comm., i., 156.]

Phoenix, several species (see pp. 884-5); also Basket- and Wicker-work (p. 115).

Phragmites; of the reeds proper there are two species, P. communis (dīla or dāmbā), met with in the marshes and on the margins of lakes in North-West India up to altitude 10,000 feet, and P. karka (nala, nāl, nar, sur, kaing, karka, etc.), found in the swamps of the more tropical India.

The former is employed on the Dal Lake of Kashmir as the radhe that constitutes the foundation of embankments and floating islands. The culms of both species are extensively utilised all over India in the construction of chairs (morhas) and baskets; they are also largely used for lutes and the tubes of smoking-pipes (hukhās). Split open they are made into mats, and thus constitute one at least of the sources of the dārmā mats of Bengal. These are produced cheaply and in great abundance, being universally employed in house-construction. They are also utilised as lining (dunnage) of ships to protect and isolate cargoes, and they might with advantage be used to line the inside of iron roofing. The flowering stalks are beaten out and afford a useful rope-fibre. [Cf. Lisbon, Bomb. Grass., 116; For. Admin. Repts.; Rec. Bot. Surv. Ind., ii., 155, 240, 247, 360.]

Pseudostachyum (see Bamboo, p. 104).

Saccharum arundinaceum, hets. (see pp. 929-30).

Tachardia laca, kerr.; for mats made of lac, confer with account given by Birdwood (Indust. Arts Ind., 1880, ii., 223-4). A thread of lac is wound around a stick, and, after drying, is drawn off and broken into sections of three or four turns each. These are then linked together into mats of all sorts of variegated colours.

Typha; Fl. Br. Ind., vi., 488. There are three species of Reed Mace, Elephant Grass or Cat's tail Bullrush, between which, for the present purpose, it is hardly necessary to draw distinctions since their properties and uses are practically identical. These are known as T. angustata, the luhk of Upper India; T. elephantina, the pater, hogāl, bora, dīb, pun, rāmābāna, etc.; and T. luxmanni, the pīt of Kashmir.

The culms, as also the leaves of all three forms, are extensively used in making sieves, thatching mats and house-boats, and in the manufacture of mats, ropes and baskets. In Sind they are also employed in the construction of crude boats called tībā, also floats and buoys to support swimmers. They are much valued for their long roots, which bind loose soils and embankments. The pollen is regularly collected, and on the Indus forms a fairly important article of food, being baked, in the form of Bāzās, Bhaduri (Rept. Labor. Ind. Mus. (Indust. Sec.), 1902-3, 27) has given the results of his chemical analysis of this article of food. It contains carbohydrate, 44-50; albuminoid, 19-75; cellulose, 17-80; oil, 2-70; the balance ash and water. The young shoots and tender roots are also eaten, and the lower succulent parts of the fruiting spike, soaked in oil, are used as a torch, whilst the down of the ripe fruit is mixed with mortar as a binding material.

The rushes are split and woven into coarse mats for covering boats and for making walls or partitions of houses. The leaves also find a purpose in the construction of soft matting as, for example, in Kullu, Kumaon, Sind and elsewhere. In the Panjāb, Typha is generally adopted as a matting material when mazri (Vannohrops) is not available. [Cf. Ain-i-Akbari (Jarrett, transl.), ii., 123;
Mats and Matting

**Trade and Commerce.**—The statistics of mats and matting given in the annual official returns of trade exclude Coir manufactures, and it is not shown to what extent they include mats or rugs other than grass-mats. The Exports to foreign countries during the years 1899–1900 to 1906–7 showed no great fluctuation in quantity but a remarkable undulation in value, due perhaps to the demand for cheap goods in one year being supplanted by more expensive articles in the next. The highest recorded value was Rs. 2,41,887 in 1900–1. In 1903–4 the amount stood at Rs. 58,754; in 1905–6 was only Rs. 27,267; and in 1906–7, Rs. 47,617. Madras has more than half the trade in quantity but realises less in value than Bombay. The re-exports were at their highest value in 1903–4 (Rs. 26,234), and represented chiefly trade from Bombay to East Africa, Turkey-in-Asia and Persia. Of the Imports a large share should probably appear as Carpets and Rugs, as, for example, the supply (56 per cent.) that comes from Mekran and Souniani. Other considerable contributors are China (Hongkong) and the Straits Settlements. The highest value in the years mentioned (1899–1907) was reached in 1904–5 (Rs. 2,94,182), and of that Rs. 1,52,782 and Rs. 49,473 were taken by Bombay and Sind.

As regards Coir Manufactures (excluding rope and presumably including some proportion of articles other than matting) the trade is almost entirely concentrated in Madras, which in 1905–4 exported to foreign countries some 473,281 cwt., valued at Rs. 46,78,050, chiefly to the United Kingdom and Germany, the total foreign trade of all provinces having been 483,355 cwt., valued at Rs. 47,90,110. In 1906–7 the exports from Madras were 552,703 cwt., valued at Rs. 55,24,154, and the total foreign trade 559,329 cwt., valued at Rs. 56,00,268. At the same time the Madras Presidency contributed to Bengal and Bombay a fairly large quantity, namely Rs. 9,00,000 worth. (See also Cocos nucifera, p. 362.)

**Mats and Matting**

**Lucerne**

Taleef Shereef (Playfair, transl.), 31; Gee, Monog. Fibrous Mat. Pb., 1891, 2; Dodge, Useful Fibre Plants of the World, 1897, 319; etc., etc.]

**Vetiveria zizanoides,** stayf; the khas-khas (see p. 119).

**Trade.**

Exports.

Imports.

Coir.

As regards Coir Manufactures (excluding rope and presumably including some proportion of articles other than matting) the trade is almost entirely concentrated in Madras, which in 1905–4 exported to foreign countries some 473,281 cwt., valued at Rs. 46,78,050, chiefly to the United Kingdom and Germany, the total foreign trade of all provinces having been 483,355 cwt., valued at Rs. 47,90,110. In 1906–7 the exports from Madras were 552,703 cwt., valued at Rs. 55,24,154, and the total foreign trade 559,329 cwt., valued at Rs. 56,00,268. At the same time the Madras Presidency contributed to Bengal and Bombay a fairly large quantity, namely Rs. 9,00,000 worth. (See also Cocos nucifera, p. 362.)

**D.E.P., v., 199–203.**

**Lucerne.**

According to De Candolle, the plant is a native of western temperate Asia, and is found apparently wild in Afghanistan and Baluchistan. Stein (Ancient Khotan, 1907, 130) speaks of it as extensively cultivated in Khotan and used as fodder. It is now largely grown in many parts of India and affords excellent forage for horses and cattle, if given in moderation. At least two varieties are cultivated, the Kandahár and the Persian or Arabian. The latter is the crop ordinarily met with.

**Cultivation.**—In the Poona district, according to Mallison, the best time for sowing is either early in the rains or between October and December; in the north of India, from the middle of October to the middle of November. The price of seed ranges from Rs. 0–14 to Rs. 1–8 per lb. The usual native method of sowing is broadcasting on a clean, well-prepared bed, but by this method the field gets foul by deep-rooted grasses and other weeds, and the lucerne fails when it ought to be in full vigour. A good method of cultivation is as follows:—The field should be well ploughed and brought into a thoroughly friable, smooth, clean condition during the rains. In September, 30 cart-loads per acre of well-decayed farm-yard manure should be given. The manure must be evenly spread and mixed thoroughly with the soil. Ridges are then formed
Burmese Varnish Tree

Melanorrhoea usitata, Wall., Pl. As. Rav., i., 9-12, tt. 11, 12; Fl. Br. Ind., ii., 25; Watt, Kew Bull., 1906, 137-47; also Ind. Art at Delhi, 1903, 218-24; Anacardiaceae. A large deciduous tree of the open forests of Manipur, Burma and Siam, rare in dry forests. It is generally known as The Burmese Varnish Tree, and by the following vernacular names, thitsi, kheu, suthan, kiahong, etc. (See Semecarpus, p. 981.)

In addition to affording a useful timber, it yields a natural Varnish of great interest and value, and one which may be characterised as having originated several distinct industrial and art conceptions peculiar to the Burmese, Shans and Siamese. In Maymyo the preparation of the crude black varnish may be spoken of as the chief forest industry, but it is also largely extracted in the Monghong State. In fact, wherever the tree abounds the varnish is collected. In such tracts it is rare to find a tree that has not been tapped. It is exported mainly from the Northern and Southern Forest Circles of Burma. To obtain the varnish, V-shaped incisions, 9 inches long and 5 inches apart at the base, are cut on the bark of the trees, the apex pointing down. The tongue of bark within these scars is then slightly lifted up and a specially prepared joint of bamboo driven in horizontally immediately below the apex of the incision. The sap which exudes from the inner bark drains into the bamboo receiver. This is emptied at the end of ten days, when the flow of varnish is observed to become scanty. A second cut is made along each side of the contained tongue of bark, which is also again raised up slightly and the bamboo receiver placed more conveniently to the new scariation. After this has yielded all the varnish that seems likely, a new incision is made a little higher up. It would appear that young trees yield better than fully formed ones. By the tapping process the trees become much distorted, and it is no unusual occurrence to find some that manifest 50 to 60 successive scariations. One man, it has been estimated, can look after and collect the varnish from 1,200 trees, provided they are not too much scattered. He can sacrifice and collect from about 200 trees a day. The best season for working is from July to October, and one man may collect from 146 to 182 lb. in one season. In 1904-5, 38,622 viss, and in 1905-6, 36,382 viss, were collected under license and permit. (Cf. Ann. Rept. For. Admin., 1904-5, 55.)

Thitsi is largely utilised in its liquid state as a natural varnish, and has the great merit of preserving woodwork. Thickened by sawdust, cow-dung ashes, or bone-ashes to a plastic condition, it is employed as a cement and body...
MELIA, Azadirachta

THE NEEM OR MARGOSA TREE

Moulding Material.

Chief Forms of Lacquer.

Neem.

M. Azadirachta, Linn.; M. indica, Brandis, For. Fl., 67; Azadirachta indica, Jussieu, in Mem. Mus. Hist. Nat. Paris, 1830, 19, 221. The Neem or Margosa Tree, nim, agas, limba, kohumba, vépa, taruka, bevina, thin, kamáká, etc. A large tree; according to Gamble, probably wild in the forests of the Karnátk and parts of the Deccan, and perhaps also in the drier, inland parts of Burma; elsewhere cultivated.

It is of considerable economic importance. From the bark there exudes a bright amber-coloured Gum, which is collected in small tears or fragments. This is said to constitute a portion of the commercial "gum gattam" and of "East India gum." It is considerably esteemed medicinally as a stimulant.

Gum.

Oil. From the seeds a fixed acid, bitter Oöl is extracted, of a deep yellow colour and disagreeable flavour. As an anthelmintic and antiseptic it is in much demand, and is largely used by the poorer classes for burning, but said to smoke badly. The harks of trees are often painted with it to protect them from insect pests. By the women of Sind it is applied as a hair wash. The chemistry of this oil was fully investigated by the late Dr. Warden, and a detailed account of his results is given in the Dictionary. Ním oil-cake is regarded as a useful fertiliser. In addition to the gum and oil, the bark, young fruits, seeds, leaves, flowers and sap have all medicinal properties assigned to them or are spoken of as edible. The leaves are utilised to preserve books, papers, cloths, etc., from ravages of insects. They are said, moreover, to be useful in keeping away mosquitoes. Hooper (Rept. Labor. Ind. Mus (Indust. Sec.), 1903-4, 30-1) records the results of his investigations. Fresh leaves, distilled in water, It was found that a distinct allyl- or onion-smelling compound was present in the distillate. The powdered leaf, when burnt, gave off an odour found to prove fatal to insects. The extract of the leaves was intensely bitter and contained evidence of an alkaloid.

The sap or nim Toddy is yielded by the tree either spontaneously or is extracted artificially. In the former case, a clear and colourless liquid flows in a thin stream or continuous droppings from two, three or more parts of the plant simultaneously for several weeks on end. Artificially it is obtained by exposing a healthy-looking root, cutting it through, and placing a vessel beneath to receive the exuding liquor, which is a refrigent, nutrient and alterative tonic. The Wood is durable, has an average weight of 50 to 52 lb. per cubic foot. Its chief use is for cart-construction, ship-building, agricultural implements, and in South India for furniture. The twigs are largely used as toothbrushes. [Of. Garcia de Orta, 1563; Coll., xl.; Tulaef Shereq (Playfair, trans.), 170; Jacob Breynus, Iron. Rar. Pl., 1739, 15, t. i.; Buchanan-Hamilton, Stat. Acc. Dénaj., 1833, 154; Mooden Sheriff, Mat. Med. Mad., 1891, 100-5; Banerjei, Agri. Cuttaack, 1893, 185, 187, 201; Woodrow, Gard. in Ind., 1896, 59, 233; Mukorji, Handbook Ind. Agri., 1901, 296-7; Watt and Mann, Pests and Blights of the Tea Plant, 1903, 411; Cunningham, Plagues and Pleasures of Life in Bengal, 1907, 102.]

Wood.

Tooth-brushes.

Bastard Cedar.

M. Azedarach, Linn.; Rec. Bot. Surv. Ind., 1894, i., 70, 148, 195; ii., 52; iii., 186. The Persian Lilac of Indian writers, Bastard Cedar or Bead Tree, drek, bakán, deskna, hórde ním, thamaga, chēin, mahā-limbo, malai, vembu, bhēu, tamā-ka, etc. A deciduous tree doubtfully indigenous in the Sub-Himalayan tract.
SUPPLY OF MICA

though commonly met with up to 6,000 feet in altitude, and frequently cultivated in India and Burma.

Like the nîm, this species also yields a brown adhesive Gum and the seeds afford a fixed oil; but these are not important. It has long been used in medicine by the Arabs and Persians, but the Hindus seem to have neglected it in favour of nîm. The stone from the fruit is employed all over India as a bead, being perforated and strung into necklaces, rosaries, etc., and is supposed to act as a charm against disease. According to most writers, the wood is liable to warp and split, but Gamble states that the samples used at the Imperial Forest School for Museum cases and furniture behaved well. It is handsomely marked and takes an excellent polish. [Cf. Taeleef Shereef, l.c. 30, 162; Paulus Aegineta (Adams, Comment.), 1847, iii., 449-50; Bentham, Rev. of Turgioni-Tozzetti, Journ. Hort. Soc., 1855, ix., 177; Moodeen Sheriff, l.c. 99-100; Banerjoi, l.c. 185, 195; Woodrow, l.c. 233; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 635; Der Tropenpflanzer, Oct. 1904, No. 10, 578-80.]

M. composita, will; M. dubia, Hiern (non Cav.), in Fl. Br. Ind., i., 545.
The eesir, kadâ-khajur, limbarra, dingurlong, mallay venu, bênu, etc. A large deciduous tree of the Siikim Himalaya, up to 6,000 feet; Khasia hills; hills of Western Ghats in South India and west coast forests from the Konkan south. Gamble states that the wood will probably be found useful for tea-boxes and similar purposes, and that it should be cultivated on account of its rapid growth. In Ceylon, the outriggers of native boats are made of it.

MICA; Ball, Man. Econ. Geol. Ind., iii., 524; Holland, Mica Deposits Ind., in Mem. Geol. Surv. Ind., 1902, xxxiv., pt. 2; Phosphatic Mica-Peridotites in Lower Gondwana Rocks, Beng., in Rec. Geol. Surv. Ind., 1894, xxvii., pt. 4, 129-46; also Rev. Min. Prod., in Rec. Geol. Surv. Ind., 1905, xxxii., pt. 1, 14, 63-9; 1907, xxxvi., 76. The group of minerals known collectively under the name Mica have several characteristics in common, which vary with the combining ratios of the bases and the silica of which they are composed. The light-coloured micas generally belong to the kind known as muscovite, the black to biotite; other varieties are lepidolite and lepidomelane. It has the following vernacular names:—abrâk, appracam, kokâbdarz, vairâbhra (black mica), etc.

Sources.—Though mica is one of the most widely distributed minerals in India, its occurrence in plates of sufficient size to be of commercial value is limited to a few tracts. Holland (Mem. Geol., l.c.) gives a full account of the geographical distribution of the known mica-bearing areas of India. The most important localities occur in the provinces of Bengal, Madras, Bombay and Burma, but in another publication (Rev. Min. Prod., l.c.) he states that Bengal and Madras are the only provinces in which the mica-mining industry can be viewed as established and important. In the official returns, Financial and Commercial Statistica, published by the Government of India, particulars are given of factories or works that employ 25 persons or over. Under "Mica Mines" (on that standard) there were in 1901, 17 mines employing 6,668 persons; in 1902, 16 mines employing 7,242 persons; in 1903, 18 mines, employing 6,276 persons; and in 1904, 45 mines, employing 6,559 persons. Including all grades of mica mines, there were 9,165 persons employed on the average during the three years ending 1903, of which 6,694 were in Bengal and 2,471 in Madras. In 1905, 15,244, and in 1906, 15,723 daily workers were recorded at the mica mines.

Outturn.—As regards the outturn, Holland observes that the published returns grossly understate both the quantity and value, since they are below the figures usually quoted for the exports. "As the only mica on which royalty is charged is that raised on Government land, and as many mica miners have mines in both Zemindari and Government land, there are obvious reasons for understating the production; and, besides this fact, the flourishing industry of stealing mica diminishes the returns for production without affecting the export figures. A considerable quantity of mica of the poorer grades is consumed in the country for ornamental and decorative purposes, and a small quantity of the larger sheets is used for painting pictures on, in various parts of the country. As far as the figures for quantity are concerned, therefore, the exports cannot be accepted as

781
an approximate expression of the production; but as regards value, the export returns may be accepted as a closer approach to the figures which should express production."

Uses.—The uses of mica depend on its peculiar combination of qualities, viz. its highly perfect cleavage; its transparency to light; together with a comparative opacity to radiant heat-rays; its low power of conducting electricity; its chemical stability; the great flexibility of its folia, combined with a high elastic limit and consequent power to resist violent shocks or sudden changes of temperature. It may be substituted for glass in lanterns, doors of furnaces, windows, as a glazing material for pictures, for backing of mirrors, etc. By far the largest quantity of sheet mica, however, is used for electrical purposes, for covering portions of dynamos and other electrical machines. For similar uses, thin films have lately been used for making the so-called Micanite, in which films of mica are made to adhere to one another by a highly insulating cement. According to Holland, the invention of micanite has created a new opening for the use of the smaller grades of mica, formerly rejected as waste. In India itself mica is chiefly employed for decorative and ornamental purposes, e.g. in ornamenting temples, palaces, and many of the banners, robes, etc., employed in ceremonies. In fine fragments or as powder it is also used for ornamenting pottery and fancy cloths, especially the Afridi wax-cloth (see Carthamus, p. 282). Finally, it is used to a considerable extent in Native medicine, and even more naturally and successfully as a manure.

Trade.—For the years 1897–8 to 1902–3, it is stated that the mica exports averaged 19,173 cwt. with an annual value of £77,013, or £4 05 per cwt. A table is furnished by Holland that shows the relative contributions of the mica-exporting provinces. The two chief, Bengal and Madras, during the years under review (1897–1903) contributed to the average total as follows:—Bengal, 12,282 cwt., valued at £53,272; Madras, 6,872 cwt., valued at £25,641. Of these exports to the United Kingdom took the largest share, amounting on the average to 14,843 cwt., valued at £56,799, or 77.4 per cent. of the total quantity and 73.2 per cent. of the total value. Much of this, however, is sold in the United Kingdom for transmission to the Continent and America. The United States come next, 15.5 per cent. of the average total quantity and 29.1 per cent. of the total value. The mica sent to America, it is stated, brought a higher price, as only the better qualities could face the heavy import duty imposed by the Dingley Tariff in 1897. Turning to the annual statement of the Trade and Navigation of British India with foreign countries for the year ending March 1907, we learn that the following were the actual exports from India during the past five years:—1901–2, 16,298 cwt., valued at Rs. 10,50,511; 1902–3, 20,412 cwt., valued at Rs. 13,13,909; 1903–4, 21,548 cwt., valued at Rs. 12,94,453; 1904–5, 19,575 cwt., valued at Rs. 12,68,986; 1905–6, 31,554 cwt., valued at Rs. 23,94,413; and 1906–7, 51,426 cwt., valued at Rs. 38,24,988.

THE ÁL OR ÁCH DYE

The young roots (more especially the root-bark) yield a good yellow Dye, which is used fairly extensively by the Natives of Eastern Bengal and Darjeeling, also by those in Assam, and to a small extent in Burmah. In Darjeeling and the Garo hills, McCann writes that the dye is prepared by pounding the bark of the root and boiling it in water, then straining and boiling over again till the required consistency is obtained. In dyeing cotton yarn or cloth, certain ingredients that act as mordants or acids to brighten the colour are used along with the morinda extract, or other dyes are employed along with it, to produce brilliant reds. Duncan (Dyes and Dyeing in Assam, 1896, 35) gives full particulars of the system of dyeing with Morinda angustifolia that prevails in Assam. Chips of the bark of *M. terebinthina* (Hareanae sapulata) and the leaves of the *lodh* (Synaptochloa spinata, p. 1033), by most writers said to be the chief mordants employed. [Cf. Mason, Burmah and Its People (ed. Theobald), 1883, ii., 422.]

*M. citrifolia*, tinn.: *M. tinctoria*, Rozb.; Watt, Agri. Ledg., 1895, No. 9, 2 plates. A plant often called the Indian "Mulberry," or Togari Wood of Madras; al, ách, bārtundī, surangi, nīna, nīna, sīra, maddi, nyāh-yī, etc. A small tree or large bush formerly widely cultivated throughout India; but within the past few years the industry has been entirely ruined and the cultivation practically abandoned.

Cultivation.—The cultivation of Morinda has been discontinued, or nearly so, since the introduction of aniline dyes. In many districts where it was formerly a profitable industry, as in the Central Provinces and Berar, it has for several years been practically discontinued. A full account of the methods of cultivation and position of the industry is given in the Agricultural Ledger (Lc. 137–9). It is there stated that the crop was formerly very profitable. One of the most striking features was the circumstance that from a perennial tree, which may attain a height of 30 to 50 feet, a biennial field-crop had been produced that rarely exceeded a height of 2 feet, though it flowered and fruitied freely.

The soil was prepared as for other crops. It was ploughed three times, cleared of weeds, and sown in June. The seed was procured from previous field-crops and put through a process of special preparation. This was the choti-al, and was the crop exclusively grown in certain localities, such as the Anjangaon neighbourhood. In other villages a crop known as moti-al was also grown, the seed for which was obtained from trees which grew near by, and not from the previous field-stock. The fruits were collected, piled in a heap till they turned black and the pulp softened. This was accomplished in three or four days. After separating the seeds by breaking the fruit on stones or by the mogra (mallet), the seeds were piled together for fifteen days. To remove the remainder of the pulp the seeds were placed in baskets and sunk in the river and finally spread out to dry. About 40 lb. were drill-sown to the acre. The moti-al often flowered and fruitied the first year, and would continue to do so during the second or even third. At the village of Anjangaon, the choti-al crop was usually gathered in the third year and dug up somewhere in November to January. Sandy soils were best suited, black soils being too hard for the roots to penetrate. The Anjangaon cultivators considered the three-year-old crop to be the best. After the roots were dug up and separated from the stems, they were cut into small pieces, spread out to dry, and in eight to twelve days were ready for market. The al crop was followed by cotton, which in its turn was followed again by al.

Dye.—A full account of the Native methods of utilising the dye is given in the Dictionary. The reader should also consult the Agricultural Ledger (Lc. 141–4), where it will be found an account of the process in Gondal, Kathiawar, has been contributed by Mr. M. J. Bharwada. A widespread opinion prevails among Natives that textiles dyed with al are protected against the depredations of white ants; and if this were so, it would be a powerful argument in favour of its extended use, instead of its discontinuance, but the matter has never been scientifically confirmed. Some years ago the dye was thoroughly investigated by Prof. Hummel and Mr. Perkin of the Yorkshire College, Leeds. They found that the root does not dye in its original condition, but that either the glucosides must first be hydrolysed or that certain acid substances must be removed. The former is effected by boiling with acids or alkalis, or by fermentation. The process of removing the acids consists in washing the powdered root three times, two hours each time, with water. The last steeping may occupy twenty hours. The dye-bath is then charged with the root, 1 per cent. of soda carbonate, and 1.5 per cent. of carbonyl chloride. The temperature is gradually raised to the boiling-point and the colours cleared with boiling soap solution. [Cf. Forster, Pl. Esc., 1786, 41; Rumphius, Herb. Amb., 1743, iii., 159; Hunter, Morinda and Its

783
HORSE-RADISH TREE

**MORUS, Linn.; Fl. Br. Ind., v., 491-3;** Gamble, Man. Ind. Timbs., 1902, 634-6; Talbot, List Trees, etc., 1902, 524; Prain, Beng. Plants, 1903, ii., 967-8; Brandis, Ind. Trees, 1906, 612; Urbicaneæ. A genus of trees or shrubs. Three species are said to be natives of India, of which the best known is *M. indica*. The economic information regarding each species cannot be accurately separated, as all possess very similar properties.

**M. alba, Linn.;** the White Mulberry, tát, túl, chinmì, satùr, uppùn nûe, etc. A small deciduous tree indigenous in Northern and Western Asia; cultivated in Northern India and Trans-Indus country up to 11,000 feet. It is the chief mulberry used for silk-production in the Pánjáb and Kashmir. The fruit is edible, and there are many varieties according to locality. It flowers in February and the fruit ripens in May and June. The wood weighs from 38 to 56 lb. per cubic foot (Gamble), and is employed for building, in making boats, furniture and agricultural implements. [Cf. Bentham, Rev. of Targioni-Tozzetti, in Journ. Hort. Soc., 1855, ix., 170-1; Dodge, Useful Fibre Plants of the World, 1897, 243; Hosie, Rept. on Prod. of Ssu'ch'wan, China, 1904, No. 5, 17, 50, 55.]

**D.E.P., v., 278-94. Mulberry.**

**Javan Red Dye.**

**Gum.**

**Ben Oil.**

**Perfumery.**

**Pot-herb.**

**D.E.P., v., 278-94. Horse-radish.**

**MORUS PTERYGOSPERMA, Gaertn.; Fl. Br. Ind., ii., 45;** Talbot, List Trees, etc., 1902, 118-9; Gamble, Man. Ind. Timbs., 1902, 224-5; Duthie, Fl. Upper Gang. Plain, 1903, 192-3; Cooke, Fl. Pres. Bomb., 1903, i., 282; Moringée. The Horse-radish Tree, sajuna (or sajina), shámh, sunjna, munýgha, munga arák, saragvo, sekto, mungāgá jhāda, mūsing, murrencí, dándalon bín, etc. A tree wild in the Sub-Himalayan tracts from the Chenab to Oudh but very commonly cultivated near homesteads, especially in Bengal and Assam.

It yields a Gum which is white when it exudes but turns gradually to a mahogany colour. It belongs to the tragacanth or hog-gum series, but owing to its dark colour is of no European commercial value. From the seeds a clear, limpid, almost colourless OIl is easily extracted by pressure. Both this oil and that from *M. arferta, Juss.,* are commercially termed Ben Oil, and are highly valued as lubricants by watch-makers. The oil is, however, but seldom made in India and does not form an article of export. Owing to its power of absorbing and retaining odours, it is fairly largely employed by perfumers. The tree flowers in February and produces long, whip-like beans in March and April. Leaves, flowers, pods and even twigs are all cooked as pot-herbs. The immature pod is used in making the drum-stick curry of Europeans. The pod is also made into pickles, and the root has long been known as an efficient substitute for horse-radish. [Cf. *Paulus Equinum* (Adams, transl.), iii., 65; *The Bower Manuscript* (Hoernle, transl.), 1893-7, 84, 103, 108; Acosta, *Tract. de las Drogas*, 1578, 343; Milburn, *Or. Comm.*, 1813, ii., 499; Buchanan-Hamilton, *Stat. Acc. Dinaj.*, 1833, 158; Moodeen Sheriff, *Mat. Med. Mad.*, 1891, 141-2; Banerjei, *Agri. Cuttack*, 1893, 198; Dhargalkar, *Treat. of Jamundice with Root Bark, Ind. Pharmacol.*, Sept. 1, 1896, 37-40; Waring, *Baz. Med. Ind.*, 1897, 96-7; Dutt, *Mat. Med. Hind.*, 1900, 117-9.]
M. indica. Linn.; titi, nuni, chhota kimbu, mekrap, singok, karan, jo-kul, ambor, 
kambli-puch, hoppal-nerali, pusa, etc. A moderate-sized deciduous tree of the 
Lower Himalaya and Sub-Himalayan tract from Kashmir to Sikkim, ascending 
the hills to 7,000 feet; Shan hills of Burma at 4,000 feet; cultivated elsewhere 
in Northern India and the Nilgiris for purposes of sericulture.

In the silk districts of India proper, the mulberry is reared on what is 
called the bush system, not the tree system that prevails, for the most part, in 
Europe. It can apparently be grown on any description of high and well-drained 
land, but it is said to do better on loam than on stiff clay or on sandy soil. Deep 
cultivation is absolutely necessary, and in some parts of the country, as, for 
example, in Bogra in Eastern Bengal, where the mulberry is attempted on land 
unnaturally inundated, the method prevails of raising the land in ridges. Soil is 
dug out from the sides and thrown on the top of the ridges, the result being 
the formation of bands of land (upon which the mulberry is raised) 3 to 4 feet 
wide and 3 to 4 feet above the rice-growing intervening strips. The follow-
ing is the system pursued in the Bardwan district of Bengal, which may be 
accepted as representative of that which prevails through the chief districts 
of Indian mulberry silk-production. When the rains are over, the land is dug 
to a depth of about 18 inches, from September 15 to November 15. The field 
is then ploughed twice, levelled and well watered. Propagation takes place 
from November 15 to December 15, and is made by cuttings set in holes 18 
inches apart, each hole being 18 inches in diameter and 6 inches deep. When 
an exhausted crop is cut down, the plants are divided into pieces 9 inches long, 
the tops and all thin, dry stems being rejected. The cuttings are then tied 
into bundles. A pit is excavated near a tank, and the bundles of cuttings are 
sunk in mud at the bottom, to the depth of a few inches. They are kept in that 
condition for about a month, and watered till the buds have put forth shoots 
about 2 inches long. When this happens, they are taken out of the mud, planted 
horizontally in the fields, as above described, one to three in each hole, covered 
with earth, and watered once a week till they take root. When the plants are 
about a cubit high, the whole field is flooded, but when they are 2 to 3 cubits 
high, irrigation is necessary only once every 1½ or 2 months. In February-
March the plants are fit for leaf-plucking. After the May plucking the field 
should be hoed, and at the end of June and beginning of July weeds should be 
smothered by turning up the soil. Before the commencement of leaf-plucking 
in the second year, the field is top-dressed with pond mud, about 400 maunds 
per bigha. The plants are thus treated once every 3 years and are kept 
up for 10 or 12 years, when they are cut down to the ground. By hoeing and 
manuring, however, new plants spring from the stools, and these may be kept 
growing for a further period of 5 years, when a new field is regarded as 
necessary.

The fruit is edible, and employed in Kashmir in the distillation of spirit; 
fruit, bark and root are all medicinal. The wood is very similar to that of 
M. alba, and is used in Assam for boat oars and furniture. Stein mentions 
that he found a saddle made of mulberry-wood in ruins explored by him in Khotan, 
of the third century (see Paper p. 635). [Cf. Marco Polo, Travels (ed. Yule), i., 378; 
Buchanan-Hamilton, Stat. Acc. Dinauj., 1833, 210–4; Roxburgh, Repts. on 
Cultivation in Manuf., Cotton-wool, Raw Silk, etc., E.I.C. (ed. 1836), 66 et seq.; also

1904, 211; Butler, Mulberry Disease in Kashmir, in Agri. Journ. Ind., 1907, 
ii., pt. i., 97–8; Stein, Ancient Khotan, 1907, 130, 332.]

(Mammalia), 552–3; Cervidae. The Musk-deer, kastura, mushk, raos, 
rous, la-lawa, rib-jo, bena, mussyuck-naba, etc. 

A solitary animal, more than two being seldom found together. It frequents 
wooded slopes of often very steep. It is very active and sure-footed and pro-
gresses by a series of bounds. Is by no means shy, where it has not been much 
hunted. Is of nocturnal habit and not much larger than a greyhound. Of all 
ruminants it is reported to eat the least, and although no connection can be 
traced between the nature of the food and the production of musk, those 
reared in forest-clad mountains are better than those met with in open
rupee. Occurs on the Himalaya west to Gilgit and east to Sikkim, usually at altitudes of 8,000 to 12,000 feet, and is also met with in Tibet and Central Asia as far as Siberia. The rutting season is in January, the period of gestation about 160 days, a single young one being usually produced.

Musk is the secretion of the abdominal gland—the preputial follicle. Within is a secretion that looks like coagulated blood, has a greasy touch and a strong penetrating odour. It is only developed in the rutting season, and as sold is a brown, soft mass possessed of the well-known odour. An ounce is about the average produce of one animal. Good and pure pods fetch from Rs. 10 to Rs. 15 according to size, but they are often much adulterated with blood and other material. Musk-deer are snared or shot to secure the "musk-pods," but the flesh is said to be well-flavoured and not at all tainted, as might have been expected, with the penetrating odour of the musk. The males smell of it, but the females never do so.

There are recognised in trade three chief grades, viz., (1) the Cabardien or Russian musk; (2) Assam musk (which includes all grades of Indian musk); and (3) Tonquin or Chinese musk. The Assam and Tibetan musks do not reach Europe via Calcutta. When dried within the follicle, it bears the name of "Musk-pods"—when scraped out and sold in granular form it is called "Grain Musk." It is shipped in bags enclosed in wooden or tin-lined chests that contain about 200 pods. In the Dictionary will be found an interesting note on the Bashahr Musk, contributed by Mr. G. G. Miniken. The Himalayan Musk has been known from ancient times and Baber in 1519 refers to it, but within the past decade or so the demand for the Indian article seems to have been declining.

The following were the exports to foreign countries:—In 1899-1900, 611 oz., valued at Rs. 11,900; in 1900-1, 647 oz., valued at Rs. 18,873; in 1901-2, 309 oz., valued at Rs. 13,320; in 1902-3, 44 oz., valued at Rs. 1,500; in 1903-4, 53 oz., valued at Rs. 2,425; in 1904-5, exports nil; in 1905-6, 223 oz., valued at Rs. 11,180; and in 1906-7, 668 oz., valued at Rs. 14,500. Capital (Oct. 29, 1904) gives an instructive account of the traffic in this substance and exhibits the official statistics of imports into Bengal from Tibet and Bhutan for 16 years prior to that date. The Bhutan had preserved a mean valuation of Rs. 15,000, while the Tibetan had fluctuated from a valuation of Rs. 3,343 to Rs. 1,27,144.

"The official valuation of the Tibetan musk last year was Rs. 40 per oz. and that of Bhutan Rs. 32. The price of the Tonquin musk in England has been as high as 11s. an oz. and as low as 4s. Ten years ago the price was from 90s. to 95s. the oz. The latest quotations in the London market for genuine grain musk of good quality is 72s. 6d. to 75s. per ounce." [Cf. Marco Polo, Travels (ed. Yule), ii., 35; Baber, Memoires (Leyden and Erskine, transl.), 313; Barbosa, Coasta E. Africa and Malabar (ed. Hakl. Soc.), 186-7; Terry, Voy. E. Ind., 1655 (ed. 1777), 109; Tavernier, Travels (Ball, transl.), ii., 143-6, 256-60; Linschoten, Voy. E. Ind. (ed. Hakl. Soc.), ii., 94-5; Pyrard, Voy. E. Ind., 1601 (ed. Hakl. Soc.), ii., 338; Fryer, New Acc. E. Ind. & Pers., 212; Boyne, Fl. Sin., Z; Birdwood and Foster, E.T.O. First Letter Book, 191, 255, 281, 287, 428, etc.; Midburn, Or. Ceylon, ii., 133-4; Ann. Zool., 1829, i., 41-5, t. 7; Paulus ’egineta (Adams, Comment.), 1847, iii., 468-70; Rockhill, Mongolia and Tibet, 71; Cordemoy, Le Prod. Colon. D’Orig. Animale, 1903, 362-5; Fulton, Notes on Mammalia of Chitral, in Journ. Bomb. Nat. Hist. Soc., 1903, xiv., 760; Waddell, Lhassa and Its Mysteries, 1905, 483.]

Musk Substitutes.—The term "Musk" is in common usage applied in compound names to a number of products both of animal and vegetable character, possessed more or less of the scent of the true perfume. Amongst these may be mentioned the musk-rat (or shrew); the musk-plant (Mimitus moschatus); and the Aemotomoschus of India (Hippocus Aemotomoschus). The last mentioned is the only substitute that has so far attracted serious attention, but the experiments in its cultivation on a commercial scale cannot be regarded as having proved successful.

BANANA.
**The Species of Banana**

A genus of tree-like herbs with thick stems largely composed of the convolute leaf-sheaths. It contains some 40 species, several of which are often considered as mere cultivated varieties.

**M. sapientum**, Linn.; The Banana, *kela, kach-kula, kantali-kela, múz, vashaip, pasham, anati, arti, bâlub, vasha, ya khaing*, etc. A perennial herb, 8 to 15 feet in height, indigenous in the hills of Bihar, the Eastern Himalayas and the mountains of Assam, Manipur and Burma, ascending to 4,000 feet; cultivated throughout India and the tropics. By some writers the Plantain is considered a distinct species, and placed under the name *M. paradisiaca*, but by most authorities it is simply a cultivated variety of *M. sapientum*. According to Schumann, both should be placed under *M. paradisiaca*.

J. G. Baker, in the *Flora of British India*, gives ten different forms of this plant. The more important of these from the Indian standpoint are:

**M. Dacca**, Horan., *Prod. Monog. Scit.*, 1862, 41. Distinguished by the pale green leaves and stem, white pruinose below, the petiole having a broad red border and the fruit being pale yellow. Cameron adds that the tip and stout stalk remain of a bright green, while the fruit is still firm on the bunch when fully ripe. Cameron also suggests that this is the *Dacca* or *Dacca-Martaban*; is doubtless the *dhakkai* described by Liotard as abundant in Eastern Bengal.

**M. Champa**, Hort. Stem and mid-rib of the leaf red, fruit pale straw-coloured, about 6 inches long. Cameron makes two forms. These are the *Champa*—the finest of all the plantains, but not fit to be eaten till it can be removed from the bunch without the slightest effort: and the *Chini-Champa*, which differs only from the preceding in being much smaller (in fact, not much larger than the thumb). These two are the plantains most generally seen in Calcutta.

**M. sikkimensis**, Kurz. A wild form.

**M. paradisiaca**, Linn. Fruit large, long and firm—the field plant of India generally; is eaten only after having been cooked. This is the plantain of Cameron, while *Dacca* and *M. Champa* above, with the Bombay red fruit below, would be the Bananas of India. Under this form should be included the *kantele* and *kach-kela*, the large coarse fruits eaten by the poorer classes throughout India.

**M. corniculata** (Rumphius), Kurz, a form closely resembling *M. paradisiaca*, and its representative to a large extent in Western and Southern India.

**M. textilis**, Née (see below).

**M. arakanensis**, Ripley. In the *Flora of British India* this is simply mentioned as a fibre-yielding form, but Capt. Ripley sent to the Agri.-Horticultural Society of India (in 1857) 19 forms of Arakan plantains, each possessing special properties of its own, some having red, others pale yellow, and still others dull white fruits. The one which he specially designated *M. arakanensis* yields, he says, both a fine fruit and a useful fibre. One of these Arakan plantains—the Royal Plantain—he further observes, bears fruits 15 inches long. The most characteristic plantain of Burma much resembles the Bombay red plantain, which Cameron calls—

**M. rubra**, Firminger (non Wall.); Baker, *Ann. Bot.*, vii., 221; *ram-kela* or Red Plantain. This is a remarkably fine fruit; in flavour and buttery consistency recalls the *Dacca* plantain. The plant is unmistakable at a glance, as it has the stem and leaf-stalks and mid-ribs of a dull red colour, as also the flowers. The fruit is about 7 inches long and rather thin, is at first of a very dark red colour, but ripens into a yellowish red. Though not very common in India as a whole, it is the characteristic better-class plantain of Bombay. Hence the plantains of Calcutta and Bombay are widely different, both in appearance and flavour.
THE BANANA PLANT

History.—The name "Banana" is very seldom used by the English in India, though it is universal in the fruit-shops of England. In India all kinds are indiscriminately called plantains. But neither name would appear to be originally Indian. The plant grew in Palestine before the Crusades. Garcia de Orta, 1563 (Colli, xxil), says the word came from Guinea, and that the Arabs call "these figs" "Musa," or "Amusa," names which of course come from the Sanskrit moca. The origin of the name "Plantain" is perhaps even more obscure. In Hobson-Jobson it is said that according to Oviedo (1516), "it or rather platano appears to have been the name under which the fruit was first carried to the W. Indies." But according to Oviedo the plant was improperly so called, as it was quite another thing from the platanus described by Pliny. Early mediæval travellers generally call the fruit either "Fig of Paradise" or "Fig of India," and in the West Indies to-day the common small plantains are called figs. Ligon (Hist. Barbados, 1657, 80–2) is perhaps the first author who attempted to describe and figure the two plants, calling them by the names of banana and plantain. [Cf. Joret, Les Pl. dans L'Antiq., etc., 1904, ii., 301–2.]

Cultivation.—The plantain is cultivated very nearly throughout India, except in the extreme north-west and from sea-level up to 5,000 or 6,000 feet in altitude. In certain localities large gardens (of many acres) are planted almost exclusively with the fruit, and the produce is systematically sent to Calcutta, Bombay and other large towns. More frequently it is cultivated merely in small patches around the homesteads and for home consumption. Throughout the plains of India the plantain is extensively produced, especially along the banks of rivers, canals and tanks. Many distinct races exist and these may be grouped under two heads, those grown for their ripe and those for their half-ripe fruits; the latter being used as green vegetables. The vegetable forms are known by the general name of kach-kela and are raised on inferior lands as field crops. The fruit forms require more careful cultivation and on garden soils. Kach-kela plantains will grow on almost any soil except stiff clay and barren sand, but both field and garden varieties do best on newly raised earth, as, for example, on embankments. On laying out a garden it is customary to excavate a tank and to plant as a first crop, on the new soil spread on the surface around, a quantity of plantains.

Propagation is entirely by rooted cuttings or portions secured from old stools. These may be deposited in holes made within fields of standing dus paddy, kachu (Colocasia antiquorum), began (Solanum Melongena) or turmeric (Curcuma longa). The pits or holes are ordinarily 12 to 15 feet apart and the transplanting is usually made in the rainy season (beginning of June to end of July). The pits should be about a cubit deep and manured with cow-dung. When the secondary crop is off the field (April 15 to June 15) the ground is ploughed two or three times. The plantains begin to bear fruit one year after setting, and the ground is then usually devoted to the plantain crop alone. When a sufficient bunch of fruit has set, the pendent extremity of the inflorescence, with its remaining flowers and conspicuous bracts, should be cut away, so that all the available nourishment may go to the formation of fruit. No clump should at one time have more than three suckers at the base. Extra suckers that appear must be removed in June or July and transplanted into fresh ground. When the bunch of fruit has ripened and been cut off, the stem should be severed at the base, so as to make room for the other fruiting stems of the stool. The cost of cultivating 100 trees has been estimated at Rs. 12–12 annas, and from 300 to 600 bunches of fruit may be obtained, which fetch about Rs. 150 per acre per annum.

Of the Madras Presidency it is stated that plantains are grown chiefly
on wet lands. The land is thoroughly ploughed and the shoots planted in pits, almost any month, but more especially during the monsoons. Cameron (For. Trees Mysore and Coorg, etc., 323) suggests that planting should be made every two months so as to keep up a succession of fruiting. Irrigation is effected by flooding the soil, and after the water has soaked in for a day, the superfluous water is run off through drains. The land is then hoed once a month, and three months after planting a surface dressing is given of wild indigo and dung. Hoeing is stopped as soon as the flowers appear, but begins again after gathering the crop. The plants last three to four years.

Food and Fodder.—Plantains, after mangoes, are the commonest and most highly prized of all Indian Fruits, while the coarser kinds constitute one of the staple articles of diet in many parts of India and the Malay Peninsula, being mostly cooked before being eaten. It has been proved that the produce from one acre will support a much greater number of people than a similar area under any other crop, and the immense yield may be preserved for an indefinite period by drying the fruit and preparing meal from it. Plantain meal is made by stripping off the husk, slicing the core, drying it in the sun and then reducing it to a powder and finally sifting. It is calculated that the fresh core will give 40 per cent. of meal, and that an acre of average quality will yield over a ton. [Cf. Bhaduri, Rept. Labor. Ind. Mus. (Indust. Sec.), 1902–3, 26.]

In the Kew Bulletin of 1894 will be found a complete review of the available information regarding the production and trade in the bananas and plantains of the world. The recent demand has given the West Indies a new and profitable industry. There seems no very good reason why India should not participate in the supply of the finer bananas.

Besides the fruit, other parts of the plant are used as food. The flower-heads of many kinds are cooked, generally in curries, and the inner portion of the stem, called thor, is also edible. The shoots and tops of young plants are occasionally used as a vegetable, and are given as fodder to sheep and cattle. The outer sheaths are valued as elephant-fodder, and the root-stock is said to be given to cattle to increase the quantity of milk. [Cf. Rept. Labor. Ind. Mus., 1900–1, 24.]

Industrial Uses.—For long the Fibre of the plantain has been used by the Natives of India for cordage purposes, mats and coarse paper. It early attracted attention from the fact that it so closely resembled Manila hemp, (the product of M. textilis), though it is not so strong as the latter and can never hope to compete with it in the European markets. The special Arakan form might, however, prove a useful substitute for the true Manila hemp, and is worthy of special attention. Moreover, vast numbers of the common plantain stems are available for extraction of the fibre, and as at present these are simply thrown away, efforts have been made in recent years to encourage the extraction of the fibre as an additional source of profit. The rapidly increasing demand for cheap string to be used as "binders" should render this suggestion of interest to both the cultivators of the fruit and the cordage manufacturers. The subject of the wild species of Musa as sources of fibre has aroused some attention, and it seems possible that this idea may come to be of value, especially in some portions of Burma. The chief difficulty in the utilisation of plantain stems as sources of fibre or as paper materials is the expense of collecting and carting
THE MANILA HEMP PLANT

to the factory. Profitable results are only likely to be attained with large plantations.

In MEDICINE, the unripe fruit is considered cooling and astringent. The young leaves are used as a dressing for blisters, burns, etc. The root and stem are reputed to be tonic, antiscorbutic and useful in blood disorders and venereal disease.

M. textilis, Née; Fl. Br. Ind., vi., 263; Manila Hemp. A native of the Philippine Islands and experimentally cultivated in India for its fibre, especially in the Andaman Islands and in the Arakan hills. By the Natives of the Philippines both plant and fibre are called Aboac.

It is said that the plant thrives best on soils largely composed of decayed vegetable matter. Hilly land, about 200 to 600 feet elevation, is considered more suitable than low-lying land. The Manila hemp plantations are situated where there is a rich volcanic soil and where the climate is hot and humid with a heavy rainfall. Plantations are usually established by means of suckers put out when about 3 feet high and placed 8 to 9 feet apart. The land is cleared of weeds twice a year and the first crop is reaped at the end of the second year after planting, though a full crop is not obtained till the fourth year. The stems are ready to be treated for fibre just before the trees begin to flower, when they are cut about a foot from the ground and the leaves removed. Each stem is then stripped into its component layers (or leaf-sheaths). In other words, each leaf-sheath is usually cut lengthwise into three strips about 3 inches wide. The outer leaf-sheaths contain a coarser and stronger fibre than the inner, while the fibre from near the middle is of a fine silky texture.

In preparing the fibre, each strip is taken by hand and drawn between a blunt knife and a smooth board attached to a light frame. This process removes watery particles and pulp. The fibre is then dried in the sun and packed in bales for shipment. The chief characteristics of the fibre are its great strength and extreme lightness. Hence it is eminently suited for rope-making. The waste materials and worn-out ropes afford the much-prized Manila-paper. The importance of the Manila fibre in the commerce of the world may be judged of from the fact that in official statistics it is stated the annual production comes to close on 1,000,000 bales, which go to the United States and Great Britain in about equal proportions. In the trade returns of Great Britain, the Philippine and Ladrone Islands are shown to have supplied hemp on an average (1902–6) of over 50,000 tons, valued at fully ½ millions of pounds sterling. It is stated that Manila rules the market of white fibres and that it has ranged from £14 to £20 a ton, the average price being from £25 to £30 a ton.

THE NUTMEG TREE

**MYRISTICA**

They expression, bearing. leaves are contains to cases the climate

commence best the species, coast great consists to bushy, to nutmeg-tree of Sec), 550

Ca»/var/on.— to M. *gibbosa*. Hook, f. & T., which he describes as the Assam nutmeg. The Kernel of the fluid he speak of as resembling that of kino.

*M. canarica*, Bedd.: Talbot, *List Trees, etc.*, 165; Gamble, *Man. Ind. Timbs.*, 550; the *pindi*. This is discussed by Hooper (*Rept. Labor. Ind. Mus.* (Indust. Sec.), 1906-7, 9) under the name *pundi-kai*. The seeds are made into candles and they contain half their weight of fat, which melts at 39°C. It saponifies with great facility, yielding 92 per cent. of crystalline acids, melting at 41°C. The fat consists largely of *myristin*. In another report (i.c. 1903-4, 31) Hooper refers to the juice of *M. gibbosa*. Hook, f. & T., which he describes as the Assam nutmeg. The Kernel of the fluid he speaks of as resembling that of kino.

*M. malabarica*, Lamk.: *kōagnī, shola vengai, pathiri*. A large tree of the western coast from the Konkan southwards in evergreen forests. Like the previous species, the seed yields a yellowish oil when bruised or boiled. It is used medicinally and for illumination (Hooper, i.e., 1906-7, 9). The fruit appears to have been used for adulterating the nutmegs and mace of *M. fragrans*. The wood is moderately hard and used in building. [*Cf. Pharmacoq. Ind.,* 1893, iii., 197.]

*M. fragrans*, Hoult.: Nutmeg, and Mace; *jaiphil* (nutmeg), *jati, jatri* (mace). A bushy, evergreen tree, native of the Moluccas. Cultivated in India but not to a great extent. It has succeeded best at the Botanic Garden of Barliyar, in the Conoor Valley at the eastern side of the Nilgiri hills. The fruit yields the valuable spices "nutmeg" and "mace," the former being the hard ruminated albumen and the latter the aril (*kavanga*, see p. 313).

**Cultivation.**—According to Nicholls (*Textbook Trop. Agr.*, 1892, 178-84), the best soil for the nutmeg-tree is a deep, rich loam, with good drainage. It will not thrive on sandy soils, and stagnant water about the roots soon kills it. Theclimate must be hot and moist with an annual rainfall of 60 to 70 inches. Plants are raised from fresh seeds, sown in nursery beds, sheltered from sun and wind. They require to be watered every day in dry weather. When 2 to 3 feet high they are transplanted at distances of 25 to 30 feet apart. The young trees must be shaded and well watered, and the land constantly weeded. Should dry weather come, the ground around the stems is improved by being mulched with straw, leaves or stable litter. All parasitic or epiphytic plants on stem or branches should be at once removed. When the trees flower the sexes must be determined and about one male left to every eight or ten females. The males should be on the windward side, so that pollen may be carried to the female plants. The trees commence to bear about the seventh year, and the produce increases till about the fifteenth.

**Manufactures.**—The fruit is picked up every morning after it has fallen from the tree. From 1,500 to 2,000 nuts should be obtained from each tree in full bearing. The mace is stripped off and the nuts dried in sheds in trays raised above smouldering fires. When dry the shells are broken with mallets, and the nuts rubbed with lime to prevent attack from worms and then packed in tight cases for export. The mace, after being stripped off, is spread on mats or trays to dry, when it turns yellowish brown and becomes the mace of commerce.

**Oil.**—Nutmeg yields an essential and a fixed oil, while mace also contains a peculiar essential oil. The fixed Oil, "nutmeg butter," is obtained by expression, the powdered nuts being steamed and pressed while hot. It occurs in blocks of a yellow colour. The essential oil is obtained by distillation, and is white in colour, with the odour of nutmeg. The essential oils of both nutmeg and mace are largely used in perfumery.

THE SPIKENARD

In Medicine, nutmeg is an aromatic stimulant, carminative, and in large doses narcotic. The widespread use of both nutmeg and mace in European cookery is well known.

Trade.—As regards trade, the Exports of Indian merchandise for the six years 1901–7 were as follows:—In 1901–2, 170 lb., valued at Rs. 106; in 1902–3, 5,287 lb., valued at Rs. 2,683; in 1903–4, 2,596 lb., valued at Rs. 1,169; in 1904–5, 5,086 lb., valued at Rs. 2,580; in 1905–6, 560 lb., valued at Rs. 194; and in 1906–7, 793 lb., valued at Rs. 691.

The Imports for the same years were as follows:—In 1901–2, 589,295 lb., valued at Rs. 2,54,259; in 1902–3, 626,871 lb., valued at Rs. 2,32,225; in 1903–4, 571,118 lb., valued at Rs. 2,17,870; in 1904–5, 854,818 lb., valued at Rs. 3,10,071; in 1905–6, 671,445 lb., valued at Rs. 2,15,137; and in 1906–7, 715,018 lb., valued at Rs. 2,28,453. Almost the whole of the imports come from the Straits Settlements, viz. in 1906–7, 706,366 lb. There is, moreover, a Re-export trade, which shows the following returns:—In 1901–2, 10,130 lb., valued at Rs. 7,940; in 1902–3, 69,975 lb., valued at Rs. 44,549; in 1903–4, 16,050 lb., valued at Rs. 9,667; in 1904–5, 21,677 lb., valued at Rs. 10,026; in 1905–6, 15,217 lb., valued at Rs. 8,392; and in 1906–7, 21,287 lb., valued at Rs. 10,542. The United Kingdom receives the largest share of the re-exports, while British East Africa, Aden, Turkey-in-Asia, and in some years France and Egypt, also take considerable quantities.

[D.E.P., v. 388-41.]

NARDOSTACHYS JATAMANSI, DC.; Fl. Br. Ind., iii., 211; Valerianaceæ. Spikenard, jatamansi, bâlu-char, bekh-kurphus, haswa, pamep, mäsi, bhutt-jatt, bala-chara, etc. A perennial herb of the alpine Himalaya, which extends eastwards from Garhwal and ascends to 17,000 feet in Sikkim.

Through the researches of Sir W. Jones (As. Res., 1790, ii., 405–7) this perfume was first identified with the spikenard of the ancients. In The Bower Manuscript (Hoenrle, transl.) numerous references are made to mamsi and naralas, which the translator regards as the present plant. The manuscript in question dates from the 8th century and was found at Kucha in Khotan. García de Orta (Coll., I.) gives an account of the spikenard, but as he speaks of it as procured from Mandu, Chitor and parts of Bengal bordering the Ganges, it seems likely that he confused Cymbopogon with Nardostachys. The drug consists of a portion of the rhizome, about as thick as the little finger, surmounted by a bundle of reddish-brown fibres, the remains of the radical leaves. It is aromatic and bitter, and yields on distillation an essential oil. In India it is largely used as an aromatic adjunct in the preparation of medicinal oils, and is popularly believed to increase the growth and blackness of the hair. [Cf. Pliny, Nat. Hist., bk. xii, ch. xiii. (Holland, transl.), 364; Paulus Aegina (Adams transl.), iii., 264; Amatus, Comment. on Dioscorides, 1558, 12–5; Acosta, Tract. de las Drogas, 1578, 173–81; Celsius, Hierobot., 1747, ii., 1–11; Roxburgh, As. Res., 1795, iv., 433–6; Lambert, Genus Cinchona, etc., 1821, 177–80; Tallef Sgeois (Playfair, transl.), 1833, 67; Pharmac. Ind., 1891, ii., 233–8; Dutt, Mat. Med. Hind., 1900, 180–1.]

N
THE LITCHI FRUIT

The tree grows well in all parts of India, but in the north-west is apt to be killed by cold. It prefers a damp climate and abundance of water. The finest quality of fruit has hitherto been produced in Bengal and Assam, more especially the latter province, but fine fruit is also obtainable in Lucknow and in Saharanpur. It may be propagated by seed, but the surest way to obtain good fruit is to propagate by gītā, about the end of May. For this method of propagation the reader should consult an article by Masters (Agri.-Hort. Soc. Trans., 1839, iii., 2; vi., 18) quoted by Firminger (l.c. 99). The gūtā made in May will be ready for removing and potting off by the commencement of the cold weather, and may be planted out in the following rainy season. The fruit is nearly round, about an inch and a half in diameter. The edible portion is the semi-transparent pulp or aril which covers the seed. The Chinese dry the fruit, which thus becomes blackish, and in this state it may be seen in London fruit shops, but it is incomparable with the fresh fruit. [Cf. Boyen, Fl. Sin., 1656, D.; Sonnerat, Voy. aux Indes, 1782, iii., 255–8; Breitschneider, Hist. Europ. Bot. Disc. in China (quoting Mendoza, 1585), 1898, 11 and (quoting Trigault, 1615) 10–1; Woodrow, Gard. in Ind., 1903, 238; Firminger, Man. Gard. Ind. (ed. Cameron), 1904, 265.]

NICOTIANA, Linn.; Lobel, Hist. Stirp., 1576, 316; Everart, De Herba Panacea, 1587; Casper Bauhin, Pinax, Theat. Bot., 1623, 169; Parkinson, Parad., 1629, 363–4; Gerarde, Herb., 1636, 357–61; Simon Paulli, Comment. de Abusu Tabaci, etc., 1665; Tourn., Inst. rei Herb., 1719, i., 117; Miller, Gard. Dict., 1st ed., 1731; Tiedemann, Gesch. des Tabak, etc., 1854; Koning, Der Tabak, etc., 1900; Comes, Monog. du genre Nicotiana, 1899; also Della Razze dei Tabacchi, etc., 1905; Prain, Beng. Plants, ii., 751–2; Cooke, Fl. Pres. Bomb., ii., 276; Kissling, Handbuch der Tabak, etc., 1906; Anastasia, Le Varità Tipiche della Nicotiana Tabacum, 1906; SOLANACEÆ.

Prof. Comes of Naples has described some 41 species of Nicotiana. The majority are natives of the New World, though a few are met with in the Philippine Islands, Australia and New Caledonia, etc. Only two, or perhaps three, can be regarded as affording the commercial products TOBACCO and SNUFF, but under each of these Comes has assorted numerous varieties and races, some of which possess special properties, and would seem to constitute the trade qualities famed throughout the world. The following are some of the chief forms, and the countries with which these are mainly associated:—

N. Tabacum, Linn.; Fl. Br. Ind., iv., 245; Comes, Monog., l.c. 7–19; also Della Razze, etc., 1–222; Sadoveck, Kulturgew. der Deut. Kolon., 1899, 206; Wiesner, Die Rohst. des Pflanzenr., 1903, 613. A native of tropical America, which Comes views as embracing some six varieties as follows:—

<table>
<thead>
<tr>
<th>Varietal Name</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Var. fruticosa</td>
<td>Narrow-leaved shrubby Tobacco. A native of Mexico and Brazil. Appears to be the plant described by some of the older authors—e.g. the herba sancta minor of Lobel, and the Nicotiana minor angustifolium of Bauhin. According to Comes, the following are some of the races of this plant—Carabobo, China, Nepal, Doniaiku, Singapore and the South Indian.</td>
</tr>
</tbody>

NICOTIANA TABACUM

Species and Varieties.

Kashmir.
Habitat, 1906, N. A. Extensively comes, Virginian Nicotiana, or Virginia Broad-leaf, Yellow Orinoco, Blue Pryor, Yellow Mammoth Golden-leaf, etc.

Brazilian.

V. brasiliensis, Comes, L. c. tt. i., vii.; also Della Razze, etc., 79–119; Anastasia, L. c. 101–5. This is the Broad-leaved Tobacco, known in Brazil by the name petum or petun. A native of Brazil, Guinea, Venezuela and Bolivia. According to Comes was introduced into France by Thevet in 1556, and thence to Europe generally. Is the stock from which the so-called indigenous tobacco of Europe has been derived, and is valued on account of the thickness of the leaf rendering it suitable for the manufacture of snuff. The following special races may be mentioned:—Brazil, Bahia, Paraguay, Pernambuco, Florida, Maryland, Ohio, etc.

Var. havanaensis, Comes, L. c. tt. i., viii.; also Della Razze, etc., 153–97; Anastasia, L. c. 97–105. Indigenous to the valleys of Mexico. It was conveyed thence by the Spaniards to the island of Cuba, is the plant most highly valued as Havana tobacco, and known by many trade names such as Havana Seed-leaf, Cuban Seed-leaf, etc. This plant is accordingly most largely selected for the improvement of other stocks, and it would appear to be the chief source of the so-called Java and Sumatra tobaccos. The following are some of the chief races mentioned by Comes:—Seed-leaf, Connecticut, Pennsylvania, Ohio, Maryland, Wilson's Hybrid, Zimmer's Spanish, Mexican, Manilla, Deli-Tabak, etc. [Of Shamel, Imp. Tob., by Breeding and Selection, etc., in U. S. Yearbook, 1904, 435–52; 1906, 387–404.]

Var. macrophylla, Schrank: Comes, L. c. tt. i., viii.; also Della Razze, etc., 199–22; N. Tabacum, var. purpurea, Anastasia, L. c. 1906, 43–96. A native of Mexico and introduced into may countries—India, Persia, Egypt, Porto Rico, Peru, etc. This appears to yield much of the Maryland tobaccos of commerce. The flowers are usually of a deep purple colour and the leaves exceptionally large. The following are some of the special races mentioned by Comes:—Cuban, Varinas, Venezuela, Makala, Salomiki, Argos, etc.

N. rustica, Linn.; Heuzé, Les Pl. Indust., 1895, iv., 19; Sadebeck, Lc. 220; Wiesner, l.c. 614. This is the Nicotiana minor of some of the older authors, and is at once distinguished by its being a smaller plant with almost orbicular-stalked, leathery leaves and pale-greenish white flowers, with the limb of corolla imperfectly developed. It is commonly known as Turkish or East Indian Tobacco. Comes regards it as a native of Mexico and Texas. In the former it is known as piceti or pyeciell, and he is of opinion that this was the plant introduced into France by Jean Nicot (after whom the genus was subsequently named). It was cultivated in America before the arrival of Columbus. Comes places under it the following varieties:—

Var. texana, Comes, L. c. tt. ii., ix. A native of Mexico and the plant seen by Nicot under cultivation in Portugal in 1560, the seed of which was sent to Queen Catherine of Medicis.

Var. jamaicensis, Comes, L. c. tt. ii., x. A form met with under cultivation in Jamaica, Guatemala and Mexico, but doubtfully distinct from the preceding.

Var. brasilia, Schrank.; Comes, L. c. tt. i., xi. Habitat, Brazil. This is the tobacco which the Brazilians call fumo-crespo. It is often used in the manufacture of snuff.

Var. asiatica, Schrank.; Comes, L. c. tt. ii., xii. This is the so-called Syrian tobacco, but is also grown in Arabia, Persia and Abyssinia. It came, however, from America and is sometimes designated as the common or English tobacco, and when made into snuff is held to be superior to most other grades, though in many trade samples it has been flavoured with aromatic herbs.

Var. humilis, Schrank.; Comes, L. c. tt. ii., xiii. Extensively cultivated for the manufacture of snuff, and in Germany is regarded as superior to the product of var. brasilia.
COMMERCIAL CLASSIFICATION

**Var. scabra**, *Comes*, l.c. tt. ii., xiv. A native of South America. Hardly ever used commercially because of its disagreeable odour.

**N. alata**, Lk. et O.; *N. persica*, Lindl., Bot. Reg., 1833, xix., t. 1592; Riach, *Sheeas Tobacco*, Trans. Hort. Soc., 1835, i., 205-7. A native of Brazil and cultivated in gardens in Europe, Persia, etc. At one time it was thought that this plant was the source of the *tumbeki* of Persia. In the *Kew Bulletin* (1891, 77-84) full particulars will be found, the final conclusion of which appears to be that the merits of the *tumbeki* leaf, like that of most other special tobaccoes, proceed from the climate and soil, together with the methods of cultivation and curing, more than from specific differences. Comes seems, however, to think that *N. alata* is the source of the Persian leaf, while the numerous writers quoted in the *Kew Bulletin* regard it as derived from the ordinary *N. Tabacum*.

**N. plumbaginifolia**, *Viv.*; *Fl. Br. Ind.*, iv., 246; *Comes*, l.c. 45. This is believed to be a native of Mexico and the West Indies. In India it has become completely naturalised, especially on sandy islands within the rivers and in damp situations by the roadsides. It does not appear to be put to any economic purpose. It is not mentioned in Roxburgh's *Flora Indica*, consequently its introduction may date subsequent to 1832.

To conclude this brief statement of the species, varieties and races of tobacco, it may be pointed out that Shamel and Cobey (*Varieties of Tob.*, 1905-6, U.S. Dept. Agri., *Bureau Pl. Indust.*, No. 91) give the following classification according to uses:

1. *Cigar-wrapper Tobaccoes*—Sumatra, Connecticut, Havana and Connecticut Broad-leaf, etc.
2. *Cigar-filler Tobaccoes*—Cuban, Zimmer's Spanish, Little Dutch, etc.
3. *Pipe Tobaccoes*—North Carolina, Bright Yellow, Maryland Smoking, etc.
4. *Plug Tobaccoes*—White Burley, Orinoco, Yellow Mammoth, Virginia Blue Pryor, White Stem, etc.

Tobacco breeding, Shamel and Cobey have shown (*U.S. Dept. Agri., Bureau Pl. Indust.,* 1907, No. 96) is of necessity a subject of the greatest possible interest and value.

**History.**—The practice of tobacco-smoking was unknown in Europe and Asia prior to the discovery of America in 1492. It has since been ascertained that the knowledge of the properties of tobacco was very ancient and widespread in the American Continent and Islands. Some difference of opinion prevails as to the locality where tobacco-smoking was first witnessed by Columbus and his associates. By some authorities Cuba is mentioned, by others San Salvador. The plant and the habit of smoking were found by Cortes in the very heart of Mexico. The Spaniards witnessed tobacco-chewing in 1502 on the coast of South America. Monardes published, in 1517, an account of tobacco in which he says that it was known to the Indians (American) by the name *picietl*. In 1518 Fernando Cortez occupied the island of Tobago, and found the plant being there cultivated. About the same time the prepared leaves were brought by Oviedo from San Domingo to Spain. In 1531 the Spaniards commenced the cultivation of tobacco in San Domingo, employing for the purpose African slave labour. Oviedo described a smoking-pipe (*Hist. Gen. de las Indias*, 1535). In 1539 Hernandez brought seed to Europe. Jean Nicot, French Ambassador, saw the plant cultivated in Portugal, and in 1560 sent seed of it to Catherine of Medicis, from which circumstance the genus obtained its botanical name. In the same year tobacco was conveyed to England by Thomas Hariot; Sir Francis Drake and, subsequently (1570-84), Sir Walter Raleigh and others made tobacco-smoking popular in England, and about the same time cultivation was started in Virginia. In 1596 Ben Jonson, in his *Every Man in his Humour*, represented the arguments for and against tobacco.
Babar (Conqueror and Emperor of India) wrote his Memoirs with special reference to 1519-25, and while describing all the useful and interesting animals and plants found by him in India, makes no mention of tobacco. So also a little later (1563) Garcia de Orta published in Goa his historic work on the drugs of India, but makes no mention of tobacco. The first direct reference to it, in connection with India, centres around certain Portuguese missionaries at the Court of the Great Mughal. Doubtless to the Portuguese is due the credit of having conveyed both the plant and the knowledge of its properties to India and China. It is said in the Daro-shikoh that they had conveyed it to the Deccan as early as 1508. Asad Beg, of date 1605 (Elliot, Hist. Ind., 1875, vi., 165-7), says of Bijapur that he found some tobacco and, "never having seen the like in India I brought some with me and prepared a handsome pipe of jewer work." These he presented to the Emperor Akbar, who attempted to smoke, until he was forbidden by his physician. It would thus seem to have been known in the Deccan for nearly a century before it was carried to the rest of India. On the other hand, Comes affirms that the seed cultivated in India in 1605 had been brought from Brazil. In 1610 tobacco was grown in Ceylon, and in that same year it was introduced into Turkey (George Sandys, Journey, 66). In 1614 Floris produced a sketch of a Hindu woman of Masulipatam smoking tobacco. By 1617 smoking had, in fact, become so general in India that the Emperor Jahangir forbade the practice, as also had Shah Abbas of Persia (Elliot, l.c. v., 851). Foster, in his work The English Factories in India (1906, 64, 92, 109), quotes various letters and invoices of date 1619 which speak of tobacco being sent from India to Red Sea ports. Mandelson (Travels, 1638, in Olearium, Hist. Moscovy, etc., 1662, 74) speaks of the Parsis of Gujarat living peaceably and "sustaining themselves out of the advantage they make of the tobacco-plant and the terry they get out of the palms." Cultivation in Gujarat in 1635 is spoken of as successful. In 1645 the plant was introduced to Golconda. Edward Terry, of the Court of the East India, 1655-66, speaking of Surat, says that "the tobacco which grows there is doubtless in the plant as good as in any other place of the world but they know not how to cure and order it, like those in the West Indies," Fryer (New Acc. E. Ind. and Pers., 1672-81, 223, etc.) says, "The Persians smoke tobacco in their most solemn assemblies, and for this purpose are provided with spitting-pots or pigrdans." Tavernier (Travels in Ind. (ed. Ball), 1676, ii., 23) tells us that he found tobacco grown abundantly at Burhanpur, and adds, "In certain years I have known the people to neglect saving it because they had too much, and they allowed half the crop to decay." Ovington (Voy. to Suratt, 1689, 428) speaks of the people of Muscat abhorring tobacco and burning all that is brought to their city. Strachan (in Phil. Trans., 1702, xxiii., 1134, (abrid. ed.) iv., 667), gives an account of the cultivation and manufacture of tobacco in Ceylon. He speaks of two forms, one much stronger than the other. The Bahar-i-Ajam, 1760 (Blocke, in Hist. Ind., 1641), speaks of the tobacco being carried to the Dakhim and thence to Upper India during the reign of Akbar Shah a fact already indicated. Col. Kyd (in his letter in 1786 to the Court of Directors, proposing the formation of the Botanic Gardens, Calcutta) mentioned the improvement of tobacco as one of the subjects that might engage attention. Macpherson (Hist. Europ. Comm. with Ind., 1812) makes only a passing allusion to the tobacco trade of India with France, and Milburn (Or. Comm., 1813) does not even mention the name of the "weed." It is thus a fact beyond dispute that tobacco, less than a hundred years ago, was an article of comparative unimportance in India, whereas to-day its use is all but universal—men, women, and even children smoke—and, moreover, the export traffic has become of the greatest importance to the country. The Sikhs, Wahabis and certain Hindus are, however, prohibited the use of tobacco, though allowed indulgence in hemp and opium to any extent. As in other parts of the world, so in India, tobacco passed through a period of persecution, but its ultimate complete distribution over the whole is one of the numerous examples of the avidity with which advantageous new crops or new appliances have been absorbed into the agriculture and social customs and even literature of the people of India.

It is a matter of every-day knowledge that King James I. issued his famous "Counterblaste" in 1603, and raised the tax to 6s. 10d. on the pound. King Charles, in 1630, prohibited the cultivation in England and Ireland, where it seems, according to Macpherson, great quantities were still raised. In 1633 the King issued a proclamation to regulate the vendors of tobacco in cities and towns. Pope Urban VIII. prohibited smoking in church. By an Act of 1663 cultivation

796
in England was again prohibited, and in 1670 Charles II. passed a further Act, by which imports intended for Ireland had, in the first instance, to be conveyed to England. In 1709 the net consumption of tobacco in England came to 11,260,659 lb. In 1731 Virginia and Maryland were regarded as most valuable acquisitions to Britain because, among other considerations, of the tobacco they produced. An interesting account of the cultivation of tobacco in Virginia in 1776 is given by Mr. Thomas Glover in a paper delivered to the Royal Society (Phil. Trans., June 20, 1676, xi., 623, (abrid. ed.) ii., 301—reprinted, Oxford, 1904). By a special Act of George III. (1780) tobacco cultivation in Ireland was allowed, but not in England nor Scotland; and, lastly, in 1830 William IV. prohibited the Irish cultivation.

Prior to the separation of the United States, the British supply of tobacco came almost entirely from Virginia. During the reign of Queen Anne the annual revenue from tobacco was only about £250,000. In 1903 the net imports (that is to say, imports less exports) were valued at £3,136,228, or a total weight of 75,915,759 lb., and the traffic gave a revenue of over 12½ million pounds sterling.

**CULTIVATION.**

**Area.**—The crop occupied in 1905-6, 1,018,506 acres in British districts and 24,284 acres in the Native States for which returns are available. But since several important States furnish no returns, it may be accepted as a safe estimate to put the total tobacco area of India at 1,100,000 acres. It would, moreover, seem fairly certain that it has not expanded materially during the past ten years. Of the total, Bengal (including Eastern Bengal and Assam), has fully one-half; Madras a little over 130,000 acres; Burma, Bombay, the United Provinces and the Panjáb have each about 60,000 acres.

As a rule there are three distinct persons concerned in the tobacco trade. In Rangpur (of Bengal) the cultivators sell the leaf on the field to up-country traders and curers—dalals, as they are called—who own large curing-sheds, at certain convenient intervals, through the chief tobacco-producing localities. The curers next sell it to Burmese dealers, who come and supervise the leaf as it is being cured; they then pack and dispatch it themselves. These three classes are fairly general throughout Bengal, the chief tobacco-growing province of India. Tobacco with the Natives of India is either used up in the crude form or is worked into a paste with several ingredients (to be detailed later on), and in that form smoked. The more elaborate curing of higher-grade leaf is pursued over a comparatively limited area, and to meet the demands of the European rather than the Native population. Bengal, the chief growing province, takes practically no share in the higher-grade manufacture. The crudely manufactured leaf (in trade returned as "unmanufactured tobacco") is exported to Burma or to foreign countries, and in these is worked up into special grades of smoking-tobacco, cigars, etc. In South India (and within comparatively recent years) a new trade has arisen in the manufacture of cigars for the European consumer, both within India and throughout the East generally. Indian cigars have, moreover, found their way to Europe, and the traffic in them is yearly increasing. In the whole of India there are nominally, say, 25 curing farms and factories that give employment to 2,150 persons, but this must be regarded as over and above the large number of persons already indicated as concerned in the cultivation and crude manufacture of the Native article.

**Bengal, Eastern Bengal and Assam.**—Tobacco is grown for local consumption in almost every district, more especially in Rangpur, Jalpaiguri, Kuch Bihār, Darbhanga, Purnea, the 24-Parganas, Nadia, Bengal, Eastern Bengal and Assam.
THE TOBACCO PLANT

Chittagong, Sylhet and Kamrup, etc. In some of these districts it is, moreover, largely grown for trade and export. In 1905-6 the total area under tobacco in the two provinces of Bengal was 535,525 acres, more than half that of all India, and in Assam 4,911 acres. The districts of Rangpur and Jalpaiguri and the Native State of Kuch Bihar contain the largest areas. In 1904-5 the area in Rangpur was 181,100 acres and in Jalpaiguri 119,300 acres. Two species, \textit{N. Tabacum} and \textit{N. rustica}, are grown. The former is generally called \textit{desi}, and the latter \textit{vilayati} (foreign). \textit{Vilayati} is largely cultivated in Purneah and neighbourhood. So little attention has been paid by writers on this subject that it is said no cultivated races of \textit{vilayati} are known, but that the \textit{desi} has many such, the most important of which is known as \textit{hingli}, produced in parts of Nadia and Jessore.

One of the most striking features of Rangpur is the extent of tobacco cultivation (\textit{Agri. Ledq.}, 1898, No. 15, 503). Both \textit{N. Tabacum} and \textit{N. rustica} are grown, wherever the soil is a rich, sandy loam with water only a few feet below the surface. Shallow wells are dug all over the tobacco-fields, and during certain stages in growth hand irrigation is daily pursued. The water is thrown from the wells so as not merely to supply moisture to the roots but to wash the dust off the leaves. The agricultural system pursued is of a very high order, and it is not to be wondered at that tobacco should prove so valuable and remunerative a crop, in a country pre-eminently the tobacco area of India. The railway to Jatrapur cuts the district practically in two. In the one half, the northern, with its rich sandy loam, \textit{N. Tabacum} is cultivated; and in the other, the southern, with its lower, damper soil, \textit{N. rustica} prevails. But wherever the red-clay soil appears, tobacco cultivation at once disappears. In Rangpur and Kuch Bihar it is no unusual occurrence to find a single leaf of \textit{N. Tabacum} measuring 3 to 4 feet in length.

The following account of cultivation has been derived mainly from Mukerji and Roy. The crop requires a good soil and heavy manuring. The best kind is a well-drained friable, sandy loam, not too rich in organic matter, but rich in mineral salts, especially those of potassium. It may be grown after jute or Indian corn, but often forms the only crop of the year. If properly manured, it can be grown three or four years on the same ground. The seeds are sown in seed-beds in August or September, and the seedlings transplanted a month later. The soil of the seed-bed is dug and manured with cow-dung and ashes until raised about 6 inches. After the soil has been well pulverised the seed is sown thin and lightly covered with earth. About half an ounce is required to produce plants for one acre.

When the seedlings are about 3 inches high they are fit for transplantation, which takes place from the end of September to the middle of November. The soil must previously be prepared by eight or ten ploughings. Deep cultivation and thorough pulverisation are important, and a liberal manure of rotted cow-dung and ashes is necessary. The seedlings are planted in the evening 3 feet apart. They must be carefully watered the first few days, and irrigation is necessary afterwards at intervals of ten to twenty days. In Rangpur and Jalpaiguri a hand-plough is repeatedly drawn along and across the fields until about the time that the flower-buds appear. Where artificial irrigation is required, regular hoeing is necessary.
Before the plants begin to flower, their buds and lower leaves should be stripped off, and they should be pruned so that only eight or ten leaves are left to each plant. To prevent bleeding, finely powdered earth is sprinkled over the broken parts immediately after pruning. When the leaves begin to turn yellow with brown spots and have a gummy feeling, they are considered mature and ready to cut. The best time for harvesting is morning, as soon as the dew is off the plants. It is better to cut whole plants than to gather the leaves singly, and they should be allowed to lie for some time in the sun before they are conveyed to the drying and fermenting house.

United Provinces.—The crop is not an important one, and its cultivation appears to have been practically stationary for some years. In 1905–6 the total area in Agra was 82,904 acres, and in Oudh 14,566 acres. The districts with the largest area are ordinarily Farukhabad, Aligarh, Balandshahr and Meerut. In no district does the area under tobacco exceed 1 per cent. of the cultivation. Moreland (Proc. Board Agri., lc. 113) gives a concise account of tobacco cultivation. It is grown (1) in heavily manured land close to villages; (2) on the sites of old towns where the soil and well-water are rich in nitrates; (3) rarely in virgin soil in forest tracts. The seed is sown in nurseries and the young plants put out at different times of the year, from July to February, and harvested from February to April. According to Duthie and Fuller (Field and Garden Crops, pt. i., 69–74, tt. xvi–xvii.) the seasons of sowing may be grouped into two: (1) sown in July and August, planted out in October, cut in February; (2) sown in November, planted in February, cut in April and May. Tobacco grown in the former season is known as sāwani, that grown in the latter as asārhi. The rotations are various. Where nitrates abound, the crop may be grown for several years successively on the same land, and where poudrette is available, the commonest rotation is maize, potato, tobacco, all within the year. In preparing the seed-bed the ground is first dug a foot deep and then completely pulverised. Usually from 10 to 30 tons per acre of cow-dung, sheep-dung or poudrette are worked thoroughly into the soil. Crude saltpetre earth may be applied as a top-dressing where the available water is not salt.

After transplanting, the land is kept loose and free from weeds, and all flower-buds and lateral branches or shoots from leaf-axils removed as soon as formed. The plants are usually hand-watered after transplanting, and later, water is run on to the fields as required. From fifteen to twenty waterings are usually necessary. When ripe, the leaves are stripped from the plant, or the whole plant is cut down. The crop is dried in the sun and then stacked under cover. After a period which varies in different localities, the crop is carried home for fermentation.

The cost of cultivating an acre of sāwani tobacco is estimated by Duthie and Fuller at Rs. 46–7a. [Cf. Sir E. C. Buck, Note on Tobacco Cult. and Curing, U. Prov., 1787; Novill, Dist. Gaz. U. Prov.]

Central Provinces and Berar.—The area under tobacco in 1905–6 C. Prov.
THE TOBACCO PLANT

NICOTIANA

Panjáb and Kashmir

Areas.

was 12,194 acres in the Central Provinces, and 14,220 acres in Oudh. The districts with largest areas are usually Raipur 1,105 acres, Bilaspur 995, and Chanda 1,023 acres, in the Central Provinces; Amrāoti 5,331 acres, Buldana 3,602, Wun 2,374, and Ellichpur 1,178 acres in Berar. The plant is cultivated in patches near the villages, and the whole produce is consumed locally. The seasons of sowing and reaping vary. In Narsingpur the crop is harvested in October; in other districts the stems are cut usually in February and March.

Rajputana.

Rajputana and Central India.—In these provinces cultivation is almost confined to the Native States of Gwalior, Jaipur, Bharatpur and Tonk, which in 1905–6 grew respectively 3,590 acres, 2,563 acres, 1,072 acres, and 147 acres. A description by Dr. R. H. Irvine of the famous Bhilsa tobacco, grown in Gwalior, is quoted in the Dictionary. According to O’Conor, tobacco in Central India is raised on high, well-ploughed lands. A second crop is frequently taken from the stems left after the first crop has been gathered.

Panjáb.

Panjáb and North-West Frontier.—The area in 1905–6 was 67,594 acres in the Panjáb and 9,666 acres in the North-West Frontier. In the Panjáb the districts with largest areas are usually Jalandhar, 3,756 acres, Sialkot 4,400 acres, Lahore 4,524 acres, Gujrat 3,137 acres, Amritsar 2,890 acres, Gujránwala 3,465 acres, Jhang 2,708 acres; in the North-West Frontier, Peshawar 8,513 acres. The soils generally preferred are garden and manured lands near the villages. Alluvial lands are not considered suitable; in three cases only—namely, parts of the Sialkot, Ludhiana and Rawalpindi districts—are alluvial tracts selected. Irrigation is practised, the plots being watered about once in every four days, and extensive manuring is necessary. Night-soil, sheep- and goat-dung, stable litter and cow-dung, are used, and an admixture of saltpetre is found beneficial. The sowing season in most districts is October and November, but may in some places continue till December and January (Shahpur, Multan, Dera Ghazi Khan) and February (Peshawar, Amritsar, Rawalpindi). Transplanting takes place from January to March, and cutting during May, June and July. The plant is cut to the roots and no second crop taken. [Cf. Purser, Sett. Rep. Jalandhar, 1892, 127–8; Dist. Gaz. Pb.; Exper. Farm Rep. Lyallpur, 1901–2, 20; Renouf, Tobacco in Pb., in Proc. Board Agri., Pusa, Jan. 1906, 115–6.]

Kashmir.

Kashmir.—According to Sir W. Lawrence (Valley of Kashmir, 1895, 345–6) tobacco is cultivated in many parts of Kashmir, but chiefly in and around Srinagar and the smaller towns. Cultivation is almost entirely in the hands of the gardener class. The plant yielding the best produce grows in Srinagar, and is known as brevări (N. Tabacum, var. lancifolia). Another species, chilăsi (N. rustica), has been introduced from the Panjăb. It is sown in April and picked about the end of August. It requires very rich soil and is irrigated by the dip-wells of the country. The consumption of tobacco in Kashmir is almost entirely in the form of snuff.

Bombay.

Bombay and Sind.—The area in 1905–6 was 64,539 acres in Bombay and 9,048 acres in Sind. The districts with the largest areas are Belgaum 22,856 acres, Kaira 21,276 acres, Satara 4,215 acres, Ahmadabad 3,187 acres, Khandesh 4,364 acres, Broach 2,685 acres, and Hyderabad 4,847 acres. Mollison gives a very full account of the methods pursued. The best kind is grown on deep alluvial lands near the Krishna. Throughout the Kaira
SYSTEM IN WESTERN INDIA

district and the adjoining Baroda Territory, where cultivation is extensive, wells with salt water are common, and the water is used for irrigating the tobacco, often with remarkable manurial effects. Wells of special value occur in the neighbourhood of Nadiád (Kaira district) and Pettád (Baroda Territory). For details regarding the manurial value of these salt wells, consult Leather (Agri. Ledg., 1895, No. 14). A free-working and satisfactorily drained soil is best. On such land in Gujarat mild-flavoured tobacco of good quality can be grown. A stronger tobacco with large, coarse leaves grows best on medium clay loams, irrigated with sweet water or salt and sweet combined. In Gujarat, tobacco is rarely rotated with other crops, and it is claimed that the longer the soil is under the crop, the better the produce.

The seed-beds should be prepared on elevated ground and under tree-shade. In villages which grow a large area of tobacco, a piece of ground is usually set apart as a common nursery. The bed should be carefully prepared. The burning on the surface (before the rains set in) of refuse, straw, brushwood or cow-dung improves the mechanical condition, the ashes manure the soil, and the heat kills weeds and insects. After burning (rubing), goat manure should be well mixed with the soil, and a fine tilth obtained by hand-digging. The seed (mixed with ashes or fine sand) is sown in July, one ounce to one hundred square feet of seed-bed. The beds require protection from heavy rain, and should at first be lightly watered by hand. Weeds must be removed and the seedlings thinned out. The seedlings are ready for transplantation when they have four leaves and are 3 or 4 inches high. As soon as possible after the harvesting of the previous crop the stems and roots should be grubbed up and burned. The field is ploughed soon after the monsoon has set in, and again frequently between June and August. Twenty-five to thirty cart-loads per acre of well-rotted farm-yard manure should be applied, after the field has been ploughed several times. A better practice is to fold sheep on the fields intended for tobacco. The mud from village tanks is also considered good. Before planting the young seedlings, the field is levelled with the samár, then lined and cross-lined with the qisle. A seedling is planted carefully at each angle made by the intersecting lines, and a cloudy afternoon is usually chosen. Frequent watering is required. As soon as the young plants have made a fair start hoeing should begin, and when the flower-buds begin to open they should be removed, and with them two to four of the youngest leaves. About ten to fourteen leaves should be left on each plant. The removal of the flower-buds is followed by the appearance of side branches known as "suckers," and these also should be regularly removed.

On a stiff clay loam soil (besar), tobacco is a dry crop, but as a rule in Gujarat it is irrigated more or less according to the kind of tobacco to be manufactured. Irrigation ordinarily begins early in November. Twenty days after the first watering a second is given, and afterwards others at intervals of twelve to sixteen days until the leaves are ripe, usually about the middle of February. In Gujarat the leaves are left on the plant till they are decidedly yellow. Sometimes the whole plant is cut down, but the usual method is to strip off the leaves one by one from the stalk with a small bent sickle.

[Cf. Beyts, Gujarat Agri., 1876, 45-8; Voelcker, Improv. Ind. Agr., 1893, 272-4; Mollison, Textbook Ind. Agri., 1901, iii, 236-45; Exper. Farm Repts.]
THE TOBACCO PLANT

NICOTIANA

Madras

Poona, Nadiad, etc.; Fletcher, Cult. Tobacco in Bom., in Proc. Board Agri., Pusa, 1906, 116.]

Madras.—The area under the crop amounted in 1905-6 to 132,458 acres. The districts with the largest areas are usually Guntur 41,798 acres, Coimbatore 26,884 acres, Godavari 8,143 acres, Vizagapatam 5,037 acres, Madura 8,296 acres, Karnul 6,664 acres, etc. The crop is grown in all districts, though on the Nilgiris and the west coast the area is small. Benson (Proc. Board Agri., Pusa, 82-92) gives a very full account of tobacco cultivation in the various districts. In Kistna the crop is grown chiefly in the upland taluks on ordinary black cotton soil. The seed-beds are usually located near shallow pools in which the monsoon rains stand. They are well ploughed and manured. After the first ploughing cattle are penned on the plots, and they are again ploughed once or twice. Village manure, consisting of ashes, earth and dried cow-dung, is then applied at the rate of 50 to 60 loads per acre. After two or three more ploughings the seed is sown broadcast, at the rate of one local seer to 18 cents of land, and pressed in by the hand. At first, watering is frequent, three or four times a day. After twenty days, watering is reduced to once a day, and all unhealthy leaves are picked off daily.

In about two and a half months, when the plants are 8 to 9 inches high, they are trimmed and lateral shoots, if any, removed, and fifteen days later are pulled up and made into bundles for planting. The preparation of the land for the crop commences about July. Before this, village manure and tank silt are applied, and cattle, sheep or goats penned on it after the first ploughing. The land is ploughed seven to ten times, then twice with the gorr, and afterwards marked off into squares. The young plants are placed in holes filled with water at the corner of the squares, and the earth gathered round them. They are watered for two days in the morning, then for two days in the evening, but are afterwards left to themselves. The crop is topped when 2½ feet high and suckered twenty days later, and about ten days later still is ready for harvest, in February or March. No second growth occurs, and the stems are cut down and used for fuel.

In cultivating tobacco for the manufacture of snuff, the crop is never irrigated from wells, but the plants are grown by the aid of rain alone. Again, if the tobacco is for chewing, watering is withheld four or five days before harvest. The chief centres for snuff tobacco are Trichangode, Rasipuram and Uttankarai taluks in Salem district.

Mysore.

Mysore and Coorg.—The area in Mysore in 1905-6 was 14,263 acres, chiefly in Mysore, Tumkur, Chitaldrug and Kolar. The crop is grown on land where rāgi and similar grains are cultivated, a crop of which must intervene between every two of tobacco. The seed is sown in June or July, and the seed-beds are prepared near wells or other sources of water supply. The seeds are sown mixed with dung, and after being pressed down with the hand and watered they are covered with mats or the leaves of the date palm. The seedlings are transplanted into fields prepared previously by frequent ploughings and manured by cattle and

802
sheep. They are placed in holes 18 inches apart and filled in with a mixture of red earth, sand and dung. About a month and a half after being set out they are topped, six or seven leaves only being allowed to remain, and the suckers are removed. They are ripe in November and January and cut down to within 4 or 5 inches of the ground. The stems are then split lengthwise, each portion carrying three or four leaves. [Cf. Rice, Mysore Gaz., 1897, i., 126–8.]

Burma.—The total area in 1905–6 amounted to 49,205 acres in Lower Burma, 26,560 acres in Upper Burma. In Lower Burma the largest areas occur in Hennaza, 12,849 acres; Thayetmyo, 6,627 acres; Tharawadi, 5,601 acres; Prome, 3,772 acres; and Kyaukpyu, 3,525 acres: in Upper Burma, Pakokku, 5,530 acres; Mandalay, 4,393 acres; Minbu, 2,646 acres; Sagaing, 4,156 acres; and Myingyan, 3,944 acres.

Mackenna (Settl. Rept. Hennaza, 1901, 50–1) states that the bulk of the crop is grown on low lands annually flooded. A high-land portion of the holding is ploughed during July to August, and about the end of August to the middle of September seed is sown in nurseries. In four or five weeks the seedlings will be 3 or 4 inches above ground and are ready for transplantation in October to November or early in December. The ground is previously prepared by numerous ploughings, and the plants are placed in furrows 3 feet apart at a distance of 3 feet from each other. The ground must be kept free of weeds, and about a month after transplanting the small leaves are removed till only six to ten are left. About March to April plucking commences, and is continued till the rains break. On poor soil tobacco should be planted every three or four years only in the same place, but in good soil annual plantings may go on for twenty or twenty-five years. The expense of cultivation is calculated at an average of Rs. 40 per acre, and the total value of the outturn at Rs. 113–25 per acre.

DISEASES OF THE TOBACCO PLANT.—Howard (U.S. Yearbook, Agrit. Dept., 1898) gives useful particulars regarding the insect pests. So also various publications furnish details regarding Ceylon (Trop. Agrist., xxv., 825; xxvi., 130). Delacroix (Recherches sur Quelques Maladies du Tabac en France, Paris, 1906) has published a full account of the most recent researches and has described the symptoms and methods of treatment of several diseases. He deals fully, for example, with the Canker, caused by a bacterium which he has named Bacillus wrightii; with Collar Rot (Pourriture du Collet) and Pith Rot (Pourriture de la Moelle), also due to bacterial organisms hitherto undescribed; with Foot Rot (Pourriture du Pied) due to Fusarium tobacivorum, Delacroix; with Mosaic Disease (La Nielle or Mosaique); and with White Spot Disease (Maladie des Taches blanches), etc. So far as at present known, most of these blights do not seem to have appeared on the Indian tobacco plant.

Of the blights of tobacco, the best known are the broom rapes, Orobanche indica and O. nicotiana, common in most of the tobacco districts, especially in Bengal, Madras and Gujarat. Mollison states that in Gujarat a bad attack may sometimes destroy a quarter of the crop. The only practicable direct means of lessening its severity is the prevention of the parasite from forming seed. Another serious disease, in some districts, is the tobacco mildew, caused by the conoidal stage of

Broom Rape.

803
Erysiphe cichoracearum, DC. Butler (Proc. Board Agri., Pusa, 1906, 82) remarks that it is probably the grey mildew which attacks the leaves in the Azamgarh district of the United Provinces, known as kapto. The same authority states that no remedy has been proved to be efficacious. "The application of sulphur either in form of 'flowers of sulphur' dusted on, or as potassium sulphide sprayed on, is efficacious in checking many mildews, but might interfere with the curing processes and be difficult to remove from the leaves." At Pusa a leaf-spot disease, due to Cerco-
spora Raciborskii, Sacc. & Syd., is said to be common, but its effects are not very serious.

Maxwell-Lefroy enumerates the common insect pests of the tobacco plant in India under the following five heads:—

1. Grasshoppers attacking newly transplanted seedlings. Clean culture and thorough tillage are the best preventatives. The only direct remedy is to dip the seedlings in standard lead arseniate mixture as they are planted.

2. Surface caterpillars, i.e. those living in the soil, hiding by day and emerging by night to feed on young plants. Search reveals their burrows, where they can be found and destroyed. The alternative methods are to poison the young plants or to put down baits of poisoned chaff.

3. The stem caterpillar, attacking young plants. These live in the stem and cause gall-like swellings. Plants up to a foot high are principally attacked. The cultivator’s method of cutting open the gall by a longitudinal incision is probably the best.

4. Leaf-eating caterpillars. When these appear on young plants, spraying the leaves with poison is a sound remedy. On old plants, the caterpillars must be picked off by the hand.

5. In Tirhut a cricket (probably the common burrowing Brachytrypse achatinus, Stoll) is reported to injure the leaves by coming out at night and eating holes in them. Where they are not abundant they can be dug out, which is best done during August and September.

In seriously infested localities the most satisfactory treatment is to grow a crop such as lucerne and thoroughly poison it, thus poisoning off the crickets. In the United States of America flocks of turkeys are reared on the tobacco farms with a view to exterminating the caterpillars that do so much injury to the crop. [Cf. Proc. Board Agri., Pusa, 1906, 88, 94, 110-1, 113-4; Delacroix, Sur une Maladie du Tabac, le "Chancro" ou "Anthracose," in Comptes Rendus, 1903, cexxvii., 454; also La Rouille blanche du Tabac, etc., 1905, cxxl., 678; Maxwell-Lefroy, Mem. Dept. Agri. Ind., 1907, i., No. 2, 115-252.]

MANUFACTURE.

Withering.—The leaves are considered mature when the texture becomes granulated and of a dark green colour with yellowish blotches. The lower leaves ripen first, the others in succession upwards. According to one system the leaves are cut off singly or in pairs (with a connecting portion of the stem), or the stem with its entire series of leaves is severed at once. The first stage in manufacturing is the withering of the leaf. This is usually accomplished by cutting down the plants or leaves and spreading these out on the ground, thus exposing them to the action of the sun for a few minutes or hours. They are then carried to the drying-house. But if rain falls during the withering, the plants or leaves must as rapidly as possible be carried to the drying-house and the reaping dis-
continued. The withering-house may be constructed of any design or material providing free circulation of air. In the interior a framework of uprights and cross-rails has to be arranged, across which the sticks with withered leaf or withered plants suspended are placed and retained until the drying is complete. For the first two or three days the sticks with their suspended leaves are removed a foot apart and retained in that position until the mid-ribs are completely dried, which may take from fifteen to thirty days, according to the nature of the weather prevalent. In some parts of the country the first drying is accomplished by the leaves being spread on the floor over a layer of dry straw. Rapid drying produces yellow or almost green leaves, and slow drying darkens the colour.

Drying and Fermenting.—When quite dry, the leaves (or stems with attached leaves) are taken down, usually assorted and, at the same time, separated from the stems and placed in heaps or stacks to ferment or sweat. For this purpose they are flattened out carefully, the stems or leaf-stalks being placed inwards and the tips of the leaves outwards. It is preferable to select a damp day to commence this operation. In the Rangpur houses, the floors being usually mud, the stacks of leaf are placed on boarding. Great care is taken that the leaves be spread out perfectly flat, and as a rule a selection is made of the finer leaf to be used for wrappers, from the coarser to be used as fillers. For this purpose it is accordingly customary to make two stacks, one of high-class, the other of low-class leaf. The stacks of leaf may be as much as 2 to 6 feet in height and the top is usually covered with a cloth or sheet of basket-work over which a weight is placed. It is customary on the second or third day to pull down two stacks of the same quality simultaneously, and to construct new stacks, taking leaf alternately from the one and the other, observing the while that the leaf in the centre of the first stacks may be in the exterior of the new ones. A week later the stacks are similarly pulled down and remade, and this may be continued time after time for a month or six weeks—in other words, until all the heat of fermentation has disappeared. In this way uniform and continuous fermentation is ensured.

 Bundling and Baling.—The leaves are then tied into bundles of 25 or 30, a useless leaf being employed in tying each such bundle. Great skill is required in this operation, since the leaves must be left perfectly flat, the bundles being almost fan-shaped. In this condition they are baled, the broom-like ends projecting outwards.

It may be as well to contrast this (which may be taken as the system pursued in 1902 when personally inspected by me in Rangpur) with that given by Buchanan-Hamilton as observed in Dinajpur (the adjoining district) during 1809–11. The tobacco, he says, is “fit for cutting in March and April. Each stem contains from 5 to 8 leaves, which in a good soil are 18 inches long, and in a poor are only half the length. The stem is cut, and the plants are allowed to lie three days on the ground. The leaves are then separated, and are tied in handfuls, which are hung in the open air until dry. The handfuls are made into balls, by laying them together in two rows, with their roots outward. The parcels are surrounded with straw, are tied very tightly, and the bale is then complete.”

Whitney and Floyd (Growth of Tobacco Industry, U.S. Yearbook, Agri. Dept., 1899, 429–40) show the bundles or “hands” as produced in Maryland and Virginia, also the forms adopted with the “Cigarette and Manufacturing Tobaccos,” “Connecticut Cigar-wraper Leaf,” the “Ohio Limmer

805
Changes occurring during Manufacture.—Dr. Harold H. Mann, in a communication with which I have been favoured, discusses the modern opinions on this subject:—“It has been repeatedly pointed out by writers on this subject that dry *Nicotiana tabacum* leaf is not tobacco. Delacroix (Bull. Scient. Pharm., Feb. 1905, No. 2) remarks, for example, that the quantity of albuminoids present in the normal leaf gives a disagreeable odour to the smoke that recalls that of burning wool or horn. The fermentation which the leaf undergoes during manufacture is, in fact, essential to the preparation of tobacco, and if not carried out properly, the finest leaf may be rendered entirely worthless. Many theories have been held at various times as to the nature and cause of the great changes which take place, and it has been successively believed that they were due simply to the oxidising action of the atmosphere at the high temperature which was produced (100° to 120° F.), (Schloesing, Nessler); that definite microbes or bacteria were the necessary agents in producing the flavour of tobacco (Suchsland, Koning, Vernhout), and even that each class of tobacco had its own special bacterium; and that such changes as occur are principally, if not entirely, due to the presence and action of oxidising enzymes or unorganised ferments (Loew). It is now almost universally recognised that oxidising enzymes are the principal agents in producing the development of the colour and aroma characteristic of prepared tobacco leaf.

“These enzymes, which were first isolated and examined by Oscar Loew in America, appear to be at least three in number. The first of these (oxidase) is an exceedingly active ferment, but very susceptible to noxious influences, being destroyed by heating to the very moderate temperature of 150° F.; the second (peroxidase) is not nearly so active, but is more resistant, and is only destroyed at 190° F.; the third (catalase) is of a different character, more resistant than either, but the part it takes in the processes of manufacture is not yet understood. The processes of curing (drying) and sweating (fermentation) of the tobacco leaf are accompanied by a destruction of these enzymes present in the leaves; the oxidase and peroxidase generally survive the curing process but the former of these finally disappears in the sweating (fermentation), leaving the more resistant peroxidase.

“The changes induced by these ferments are very considerable. During the drying (curing) of the leaves, the starch is transformed, and the greater part of the sugar which results disappears. The albuminoids decrease
in amount: the tamin also decreases, and it seems probable that this decrease may be the principal cause in the change of the colour of the leaf. In the sweating or fermentation which follows, the last traces of sugar disappear; nicotine decreases in quantity and there is a corresponding increase in the amides resulting from its decomposition. The leaf becomes more alkaline, and further progressive changes take place in the colour and aroma. A slow after fermentation then takes place, during which the colour and aroma gradually become ripened. During or after sweating the tobacco is often sprinkled in America with a so-called 'petuning' liquid; the composition of which is kept secret, but whose principal function seems to be to increase the alkalinity of the leaf and so hasten the changes already described."

Improved Methods of Manufacture.—In some of the experiments conducted by the Agricultural Department of the United States, it has been shown that during fermentation certain undesirable changes take place together with the disappearance of a large amount of nicotine. Accordingly the system of fermenting in stacks has been condemned and the substitution of closed fermentation tanks recommended. This American system, however, is not sufficiently used as yet to justify its being recommended for India. A small quantity of already fermented tobacco is placed along with the new leaf in order to start the fermentation.

Enough has been said to indicate the transitional stage of modern research into tobacco manufacture and the complete lack of knowledge that prevails in India. It is no matter for surprise, therefore, that the Government of India should have deemed a tobacco expert imperatively necessary. Rapid and satisfactory though the progress has been in certain directions of the Indian trade, skilled supervision and definite research locally conducted seems almost certain to effect improvements calculated to place India in the foremost ranks of the tobacco-producing countries of the world.

NATIVE AND EUROPEAN MANUFACTURED TOBACCOES.—With the Natives of India crudely cured tobacco-leaf is usually reduced to a powder, damped, mixed with ḡūr (pp. 952, 1109), also various flavouring ingredients, and thus made into large cakes. In this form it is sold to the consumer. The pipe ordinarily used is a hollow vessel or cocanaut shell partially filled with water. From this vessel arise two tubes—one the mouthpiece, the other the attachment for the actual pipe, the chilam, or vessel containing the tobacco. The smoke is thus drawn through water before reaching the mouth. The tobacco is ignited with a live coal or burning cake of specially prepared charcoal.

The crudely prepared leaf is simply rolled between the hands, compressed into a conveniently sized ball, and placed within the chilam. But with many of the hill tribes a crude pipe is used that hardly differs from that employed in Europe—the boll being made from a short joint of a bamboo and the stem a common reed. Indeed in many cases the pipe may be constructed, for each smoke, of soft mud placed on a stone, the boll having a small opening at the bottom against which the lips are pressed in smoking. It is only of South India and Burma that it can be said that smoking cigars has become so general that it can be described as a widespread habit. But within recent years great progress has been made in local cigar manufacture, and steadily the practice of cigar-smoking seems to be gaining ground with the better classes of Natives all over the country.
NICOTIANA
Manufacture

THE TOBACCO PLANT

And it is customary to read in the public press of the rapidity with which the habit of cigarette-smoking has invaded the social life of the various races and peoples of India.

Indian Cigars.—One of the first persons who realised the possibilities of an Indian cigar trade was Capt. E. A. Campbell, who, in 1876, started a company at Dindigal to improve the well-known “Trichy” of former times. Two years later, however, the company was wound up and little progress made till about 1881, when it was discovered that by importing wrappers from Java and Sumatra a cigar could be turned out that would please the eye of the consumer better than that constructed throughout of Indian leaf. This discovery gave at once the impetus that was needed to bring the excellent cigars of South India to the favourable notice of the world at large. A factory inspected by me in 1903 was found to give employment in all its departments to fully a thousand persons—men, women and children. It was ascertained that the usual rate for an expert worker was to produce 400 to 800 cigars a day, according to skill, thus earning from Rs. 20 to Rs. 30 a month in wages.

But it is perhaps one of the most remarkable features of the tobacco traffic that no attempt has been made by Europeans to organise a tobacco-manufacturing establishment either within the great producing area of Bengal itself or in Burma, where the Bengal leaf is worked up and again returned in the form of the cigars for which Burma has been so long famous.

Industrial, Chemical, etc.—It would be beyond the scope of this work to discuss all the side issues and technical investigations. The Pharmaco-graphia Indica (ii., 632–43) will be found to set forth the salient features of most of these side issues. The Kew Bulletin (Feb. 1896, 49–55) furnishes details regarding the natural sugar present in tobacco. Many publications have dealt with tobacco juice—a substance prepared in France and sold by all the licensed vendors. It is claimed to be free from all matter susceptible of fermentation and to contain no resinous substance, but a higher percentage of nicotine than would be the case with an infusion of the leaf. Tobacco juice is largely used as an insecticide. Espin published in the Bulletin of the Botanical Department of Trinidad for 1900 a highly instructive account of tobacco cultivation, manufacture and trade. This was followed up by a most instructive little book issued by Sir D. Morris, Imperial Commissioner of Agriculture for the West Indies, entitled The Cultivation and Curing of Tobacco (1905). The Tropical Agriculturist (Oct. 1905, 595; Jan. 1906, 819–26, etc.) contains papers of great interest on the cultivation and manufacture of tobacco in Ceylon. [Cf. Heuzé, Les Pl. Indust., 1895, iv., 43–90; Arthur Wigham, English-grown Tobacco; Kissling, Chem. Anal. of Tobacco; Jenkins, Effects of Fort.; Whitney and Means, Changes in Fert. Cigar Leaf, U.S. Dept. Agri., 1896, No. 60; Haase, Tobacco Free or Partly Free from Nicotine; Piotet and Rotschy, New Alkaloids of Tobacco; Julius Mohr and others, Deli Tobacco of Batavia, Tobacco under Shade, etc., etc. (numerous papers); Koning, Der Tabak, Kultur und Biologie, 1900; Loew, The New Enzyme in Cured Tobacco—Catalase; Schweiz, The Chem. of Tobacco Smoke; Thorpe and Holmes, The Paraffins of Tobacco Leaf; G. E. Williams, Nicotine, Its Use and Value in Horticult.; Delacroix, Fermentation du tabac, in Bull. Sci. Pharm., 1905, 84–93, etc., etc.]

Trade.

TRADIE IN INDIAN TOBACCO.—During the opening decade of the 19th century India was not known to the commerce of the world as a tobacco-producing country. By 1825, however, we read of Masulipatam in South India producing very superior tobacco, and that snuff was

808
NICOTIANA
Trade

about that time also sent from India to England. In 1833 was published Buchanan-Hamilton’s account of Dinajpur (which was possibly written about 1809 to 1811). He speaks of tobacco cultivation much as if it had been even then a well-known crop (see p. 805). It was apparently not fermented at all—simply dried leaf.

Exports.—By 1866–7 the Exports of tobacco from India were valued at Rs. 5,61,836, of which only Rs. 7,088 worth were consigned to the United Kingdom. But there is no mention of cigars in these early trade returns; and what is more curious still, Bombay was by far the most important source of the Indian supply. Ten years later (1876–7) the exports were rendered under three headings:—Unmanufactured Tobacco, 10,508,720 lb., valued at Rs. 7,51,375; Cigars, 190,136 lb., valued at Rs. 1,17,445; and Other Manufactured Tobaccoes, 205,033 lb., valued at Rs. 22,578. Ten years still later (1886–7) the exports were:—Unmanufactured, 9,868,834 lb., valued at Rs. 9,57,156; Cigars, 273,209 lb., valued at Rs. 2,11,391; and Other Sorts, 193,996 lb., valued at Rs. 27,036. Again, ten years still later (1896–7), the exports were:—Unmanufactured 11,257,582 lb., valued at Rs. 11,38,204; Cigars, 557,816 lb., valued at Rs. 6,37,812; and Other Sorts, 273,872 lb., valued at Rs. 37,318. For the most recent years (taking values only) the following were the exports:

</tbody>
</table>

The cheap tobaccos returned under “Other Sorts” are Native preparations consigned to the Maldives, the Straits, Ceylon and Arabia. Perhaps the most remarkable feature of the foreign traffic is the growth of the supply of cigars. The exports of this class expanded from a valuation of Rs. 1,17,445 in 1876–7 (when first separately returned) to Rs. 16,40,427 in 1901–2, and Rs. 9,57,489 in 1906–7. And it is significant that, in what might be called normal years, these exports go mainly to the United Kingdom and the Straits Settlements. The years 1901–2 and 1902–3 were abnormal, since in these years very large consignments were made to Cape Colony and Natal—doubtless to meet the demands of the British soldiers. Further, it may be added that the bulk of the cigars exported from India go to Madras and Burma.

Of the unmanufactured tobacco, Bombay exports by far the largest quantity (on an average about one-half the total). And what is remarkable, the receiving countries are Aden, the Straits Settlements, China (Hongkong) and Holland, the last-mentioned having for some time steadily increased its demands for the very cheapest of the Indian unmanufactured tobaccos. No Indian unmanufactured tobacco would appear to go to the United Kingdom. Bengal, the chief producing province, exports to foreign countries, as a rule, only about half the quantity supplied by Bombay. But the explanation of this circumstance is perhaps to be had in the fact that by the coastwise traffic Bengal is shown to export to Burma unmanufactured tobacco (in 1905–6) to the value of Rs. 27,68,296. The importance of Burma to the Indian grower is made
THE TOBACCO PLANT

still more evident when it is added that at the same time Madras contributed to Burma unmanufactured tobacco to the value of Rs. 14,72,433. Thus Burma is to the Indian grower of unmanufactured tobacco a very much more important market than the rest of the world collectively.

Imports.—Turning now to the Import Traffic, a similar expansion may be said to be observable. In 1876–7 the traffic under all classes was valued at Rs. 9,56,880. Ten years later (1886–7) at Rs. 49,53,486; the following decade (1896–7) at Rs. 26,30,258; in 1904–5 at Rs. 55,62,850; in 1905–6 at Rs. 66,08,807; and in 1906–7 at Rs. 69,33,377. The most noteworthy feature of this trade is the growth of the demand for foreign cigarettes. The year 1900–1 was that in which the returns of cigarettes were made apart from cigars. They were then returned as 1,165,399 lb., valued at Rs. 17,03,968; while in 1904–5 they were 2,518,659 lb., valued at Rs. 35,08,187; in 1905–6, 3,119,071 lb., valued at Rs. 44,97,699; and in 1906–7, 2,912,841 lb., valued at Rs. 45,97,364. On the other hand, if an opinion can be formed of a traffic for so limited a period as six years, the imports of cigars would seem to have manifested nothing like the interest taken in the cigarettes. In 1900–1 the imports of cigars were 60,157 lb., valued at Rs. 2,34,209; in 1904–5 they were 118,020 lb., valued at Rs. 3,75,958; in 1905–6, 101,293 lb., valued at Rs. 3,49,136; and in 1906–7, 111,586 lb., valued at Rs. 4,03,330. This state of affairs may be a direct consequence of the continuous improvement that for some years past has been maintained in the Indian-made cigar.

Of the imports of cigarettes in 1900–1 (1,165,399 lb.), 610,980 lb. came from the United Kingdom and 362,760 lb. from the United States, while 887,882 lb. of these imports were taken by Bengal. Of the supply for 1906–7 (2,912,841 lb.), 1,818,057 lb. came from the United Kingdom and 782,596 lb. from the United States. The supply from the Straits Settlements seems to fluctuate very greatly, but for the past two years has declined seriously. In 1903–4 the imports came to 177,294 lb., but in 1905–6 were 19,228 lb., and in 1906–7, 15,053 lb. China (Treaty) Ports have similarly given indications of a contraction: in 1903–4, 203,134 lb.; in 1905–6, 163,661 lb.; and in 1906–7, 112,528 lb. Bengal continued to hold the supremacy as the receiving province, since out of the total it took in 1906–7, 1,755,852 lb.; Burma and Bombay following with respectively 438,723 and 309,385 lb. Robertson (Rev. Trade Ind., 1904–5, 11) remarks: The cigarette imports have thus in five years increased 106 per cent., and the quantity imported last year represents 840 million cigarettes. The average value per pound was Rs. 1–4–5 British, Rs. 1–1–2 American, Rs. 6–9–1 Egyptian, and those from the East, 15 annas 9 pies, the value per 1,000 being roughly three times the value per pound. Noël-Paton (Rev. Trade Ind., 1905–6, 15) shows the quantity to have further increased by 23·8 per cent. on that for 1904–5: "The average value per lb. from each of the sources was: — British, Rs. 1–8–10; American, Rs. 1–1–6; Egyptian, Rs. 6–4–3; and Eastern 13 annas."

Speaking of the modern cigarette trade, J. E. O’Conor (Anglo-Ind. Rev., April 1903) observed: "Within the last three or four years, however, a singular modification of popular taste has been witnessed, one which would hardly have been believed possible in such a country and amongst such a people. Some enterprising firms in Europe thought they saw an opening in India for the Native consumption of American tobacco in
cigarettes in supersession of the hookah (or water-pipe) still commonly used by the people. Acting on this idea they imported cigarettes in increasing quantity at rates bringing them within the reach of the masses, and in a very short time the arrangements made for bringing the cigarettes within easy reach of the consumer had a very manifest effect. At the present moment the value of the cigarettes imported is about £150,000 a year, and allowing for the proportion of better class cigarettes imported for Europeans it is clear that the trade is already extensive. As yet, moreover, it is practically confined to a few large towns, and is only beginning. To say that it may increase tenfold is to use most moderate language. Why should the supply of these things be allowed to come from abroad?"

Of the cigar trade in 1900–1 (60,157 lb.), 18,295 lb. came from Belgium; 11,654 lb. from the Philippines; 7,605 lb. from the Straits Settlements; 5,307 lb. from the United Kingdom; and 4,777 lb. from China—Hongkong. In 1906–7 (111,586 lb.), 38,420 lb. came from Belgium; 28,448 lb. from China—Hongkong; 21,759 lb. from Holland; 5,650 lb. from the United Kingdom; 2,992 lb. from the Straits Settlements; and 450 lb. from Natal, the supply having greatly decreased.

These contain two kinds of OIL, one dark-coloured, fragrant and volatile, the other clear, nearly colourless, and of about the consistency of castor oil. Medicinally they are regarded as aromatic, carminative, stomachic and digestive. By the Natives they are much used in curries, in vinegar (p. 1110), and other dishes, and are frequently sprinkled over the surface of bread along with sesamum seed. [Cf. Pharmacog. Ind., i., 28–9; Agri. Ledy., 1895, No. 10, 108, 171; 1896, No. 28, 271; 1899, No. 12, 150; Thorpe, *Dict. Appl. Chem.*, 1889, ii., 397; Gildemeister and Hoffmann, *Volatile Oils*, 1900, 352; Dutt, *Mat. Med. Hind.*, 1900, 102–3. (For the true Cumin, see pp. 442–3; black *Caraway*, p. 283.)

**OILS, OIL-SEEDS, FATS, ETC., AND PERFUMERY.**—The Oils and Fats may be classified by many systems depending upon their chemical, physical and industrial properties and uses. Or they may be grouped according as they are derived from the animal, vegetable or mineral kingdoms. Some are spoken of as fixed, others as essential, edible, medicinal, drying, non-drying, etc., or again as illuminants, lubricants or as suitable for candle-making, soap-making or perfumery. Blount and Bloxam (*Chem. for Engin. and Manuf., etc.*, 1900, ii., 223) observe that fats, tallow, waxes, etc., are chemically of the same nature as the substances popularly designated oils. They are characterised by their unctuosity, by their insolubility in water, and by their solubility in ether, benzene, carbon bisulphide, and by their leaving a greasy stain on paper, which does not disappear by evaporation. Chemically they are ethereal salts of fatty acids, the alcohol radicle of the salt being glycerine (glyceryl), except in certain waxes where radicles of higher alcohols occur. Popularly, however, fats are viewed as distinct from oils, but it serves no good purpose to separate them.
OILS, OIL-SEEDS AND PERFUMERY

Chief Kinds

Oil Paint.

Uses of Oil

Soap.

Candles.

Kerosene.

House Illumination.

Cheap Lamps.

Chief Oils and Fats.

To the Natives of India Oils might be described as chiefly of interest as articles of diet or as illuminants. They are but rarely employed as lubricants. The painting of woodwork is a luxury of the wealthy. With the peasant, the ornamentation of the implements of his trade or the materials of his pastime are coloured, when coloured at all, on the turning-lathe and by means of lac. The dyers and leather-workers, however, all use oil, and have done so from the remotest antiquity. One of the most important Indian uses of oil, and one comparatively unknown in Europe, is the anointment of the person with mustard or rape and a few other sweet oils. The use of soap as a personal detergent cannot be said to be more than a luxury, and indeed, to the mass of the people, an unknown luxury. Crude soap is, however, largely manufactured and sold in every village to be employed by the washermen and dyers.

Candles were never very extensively used by the Natives of India, but the modern demand for kerosene oil and the cheap German lamps, specially designed for service with mineral oils, has largely supplanted the candles of former times. In fact the great popularity of kerosene and other mineral oils, within recent years, has doubtless curtailed the cultivation and manufacture of most of the minor oils, more especially those intended as illuminants and lubricants. It is a matter of twenty-five to thirty years ago, at most, since every European resident in India, and all the wealthier Natives, employed either castor or cocoanut oil exclusively for house illumination. The subsequent introduction of refined kerosene from America drove these completely out of use, and that too within a remarkably short time, just as electricity seems destined to displace kerosene and gas. The introduction of less pure though cheaper Russian oil and the invention of cheap lamps (already mentioned) may be said to have marked the still greater displacement of vegetable illuminating oils. Kerosene has, in fact, effected a revolution in the domestic economy of the people of India that is marked by an increasing demand for luxury and convenience, one of the many expressions of prosperity that come direct from the peasantry. The present article will be made, as far as possible, to exclude Petroleum (p. 875), though in some instances this may be impossible (e.g. candles) when the returns do not separate the mineral oils and their manufactures from the corresponding vegetable and animal products.

The following are the chief sources of the vegetable and animal Oils and Fats of India, in the sequence of their scientific or trade names:—

Arachis—the Earth-nut (see pp. 76, 80–3); Bassia—the Makhua (p. 120); Brassica—Mustard and Rape (pp. 183–6); Butter (pp. 475–8); Camellia—Tea-seed; Camphor (p. 247); Cannabis—Hemp (pp. 256–7); Carthamus—Safflower (pp. 281–3); Cocos—Cocoanut (Kopra) (pp. 357–60); Dipterocarpus (Eng.) (pp. 501–2); Fish-oil (pp. 544–5); Garcinia—Kokum Butter (p. 553); Ghi—Clarified Butter (pp. 478–82); Gossypium—Cotton-seed (pp. 612–3); Guizotia—Niger-seed (p. 625); Juglans—Walnut (p. 700); Lard and Tallow (pp. 701–3); Linum—Linseed (pp. 725–31); Moringa—Ben Oil, (p. 784); Papaver—Poppy-seed (p. 860); Ricinus—Castor (p. 922); Sesamum—Til or Gingelly (pp. 986–7); and Wax (Bees') (pp. 125–7).

There are many others that of course might be mentioned, but the above are representative of the Fats and Oils of commercial importance. In passing, reference may be given to Bombax (see p. 168); Cochlospermum Gossypium, DC., the White Silk-cotton Tree.
(Hooper, Rept. Labor. Ind. Mus. (Indust. Sec.), 1906–7, 9); Helianthus annuus, Linn., Sunflower (Hooper, Agri. Ledg., 1907, No. 1); and to Olea cuspidata, Wall., the Indian Olive, which in Kohat fruits abundantly (Hooper, l.c. 1904–5, 25). In the present article it is proposed to give in one place a brief sketch of the oil interests of India collectively (exclusive of petroleum and its derivatives). Collective treatment is necessary, not only to link together kindred information but to exhibit the returns of oils and fats (given in trade statistics as "Others"), which by any other treatment would be omitted from this work.

**FOREIGN TRADE IN OIL-SEEDS, OILS, FATS, ETC.**

The official returns here discussed may be viewed as separated into two great groups—Imports and Exports. Under each of these sections may be formed, such as Fixed and Essential, with sub-sections, Vegetable and Animal, and under these again still further groupings, according as the substances are raw or manufactured. Taking the first year for which fairly complete returns exist (1876–7), then twenty years later (1896–7) and the most recent years (1905–7), the following statement may be accepted as exhibiting the values of the more interesting transactions in the combined traffic:

</table>

It will thus be seen that while for approximately the past thirty years the imports have increased threefold, during the past eight or nine years they have manifested a tendency to decrease. Prior to 1906–7 the highest year on record was 1901–2, when the total of the above articles came
to Rs. 94,66,769 (or £631,118). The most significant feature of the returns is the expansion of the demand for soap, namely from a valuation of Rs. 3,32,791 in 1876-7 to Rs. 31,90,890 in 1905-6 and Rs. 32,28,156 in 1906-7. The growth of this traffic has been continuous, notwithstanding the fact that within the period dealt with India has made rapid progress as a soap-manufacturing country. So also the expansion of the demand for the goods treated under Oil and Wax Cloth is certainly remarkable, seeing that the textile used for linoleum is jute, which is specially manufactured in Calcutta and sent to Europe and America to be subjected to its final transformation into the goods which reappear under the imports indicated. The decline of the imports of ghi and the enhancement of those of butter and tallow are also worthy of note, the more so since the consumption of foreign candles has practically remained stationary for the past thirty years.

Exports to Foreign Countries.

It may now be useful to set forth in a parallel series of quotations the exports from India of the Oil-seeds, Oils, and Manufactures therefrom:

</table>

Thus in approximately thirty years the exports under the above-mentioned articles have increased from a valuation of 3½ to 9½ million pounds sterling. But to obtain a full conception of the importance of Indian foreign transactions in oils and oil manufactures, it is necessary to add the imports to the exports, when it is seen that the total traffic has expanded from a valuation in 1876-7 of 3½ million to over 10½ million pounds in 1906-7.

Perhaps the most important feature in these returns is the steady progression of the oil-seed traffic, which in 1876-7 stood at a valuation of £3,526,458 and in 1904-5 had expanded to £9,499,961, but contracted to £9,334,496 in 1905-6, and became £8,553,135 in 1906-7. And when the details of these exports are looked into it is found that the traffic in cotton-
INo indian traffic in oil-seeds

Oil-seed has expanded during the past five years from a valuation of £36,999 in 1900-1 to £410,840 in 1904-5, £681,173 in 1905-6, and £866,043 in 1906-7. That is to say, it has expanded from being utterly insignificant until now it holds the second place in quantity and the fourth in value of all the oil-seeds. The bulk of cotton-seed exports go from Bombay to the United Kingdom. Although less in value, relatively, the expansion of the traffic in oils, in ghx and essential-oil seeds is no less interesting and valuable.

INTERNAL TRADE.
But splendid though these results are, they show very possibly little more than two-thirds of the actual value to the country, the remaining third representing the consumption of raw material or of the local manufactures therefrom. But while it is easy enough, from personal acquaintance with the country, to hazard opinions that may be found fairly accurate, it is often by no means possible to substantiate such by actual statistical returns. It has been found the only satisfactory course in dealing with the above (foreign transactions) to take the declared values at the ports, since in some cases the quantities may be in gallons, in others in cwt. or in yards. On referring to the official returns of internal trade, as manifested by the rail-borne traffic, the quantities only are given, and these are expressed in cwt. No relation can, therefore, be worked out between the railway goods traffic and the valuations of the exports and imports recorded at the customs houses. Still, as they stand, the railway returns are instructive. Some of the more important materials and movements, as learned from a study of these returns, may be here briefly reviewed. So also, in the same way, a study of the transactions by sea coastwise gives additional particulars of the inter-provincial exchanges and of local consumption. These transactions are given in cwt., so that a comparison with the railway returns is possible, but not with the foreign transactions nor for years later than 1905-6.

OIL-SEEDS.—In the Agricultural Statistics the following are the headings usually accepted, and under which alone areas of production are recorded—Linseed, Til, Rape and Mustard, and Others. In the returns of Foreign Trade a more comprehensive series is given, namely Cotton, Castor, Earth-nut, Linseed, Mahua ("Mowa" or "Mowra"), Mustard, Poppy, Rape, Til, and Others. Lastly, in the published returns of rail-borne traffic we find a third grouping, namely Linseed, Rape and Mustard, Til, and All Kinds collectively, the last heading including the three separate kinds as well as the Others of Agricultural and Trade Statistics. With the exception of linseed and til, no analysis of the returns of oil-seeds is possible that would approximately exhibit the relations of production to consumption.

Area.—The majority of the oil-seeds and oil-yielding materials enumerated in the opening paragraphs above are, however, regular agricultural crops, and accordingly appear in official statistics in some position or other. A few, such as the coconut, the mahua, the walnut, etc., are, however, trees, and can hardly be classed as regular agricultural crops. Another series afford oil-yielding seeds as a supplementary crop, such, for example, as cotton, hemp, safflower, poppy, tea, etc. The others in Agricultural Statistics would, therefore, not include these by-product oils, but would consist of the minor oil-seeds proper, such as earth-nut, niger and castor. To the areas returned as oil-seeds would, therefore, have to be

815
added some portions of the acreages returned under cotton, hemp, poppy, etc., and an estimate made for the areas of the oil-yielding trees, before a full conception could be obtained of the total area of India normally concerned in its oil traffic. But taking the statistics of the oil-seeds as published, the area devoted to these crops would seem to have expanded considerably within the past few years. In 1899–1900 the total came to 10,327,641 acres in the British Provinces alone, in 1903–4 it had expanded to 14,545,966 acres, in 1904–5 stood at 13,518,768 acres, and in 1905–6 was 12,501,253, with, say, another million acres in the Native States. But to that vast area would, as just explained, have to be added some portion of the land devoted to cotton (which for the years 1904–7 has averaged 21 million acres), as also the area under all the other plants enumerated above that, like cotton, afford oil-seeds as by-products.

Of the more important oil-seeds it may be said that til or jinjili (Sesamum indicum) is the most abundant and most widely cultivated of all. It occupied, according to the Agricultural Statistics, over 4 million acres in 1904–5, distributed chiefly in Burma, the Central Provinces, Madras and Bombay (including Kathiwar and Baroda). Then come rape and mustard with almost 3½ million acres, mostly in Bengal and the Panjáb. Lastly, linseed, a good third, with some 3 million acres, very largely in Bengal, the United Provinces and the Central Provinces. The final reports issued by the Commercial Intelligence Department estimate the areas for 1906–7 under these crops as follows:—rape and mustard, 4,196,500 acres (pure) and 2,210,000 acres (mixed); sesamum, 3,863,100 (pure) and 775,000 (mixed); linseed, 3,028,200 acres (pure) and 663,000 acres (mixed); but in the case of sesamum the area for Burma is not included. Linseed is the rent-paying oil-seed crop, only about 6 per cent. of the annual average outturn being retained in the country. The other two crops, til and mustard and rape, are very much more largely consumed locally, and are accordingly not so immediately influenced by the fluctuations of the foreign markets. But a disturbing element in estimates of area and production occurs, as already partially indicated, in the very large export trade in cocoanut oil, and in the material (kopra) from which that oil is expressed, through the fact that no area of production can be given for these products. Moreover, kopra (or dried cocoanut kernel) is exported, to some extent at least, as an article of food. It is at all events not treated as an oil-seed in any of the official returns, though it affords an important oil.

Traffic.—Turning now to the official publications that furnish information regarding the internal trade, we learn from the returns of rail-borne goods that the most important receiving province is ordinarily Bengal (an average of over 1,100,000 cwt. for the years 1902–7, drawn chiefly from the United Provinces and Calcutta). Next the Panjáb, with an average of about 1,000,000 cwt. for the same period), depends upon the United Provinces almost exclusively for its external supplies, which, moreover, are chiefly classed as Other Oil-seeds. Then comes Madras with an average of about 400,000 cwt. Lastly, Bombay imported during the same period an average of about 400,000 cwt. of oil-seeds of all kinds, chiefly from the Nizam’s Territory and Mysore. But the internal transactions of the provinces (the strictly local trade) is normally only 3½ million cwt. (for example, 3,478,180 cwt. in 1904–5 and 3,307,669 cwt. in 1905–6), while the receipts of the port towns came in 1904–5 to 30,890,818 cwt., in 1905–6 to 18,075,155 cwt., and in 1906–7 to 20,804,457 cwt. This is
the supply that meets the foreign exports. It is drawn of course from the provinces, but is consigned direct to the ports, hence does not appear in the inter-provincial transactions. Calcutta and Bombay practically divide the traffic between them. Bombay in 1904–5 (the year with the largest imports during the past five years) took 13,986,721 cwt., of which 4 million came from the Central Provinces and Berar, 3½ million from the United Provinces, 2½ million from the Presidency of Bombay, 1½ million from Rajputana and Central India, and 2½ million cwt. from the Nizam’s Dominions.

The traffic with Calcutta, on the other hand, amounted in the same year to 11,165,255 cwt., of which 6½ millions came from the province of Bengal, 4 from the United Provinces, and the balance from the Central Provinces, Rajputana and Central India. The figures for 1904–5, however, were exceptionally high, and in the succeeding years were respectively—Bombay, in 1905–6, 7,289,797 cwt., and in 1906–7, 8,550,004 cwt.; and Calcutta, 6,228,115 cwt. and 6,420,501 cwt. Of the other port towns that participate in the foreign trade in oil-seeds it is hardly necessary to go into such details since the amounts are so very much smaller. Karachi, in 1904–5, drew 2,870,569 cwt.; in 1905–6, 1,826,106 cwt.; and in 1906–7, 2,972,222 cwt. almost entirely from the Panjâb, while Madras took in 1904–5, 2,868,273 cwt.; in 1905–6, 2,731,138 cwt.; and in 1906–7, 2,856,730 cwt. in the same years from its own Presidency and the Nizam’s Territory.

Turning now to the returns of coastwise trade. The oil-seed traffic in 1904–5 came to 1,294,166 cwt., valued at Rs. 79,23,531 (or £528,235), and in 1905–6 to 1,552,904 cwt., valued at Rs. 1,12,35,391 (£749,026). The most significant feature may be said to be that the chief oil-seed of these returns is sesamum (til), 431,386 cwt. having been exchanged inter-provincially in 1905–6. Of this, Burma took 316,372 cwt., the bulk being derived from Madras. The traffic in castor is also worthy of special comment. Of the total 220,419 cwt. exchanged, 143,429 cwt. were taken by Bengal, the major portion being derived from Madras. The next most important item is the supply of castor drawn by Bombay, which in the year in question came to 51,755 cwt.

**OILS.**—It has already been pointed out that the **Exports** in oils have manifested a considerable expansion, namely, in the case of fixed oils, from a valuation of £190,333 in 1876–7 to £359,965 in 1905–6, and in 1906–7, £311,820; and in essential oils from £12,008 in 1876–7 to £47,421 in 1905–6, and in 1906–7, £54,183. But by far the most important vegetable oil (exported from India) is that of the cocaanut. The total exports of that oil during the years 1902–7 have ranged from about one to three and a quarter million gallons, or, say, a valuation of from 14 to 49 lakhs of rupees (£85,952 to £325,439). The supply goes almost exclusively from Madras, and is consigned in three nearly equal portions to the United Kingdom, Germany and the United States—the only other country of importance being Belgium. The exports of linseed oil go almost entirely from Bengal, and to a very large extent represent directly the operations of the Gourapur and other oil-mills in the neighbourhood of Calcutta. The exports are consigned chiefly to Australia and New Zealand (see p. 731).

The internal traffic in oils (as manifested by the rail-borne transactions) is also interesting. Excluding kerosene, the total exports in 1906–7 came to 1,712,165 cwt. The most important is mustard and rape (726,506 cwt.), followed by “others” (638,489 cwt.); then by cocoanut (199,272 cwt.)
and by castor (147,898 cwt.). Of the traffic in mustard and rape the most significant feature may be said to be the large exports to Eastern Bengal and Assam and to Bengal proper from Calcutta. This is the direct manifestation of the oil-mills within the city, which in the year in question drew 2,353,389 cwt. of mustard and rape seed chiefly from the United Provinces to be used up in the manufacture of oil. The most significant feature of the coastwise transactions is the very large trade done in cocoanut oil. The total traffic coastwise in 1904–5 came to 8,730,737 gallons, valued at Rs.1,25,84,419 (£838,961). Of that amount fully half was cocoanut exported from Madras into Bombay and Bengal (each taking approximately 2 million gallons), and Burma 770,000 gallons. So in 1905–6, the total traffic was 10,008,074 gallons, valued at Rs. 1,53,73,114, the exports of cocoanut being 4,612,490 gallons, valued at Rs. 70,62,430.

**OIL-CAKE (Poonac).**—Incidental reference has been made to the objection to exporting oil-seed, instead of expressing the oil in this country and retaining the cake. But it may be contended that the present traffic is perhaps not quite so unsatisfactory as it might at first sight be supposed. In the present state of Indian agriculture oil-cake is less in demand than in Europe, and accordingly it may be more profitable to export the seed than were the oil expressed and dependence placed on the Indian markets for the disposal of the cake. As against that contention it may be urged that the surplus cake might be exported as a regular commercial article. India is at present, in fact, doing a fairly large trade in exporting oil-cake. In 1877–8 these exports were valued at Rs. 4,30,399; in 1901–2 at Rs. 29,84,239; in 1902–3, Rs. 34,22,616; in 1903–4, Rs. 39,18,460; in 1904–5, Rs. 43,08,621; in 1905–6, Rs. 51,99,194; and in 1906–7, Rs. 35,89,740. In 1905–6 a new item, consisting of oil-cake for manure, valued at Rs. 16,99,186, appeared, and in 1906–7 this became Rs. 40,09,381. [Cf. Mollison, *Agri. Ledg.*, 1899, No. 12.]

The present traffic in oil-cake is comparatively unimportant. The total amount carried by the railways came to 1,864,415 cwt. in 1904–5; 2,182,405 cwt. in 1905–6; and 2,008,579 cwt. in 1906–7. Calcutta and Madras (the seats of the oil industry of India) are necessarily most concerned in the exports. Calcutta supplied 810,158 cwt., and Madras 637,946 cwt. The Calcutta supply went chiefly to the province of Bengal, and the Madras to its own port towns. The exports coastwise were in 1904–5 returned at 220,000 cwt. and in 1905–6, 112,005 cwt., the bulk being consigned from Madras to Bombay.

**Oil-mills.—**The fact that India exports so large a quantity of oil-seeds and again imports a considerable amount of vegetable oils, has often been commented on as one of the directions of future reform. The loss to India through this circumstance may be said to be twofold:—(a) the loss of lucrative employment; (b) the loss of oil-cake that should more largely than at present be retained in India. Still it cannot be said that no progress has been made by India. In 1895 there were 163 oil-mills that gave employment to 3,368 persons, and in 1900 these had expanded to 212 mills and 5,084 employees. Recently the data of official returns have been changed: only mills that employ 25 or more persons are recorded. This has had the result of making a serious reduction in the number of oil-mills supposed to be at work. In 1903 there were by the new system 109 mills, 11 being worked by steam, with the total number of persons employed 4,985; and in 1904, 112 mills and 5,200
CANDLES AND SOAP

persons. The suburbs of Calcutta literally teem with private castor-oil mills. As manifesting their importance, it may be explained that while Calcutta exports a large amount of castor oil, practically no castor-seed leaves Bengal to foreign countries. Exports of castor-oil seed are made mainly from Bombay.

A detailed enumeration of the oil-mills of India would dispel the erroneous opinion that India is doing nothing in the direction of meeting its home markets for oils. A distinct advance has been made and is being maintained in every corner of the Empire.

**CANDLE AND SOAP MAKING.**—These are modern industries that are rapidly becoming of considerable importance. A striking evidence of the prosperity of the Burma candle trade may be had from the existence of an export trade in candles.

**Candle-making in India.**—Except in the new industry of manufacture of candles from the mineral wax and paraffin that has recently assumed considerable proportions both in Rangoon and Calcutta, India cannot be said to possess candle works of any great importance. Here and there all over the country the batti-saz still plies his craft of “tallow dip” making, but very few of these workers form candles by moulding. In Lahore and Bombay, candles are crudely moulded, and from time immemorial the art of rolling wax candles has been known and practised. One or two soap works have given attention to candle-making, but, as a rule, they employ mineral wax, and their candles have accordingly to be considered along with petroleum. (See Lime, p. 712.)

While India, as a whole, is very far behind other countries in the production of candles, the demand for these articles is very considerable. **Indian Imports:**—The United Kingdom and Belgium are the sources of supply, and the provinces that receive these are, in sequence of demand—first Madras, next Bombay, then Bengal, and lastly Burma. The imports have fluctuated between 8 and 12 lakhs of rupees in value each year during the past twenty-five to thirty years. It may be here added that Burma has, however, begun recently to export candles, and these are of course entirely mineral. The **Exports** were in 1900–1 valued at Rs. 15,157; in 1901–2, at Rs. 49,703; in 1902–3, at Rs. 4,41,863; in 1903–4, at Rs. 9,05,521; in 1904–5, at Rs. 9,48,156; in 1905–6 at Rs. 16,53,646 (in which year the share of Burma was Rs. 16,37,755); and in 1906–7, Rs. 14,20,943. This traffic is mainly with China, the Straits Settlements, Ceylon, Australia and New Zealand, and is thus a new feature of India’s manufacturing enterprise. (See Cocos, p. 359; Rhus, p. 914.)

**Soap.**—As already observed, to the Natives of India as a whole, soap is not of much importance, and soap substitutes (natural earths or vegetable materials), as a rule, take its place. Still, the art of soap-making has been known and practised from a remote antiquity, the impure article produced being used by the washermen and dyers. Trade statistics show, however, that India’s demands on foreign countries for soap are very considerable and yearly expanding. In 1876–7 the **Imports** were valued at Rs. 3,32,791; in 1901–2 at Rs. 17,61,427, or an annual average expansion of 17 per cent.; in 1902–3 a still greater expansion, the imports having been then valued at Rs. 22,67,801; in 1903–4 they became Rs. 26,56,673; in 1904–5, Rs. 27,23,705; in 1905–6, Rs. 31,90,890; and in 1906–7, Rs. 32,28,156. Almost one-half the total imports are, as a rule, taken by Bombay, one-quarter by Bengal, and of the remaining quarter about one-half goes to

819
OILS, OIL-SEEDS AND PERFUMERY

Trade

Burma. At the same time India exports soap, though the traffic is not extensive nor very prosperous. [Of. A. Watt, Art of Soap-Making, 1901; see also Eggle Marmelos (p. 27); Agave (p. 35); Alkalis (p. 49); Cinnamonum (p. 313); Cocos nucifera (p. 359); Fish (p. 547); Pinus (p. 890); Rosa (p. 926); Sesamum (p. 986).]

**ESSENTIAL OILS AND PERFUMERY.**—This classification is convenient rather than logical. The separation between perfumes, cosmetics and condiments is often extremely difficult and even sometimes undesirable. Though most of the articles indicated may yield oils chemically, they are often used without having their oils extracted from them, just as sesamum seeds are eaten in certain Native sweetmeats, where they serve a purpose similar to the raisins and caraways in European cakes.

The Imports of essential oils, essential seeds and of perfume are of far less consequence than the exports. In 1901–2 the combined imports were valued at Rs. 5,11,456; in 1902–3 at Rs. 4,96,622; in 1903–4 at Rs. 6,56,617; in 1904–5 at Rs. 5,88,633; in 1905–6 at Rs. 5,94,433; and in 1906–7, Rs. 6,34,111. The Exports were valued in 1901–2 at Rs. 22,44,404; in 1902–3 at Rs. 20,66,970; in 1903–4 at Rs. 20,71,940; in 1904–5 at Rs. 23,50,385; in 1905–6 at Rs. 29,46,855; and in 1906–7, Rs. 28,98,944. It is interesting also to observe that the exports of essential seeds have been steadily improving for some years. In 1876–7 they stood at Rs. 29,437; in 1901–2 at Rs. 14,58,241; in 1902–3 at Rs. 11,83,190; in 1903–4 at Rs. 12,32,950; in 1904–5 at Rs. 16,09,137; in 1905–6 at Rs. 20,74,818; and in 1906–7 at Rs. 19,20,257. The chief seeds exported under this heading are Caraway (p. 284); Ajwain (p. 285); Coriander (p. 427); Cumin (p. 443); Fennel (p. 552); Niger (Nigella, p. 811); Aniseed (Pimpinella, p. 887); Fenugreek (Trigonella, p. 1081); and the like.

**Perfumery** is one of the most ancient and honourable of Indian crafts, and one which attains greatest importance at the present day in Northern India. It is perhaps hardly necessary to go further back than to the A’in-i-Akhbari (Blochmann, transl, 73–89, etc.), where we read that the great Emperor encouraged and fostered the art of preparation of perfumes and scented oils. This gives the suggestion of the two methods of separating perfumes having been known from very ancient times, namely enfeurage and distillation. One of the earliest and most instructive accounts of the former, as far as India is concerned, was written by Dr. Jackson of Ghazipur, in a letter to the editor of the Asiatic Journal of Calcutta for June 1839 (in Edinb. New Phil. Journ., 1840, xxix., 198–9).

The following describes the method pursued in the preparation of jasmine.

"The Natives never make use of distillation, but extract the essence by causing it to be absorbed by some of the purest oleaginous seeds, and then expressing these in a common mill, when the oil given out has all the scent of the flower which has been made use of," Dr. Jackson gives particulars of the operation—layers of sesame seed (see p. 986) "wetted" in water alternating with layers of jasmine flowers are covered over with a cloth and left for twelve to eighteen hours. It may be added that, according to modern European experience, jasmine is one of the perfume-yielding products that must be treated by enfeurage, as it does not yield its perfume in water-distillation.

Turning now to the distillation process, Hoey (Monog. Trade and Manuf. N. Ind., 107–8) gives an interesting account of the gandhi or itarfarosh and his art and trade. He buys flowers from the mals (gardeners) and manu-
facts from these, by distillation, their respective perfumes. Into the still is placed the *admin* or *mawa* of all *itur*, viz. sandal *itur*, manufactured at Kanauj. The flowers are thrown into the cauldron on the fire and their perfume comes off in steam and passes through the worm into the copper *bhagka*, and there combines with the sandal *itur*. On cooling, the perfume is separated from the water by skimming the surface. In some localities, in place of sandal, lemon-grass is used as an adjunct, especially in the production of attar of roses.

Jaunpore and Ghaziapur might be described as the chief manufacturing localities, Delhi, Amritsar and Lahore the distributing centres, and Bombay the emporium of foreign transactions. The following are some of the more important ingredients and materials in Indian perfumery:—Cassie (*Acacia Farnesiana*, p. 14); Bael (*Eugle Marmelos*, p. 27); Galangal (p. 60); Himalayan Dhup (*Jurinea*); Altingia (p. 61); *Aquilaria* (p. 72); Arachis (p. 82); *Cinnamomum* (pp. 315–6); *Citrus* (p. 327); *Lemon, Rusa, Citronella Oils*, etc. (pp. 451–62); *Jasminum* (motiya, jufi, and chambeli); *Michelia* (champa); *Mimusops* (maulsari); *Lawsonia* (henna, p. 707); *Hang-ilang* (*Cananga*); *Keura* (*Pandanus*, pp. 188, 777); *Musk* (p. 786); the Spikenard (p. 792); *Patchouli* (*Pogostemon*, p. 904); *Rose Attar* (p. 926); *Sandal-wood* (p. 977); *Kut* (p. 980); *Sesamum* (p. 986); *Vetiveria* (p. 1106). [Cf. Sawer, *Odorography*, 1592; *Scient. American, Cycl. Receipts*, 1899, 383–5; Gildemeister and Hoffmann, *Volatile Oils*, 1900; Hooper, *The Perfumes of the Moghuls*, in *Calc. Rev.*, Oct. 1904.]

The root-bark, with alum as a mordant, gives a beautiful red Dye, formerly much employed in Madras for dyeing handkerchiefs (the *bandana* handkerchiefs formerly famed). Though met with in Bengal, it is not used for dyeing in that province. It is somewhat extensively cultivated in sandy situations on the Coromandel Coast, as at Nellore and Masulipatam. Previous to sowing, the land is manured, generally by penning cattle or sheep, and thereafter thoroughly ploughed. The seeds are sown in August, on the ground having been well moistened. After sowing it is again watered, and the process repeated three times daily till the young shoots appear, when water need then be given less frequently. Cow-dung should be mixed with the water once a day for the first fifteen days. Extensive watering is the chief feature of the cultivation, but weeding has also to be constantly performed. The expense of cultivating an acre is naturally heavy (estimated at Rs. 28–7a.) compared with the returns.

Only the bark of the root contains the dye. The Natives consider the roots of the wild plant best, and prefer to make their collections at the end of the second year's growth. In dyeing, the Hindus use an aqueous solution of the colouring matter, obtained by pounding the root in water. The fabric is steeped several times in this solution, then boiled for two hours in a similar solution and finally washed with clean water and dried. Various attempts have been made to introduce the dye into Europe, but these have been unsuccessful, due probably to the fact that the root rapidly deteriorates when stored in damp situations. The tinctorial properties of the dye-stuff have been investigated by Hummel and Perkin. [Cf. Alexander Hamilton, *New Ace. E. Ind.*, 1727, i., 370; Milburn, *Or. Comm.*, 1813, i., 277; Heyne, *Tracts on Ind.*, 1814, 209; *Pharmacog. Ind.*, 1801, ii., 199; Hummel and Perkin, in *Proc. Chem. Soc.*, 1893, 291; 1895, 150; Holder, *Monograph. 821
OPUNTIA TURPETHUM, Manso; Prain, Beng. Plants, 1903, ii., 731; Cooke, Fl. Pres. Bomb., 1905, ii., pt. ii., 240; Ipomoea Turpethum, Fl. Br. Ind., iv., 212; Talbot, List Trees, etc., 1902, 251; Rec. Bot. Surv. Ind., 1904, iii., 81. CONVOLVULACEÆ. Turpeth Root or Indian Jalap, nisoth, teori, tohri, chita bánsa, nisottar, tikuri, shivdai, etc. Found throughout India, ascending the hills to altitudes of 3,000 feet; occasionally cultivated as an ornamental plant.

The root (also root-bark), known as trivrit, has been used as a purgative, by Native practitioners, from time immemorial. Varthéna (Travels, 1510, (ed. Halk. Soc.), 106–7) mentions it by the name of turbádi among the spices of Cambay, and García de Orta (1563, Coll., liv.; also in Ball, Proc. Roy. Ir. Acad., 1889–91, 3rd ser., i., 677) gives an account of the plant and the uses made of it. Two varieties have been described by most writers, sueta or white, and krishna or black. The white is preferred, as the black is considered too drastic. As sold in the bazára, Turpeth consists of the root and stem of the plant cut into portions of about one-half to two inches in length. The market rate is about 1½ to 1 anna per lb. [Cf. Forster, Pl. Esc., 1786, 77; Milburn, Or. Comm., 1813, i., 293; Paulus Eginetus (Adams, Comment.), 1847, iii., 445–6; Pharmacog. Ind., 1891, ii., 527–30; Dutt, Mat. Med. Hind., 1900, 203–4.]

OPUNTIA, Mill.; Fl. Br. Ind., ii., 657; Gamble, Man. Ind. Timbs., 1902, 382–3; Talbot, List Trees, etc., 1902, 180; Prain, Beng. Plants, 1903, i., 531; CACTEÆ. Several species have been introduced into India and are now quite naturalised. In many portions of the hotter regions, such as in Madras, Bengal, the United Provinces and the Panjáb, they have overrun immense tracts of country, and their eradication has in some cases become a serious problem. For their connection with the Cochineal insect, see Cocos caeti (p. 348).

O. Dillenii, haw. The Prickly Pear, nág-phaná, pheni-mama, sámar, zhór-hátheylo, nága-dal, chappal, sha-song, lit wa, etc. This is the only species described in the Flora of British India. It is indigenous in America, but naturalised all over India from Bengal and Madras to the Panjáb, and found on the Himalaya up to 5,000 feet in altitude. The fruit is edible, and can be employed in the distillation of alcohol. The jointed, juicy, leaf-like stems, when deprived of their spines, have generally been considered a useful CATTLE FOOD, especially in times of famine. Mr. P. R. Mehta, however, in a report on prickly-pear feeding experiments carried on at the Poona and Surat Farms, gives a poor estimate of its feeding value. He states that the experiments conclusively prove that the prickly pear has hardly any value as a cattle food. A sample analysed by Leather gave the following result:—water, 18.96 per cent.; organic matter, 60.64; ash, 22.40. Hooper furnishes the following composition of the fruit from Nilgore examined by him:—carbohydrates 41.89; fibre 32.00; albuminoids 6.25; fat 3.83; water 5.67; and ash 10.66; (Rept. Labor. Ind. Mus. (Indust. Sec.), 1904–5, 30).

In India the plant is much used to form hedges about fields and for fences round homesteads. Gambale states that the chief interest in Opuntia, to the Forest Officer, has been in the hope that it would assist in the reproduction of forest trees, by protecting the young seedlings from cattle. A coarse Fibre can be obtained from it, which might prove useful as a paper material. [Cf. Mason, Burma and its People (ed. Theobald), 1883, ii., 441; De Candolle, Origin Cult. Plants, 1884, 274; Asa Gray, Scient. Papers, 1889, i., 312; Kew Bull., 1888, 105–73; Pharmacog. Ind., 1894, ii., 99; The Scrub Exterminator, Agri. Dept. Madras Bull., 1891, 23; Voelecker, Improv. Ind. Agri., 1893, 193–4; Bourne, Rept. on Destroct. of Prickly Pear by Cochineal Insect, Offic. Govt. of Madras Rev., Aug. 5, 1897; Dodge, Useful Fibre Plants of the World, 1897, 253; Maiden, Study of Prickly Pears Naturalised in New S. Wales, Dept. Agri. Sydney, Misc., 1895, 253; Wodrow, Gard. in Ind., 1899, 336–7; Mehta, Prickly Pear and Aloe as Cattle Fodder during Scarcity, in Dept. Land Rec. and Agri. Bomb. Bull., 1903, No. 22.]

While botanical writers have described some twenty species of the genus Oryza, Bentham and Hooker (Gen. Pl., iii., pt. ii., 1117) say that scarcely five of these can be easily distinguished and even these are very generally viewed as varieties of but one species, O. sativum, Linn. The chief forms are met with in the East Indies, though some are indigenous to Australia and most have been widely cultivated from ancient times in the warmer regions of both hemispheres.

Species and Varieties.—There may be said to be four fairly easily recognised forms of Oryza in India:—

Oryza coarctata, Roxb., Fl. Ind., ii., 206; O. triticaoides, Griffiths, Notulae Pl. Asiat., 1851, pt. iii., 8; Icon., t. 147; Prain, l.c.; Fl. Br. Ind., viii., 93. It is known as naiot (Indus valley), nataba (in Burma); maniklat (the plant), and baririhan (the grain) in Patuakhali, Dacca.

In this grass the margins of the leaves are spinoso-serrate. It frequencies the margins of rivers and is essentially an aquatic plant. Griffith had grave doubts as to the propriety of treating it as a species of Oryza, and suggested the genus sclerophyllum. Roxburgh gives the delta of the Ganges as its habitat, and says it was first discovered there by Buchanan-Hamilton in 1796. He then adds that he had failed to find that the plant was put to any economic use or to discover an Asiatic name for it.

In 1895 Mr. J. E. O’Conor (at that time Director-General of Statistics) proposed to have all the articles of official returns that appeared under “Others” investigated. He undertook to have specimens sent to me for determination. Almost the first, under edible substances, that came to hand was a cereal from Karachi. This was stated to be a wild grain collected from the swampy margins of the Indus and carried all over India to be eaten by the Hindus during certain ceremonial occasions. At first sight it looked like a form of wheat, but Sir George King and Lieut.-Col. D. Prain, who kindly examined it with me, suggested that it most probably would prove a form of rice. Botanical specimens came to hand in June 1895, and were at once seen to be the long-lost species O. coarctata, Roxb., which, because of its resemblance to wheat, had also been called O. triticaoides. Through subsequent investigations this interesting plant was found prevalent in the Indus valley; nowhere in the river basins of South India; occasional in the Sundribas (Saugor Island) and the lower Gangetic basin; and common near Khaton and Moulmein in Burma. It seems probable, however, that the resemblance of the grass to wheat may have originated the belief that wheat was indigenous to the Indus basin. Thus, for example, De Candolle (Orig. Cult. Plants, 356) while discussing the origin of wheat, observes that “Strabo (ed. 1707, ii., 1017), born 50 B.C., says that, according to Aristobulus, a grain very similar to wheat grew wild upon the banks of the Indus on the 25th parallel of latitude.” And it is certainly remarkable that until the discoveries briefly narrated above, the wild rice of the Indus should have remained unknown to the botanical world while it was actually being traded in all over India.

Samples of the naiot rice were sent to Church (Food-Grains of India, suppl., 1907, 5) for chemical examination, and the result showed that it is by no means an unwholesome article of food, though the edible portion, relatively to the husk and fibre, is exceptionally low. The nutrient ratio was found to be 1:7-6, while the nutrient value worked out at 84.9

O. granulata, Nees. A species found on dry soils at altitudes up to 3,000 feet. Specimens have been collected from Sikkim, Assam, Burma, Bengal (Parinatham and Râjmâhal hills), Malabar and Courtallam. It is perennial with almost woody root-stock and thin, round, firm, branching stems. The surface of the inner glume, though glabrous, is rendered woolly-looking through the presence of irregular roundish granulations.

ORYZA SATIVA

Assam and Burma Wild Rice.

O. latifolia, Desv., Journ. Bot., 1813, i., 77; O. officinalis, Wall. A tall, sparsely branched species with very broad multi-nerved leaves and profuse (almost umbellately) branched panicles; surface of inner glume composed of parallel bands of squarish corrugations. The area of distribution, from the records of its collection, may be given as from Sikkim and the Khasia hills, Assam (Gowhatty), to Burma (Pegu and Arakan). It is in Akabar known as daung-saba, and in Mergui as natsaba.

Cultivated Rice.

O. sativa, Linn. The Cultivated Rice, dhan, chával, uri, sáthi, munji, sháli, marr, dăngar, bhatta, tándula, arishi, nellü, biyam, akki, saba, etc. Cultivated throughout India, but often met with also wild (or at all events feral) wherever marshy land occurs in tropical regions. The chief area of the Indian wild forms may be given as from Madras and Orissa to Bengal, Chittagong, Arakan and Cochín-China. Roxburgh was so satisfied that the wild stock was the parent of the cultivated that he described it alone, and gave only a few of the chief features of the cultivated forms known to him. Though the task of separating the wild and cultivated states into varieties or races is by no means easy, the wild forms examined by me may be here briefly indicated:—

Var. α ruflpagon. This seems to correspond to the plant of that name described by Griffith. No specimen of Griffith's plant is known to exist, but it is probably the source of the red-coloured rice of India.

Var. β fatus; Prain, Beng. Plants, ii., 1184. This is apparently the plant that I distinguished in the Dictionary as bengatensis. Under this come by far the major portion of the submerged rice. It is the type most commonly spoken of, moreover, as "Wild Rice," being found on the margins of tanks (jales) or frequently deeply submerged fields in Bengal, Madras and Burma. Its most general name is uri or jhara, but from Madras have come samples under the names nirvari or nivaru, and from Burma daung-saba, daik-saba, nat-saba and pavo-shuc-hmat, names often also given to O. latifolia. Wild rice is met with both bearded and beardless, as also red, white or almost black in colour. In fact, the grains of the wild and cultivated plants cannot be distinguished except perhaps by the cultivators, who in this matter seem to possess an intuitive knowledge. C. B. Clarke said, "I do not know how, in the young state, the cultivator tells the uri from the aman. I cannot."

Double Rices.

Var. γ plena. This is given by Prain to include the "Double Rices." A cultivated rice exists in Chittagong with from 2 to 7 ovaries.

Tank Rice.

Var. δ abuenis. Probably the most temperate form of wild O. sativa as yet collected. It is a much smaller plant than the prevalent wild form (β), and may be the source of many of the best qualities of awnless chotan aman or rowa rices of Bengal and of the superior qualities of Upper India, Madras and the hills generally. This is probably the plant of which there was a good deal written some short time ago under the name of "Hill Rice."

The names thus suggested for the above four forms of wild O. sativa are purely provisional, since the classification by no means provides a place for all the distinctive forms of the cultivated plant. Roxburgh adopted what is perhaps the most convenient classification of the latter, viz. a system based on their peculiarities of cultivation, the early and the late rices. He specialises sixteen forms. The late rices are the "great crop." Of these, he mentions eight all of which are awnless and afford, when cleaned, white grains. Of early rices, four are awned and yield red or coloured grains; one is awned but yields a white grain, while three are awnless and afford white grains. Of the late rices, four have coloured and four white husks; of the early, six have coloured husks, two are white or pale. The general conclusion to be drawn from an analysis of Roxburgh's cultivated rices shows that the progression in value is from the awned to the awnless forms, and from the coloured to the colourless.

Progression of Awned to Awnless.

History.—Writers are agreed that the earliest mention of rice cultivation is connected with China, where, according to Stanislas Julien, a ceremony was established in 2800 B.C. by Emperor Chin-nung, in which the sowing of five kinds of grain, one being rice, is the chief observance. This, together with the well-known adaptability of large portions of China to rice cultivation, led De Candolle to presume the plant may have been a native of that country. He does not,
however, restrict its wild habitat to China, but admits it has been found both in India and Australia under such conditions as to allow of little doubt that it is native to these countries as well. De Candolle simply affirms that rice cultivation in India, though subsequent to that of China, has been a valued crop since the classic period. It is pointed out in the Dictionary that in spite of the temptation to derive the Arabic (al-ruzz, aruzz, uruzz, wiz, etc.), Greek (ōriza) and European names (rice, rício, ris, etc.) from the Tamil ari, modern philologists are agreed that they cannot be so derived, but come from the old Persian word vīrina or vinrīna, the modern equivalent of which is birīnī. Sir C. J. Lyall states (D.B.P., l.c. 518) that vīrina is exactly the equivalent we should expect of the Sanskrit word for rice, wṛhi, and the names point to the time when the two branches of the Aryan race dwelt together and developed the respective peculiarities of their languages from a common or original tongue. The Persians did not borrow the cultivation of rice from the Indians; the plant existed in the region where the two races dwelt together before their respective migrations. In other words, there is no evidence to show that its cultivation in Southern Asia was not so ancient as to have allowed of its diffusion into the Aryan home at a period prior to the division of that branch of the human family. The chief objection to this hypothesis, viz. the absence of any pointed allusion to so valuable a plant in the earliest Vedas, is not serious, since a pastoral people, like the early Aryan invaders, may not have appreciated its importance till they settled down and took to agricultural pursuits. Perhaps the oldest actual samples of rice are those collected by Stein at Kara-dong (Ancient Khotan, 1907, 448). These would appear to have been engulfed by sand about the close of the 8th century. Then, approximately in the same part of Eastern Turkestan, was found The Bower Manuscript (Hoernle, transl., 123-4), believed to date from about the 5th century. In that work frequent mention is made of "fried paddy" in the production of a drug used in the cure of coughs.

It may be repeated, however, that the chief wild habitat of the plant to-day is roughly from Southern India to Cochin-China—we have no record of its existence as a wild plant in Turkestan or anywhere in Central Asia. But in passing, it may be added that the habitat of the wild plant in India coincides with the region through which the Dravidian invaders passed till they culminated in the Tamil civilisation. Cultivation appears, in fact, to have spread eastwards to China perhaps three thousand years before the Christian era, and, at perhaps a slightly more recent date, westwards and northwards throughout India to Persia, Central Asia, Arabia, and ultimately to Egypt and Europe. An early record of the exports of rice from India is the passage in the Erythrean Sea (ed. McRindle, 113). This may be put at 60 A.D., and refers to Gujarat. [Cf. Acc. Ind. and China by Moh. Trav. in 9th Cent. (Renaudot, transl.), 1733, 13; Vortomannus, Travels, 1503, in Hakl. Voy., iv., 1811, 577; Ain-i-Akkari, 1590, (Jarrett, transl.), ii., 121, 350; Pyrrard, Voy. E. Ind., 1601 (ed. Hakl. Soc.), i., 326-7, etc.; Jahangir, Memoire (Price, transl.), 1829, 98; Mandesilo, Voy. E. Ind., in Olearius, Hist. Muscovy, etc., 1602, 62, 68; Fryer, New Acc. E. Ind. and Pers., 1675, 110; Tavernier, Travels (ed. Ball), 1676, i, 382, 391, etc.; Herbert, Travels, 1677, 310 and t.; Alexander Hamilton, New Acc. E. Ind., 1688-1725, i., 161; Ovington, Voy. to Suratt, 1698, 397; Symes, Emb. to Ava, 1800, ii., 307; Turner, Emb. to Thibet, 1800, 24-6; Joret, Les P. dans L'Anat., etc., 1904, ii., 242-314.]

**PROPERTIES AND USES.**—The grain of rice is one of the chief articles of human food throughout India, while in many parts (e.g. Manipur) it was in 1882 one of the chief foods given to horses and even to cattle, and throughout India the straw of the better qualities is invariably collected, cut into small pieces and given to cattle, along with several flavouring liquid preparations, oil-cake or grain, designated the currie stuffs. The chaff and waste obtained in winnowing and husking also constitute important articles of human and cattle food. But husking is a troublesome process. In India a large part of the rice sold in shops and exported to Europe as an article of human food has been prepared by being first half boiled, then dried in the sun, and finally husked by the ordinary pestle and mortar. Such rice is, in trade, termed "par-boiled." Husking without boiling is a tedious process when done by hand. In Yarkand there is a mechanical contrivance for husking rice in which water is the motive power. In the plains of India, rice is frequently husked by the same appliance as is used in pounding bricks. A pestle suspended from the end of a beam, worked by the foot, is made to fall with considerable force on the grain. A woman, standing at

the further end of the heavy beam, alternately rests and removes her weight from its extremity, thus causing the pestle to rise, then fall on the rice, while a second person attends to the grain, sweeping it into a little mound under the stroke of the pestle.

The preparations of rice made in India are very numerous. Dutt (Mat. Med. Hind., 1900, 268-9) gives the vernacular names of various medicinal ones and their properties. Their use in brewing and distilling is, in India, almost universal. Sprouts from rice (sura) are alluded to by Linschoten as having been largely consumed in Southern and Western India three hundred years ago, while sura is frequently mentioned in the Institutes of Manu—a work written (the earlier portions of it, at least) some fifteen hundred years ago. At the present day a kind of beer (pachwai) made from rice is extensively consumed. [Cf. Ray, Hindu Method of Manuf. Spirit from Rice, in Journ. As. Soc. Beng., n.s., 1906, ii., No. 4, 129-42.] See Malt Liquors (pp. 757, 760), Spirits (pp. 1043, 1045, 1048), and Vinegar (p. 1111).

The properties and uses of rice are, in fact, extremely varied, and to the people of India an infinity of forms, many of which have each some special merit. A Dye is made from the husk, and the straw (even the stubble and roots) may be used in paper-making. (For Baskets, see p. 116; Mats, p. 776.) As an edible grain there may be said to be three chief grades—the finer qualities or table (Patna) rice: the lower grades suitable for distillation or for the manufacture of starch (Blount and Bloxam, Chem. for Engin. and Manuf., 1900, 186). The rices of Burma are employed for distillation (and for that purpose very largely go to Holland and Germany) and for conversion into starch (mainly to England). They are thick, coarse, highly glutinous rices, and when boiled assume a heavy, somewhat repulsive appearance to persons not accustomed to them. Such glutinous rices are, however, much prized in the manufacture of Cements. A special Indian cement is made from the water in which rice has been boiled, mixed with a small quantity of pumice (see p. 293). Rice Husk is utilized (Cew. Bull., 1892, 232-4) may be spoken of as an exceptionally glutinous grain.

Leather (Agri. Ledg., 1903, No. 7, 175-8) gives the following chemical analysis of rice: Undecorticated (fine sorts):—moisture, 12-55 per cent.; oil, 2-14; albuminoids, 6-35; soluble carbohydrates, 65-29; woody fibre, 7-84; soluble mineral matter, 1-89; sand and silica, 4-44; total nitrogen, 1-09; albuminoid nitrogen, 1-01. Decorticated (fine sorts):—moisture, 12-25 per cent.; oil, 9-2; albuminoids, 6-45; soluble carbohydrates, 78-83; woody fibre, 21; soluble mineral matter, 82; sand and silica, 51; total nitrogen, 1-19; albuminoid nitrogen, 1-03. Further analyses of coarser kinds of rice, rice husks, bran and straw, will be found in the same article. Following up these results, Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1906-7, 11) gives particulars of the comparative nutritive value and glutinoity of some of the chief kinds of rice. Certain forms were found to be more nutritious than previous analyses would indicate. Hanausek (Micro. Tech. Prod. (Winton and Barber's Transl. 1907, 42) gives interesting particulars of rice-grains as seen under the microscope. [Cf. Church, Food-Grains of Ind., 1886, 66; Dodge, Useful Fibre Plants of the World, 1897, 254; Browne, Prop. and Util. of Rice Oil in Louisiana, Planter and Sugar Manufacturer, 1905, xxxiv., 352-3; Excise Admin. Repts. Beng., Burma, etc.]

CULTIVATION.

Rice "is essentially a crop of damp tropical or semi-tropical climates. The finest varieties and the largest yields are produced in tracts which, during the growing season, afford a moderate degree of sunshine and a damp, warm atmosphere. Rice is therefore the staple crop of all areas of heavy and assured rainfall; but good crops are produced in districts which receive moderate or even light rain, when this can be assisted by sufficient irrigation."

"Rice is sown in three ways—broadcast, by drill and by transplantation from a seed-bed where it has been broadcast sown. As a rule, the first method is practised on inferior soils, or where labour is scarce. Rice is drilled in some districts of Bombay, but this system is not common. The third method is much more usual than the others and is less risky. Broadcast or drilled rice requires 80 to 120 lb. of seed per acre, while the seed-rate of the transplanted crop varies from 30 to 80 lb. per acre."
AREA UNDER THE CROP

"The yield in different tracts, from different soils, and from different methods of cultivation varies very greatly. In good soil an average transplanted crop yields probably about 2,400 lb. of paddy per acre in a favourable season. Broad-cast and drilled rice yield much less" (Imp. Gaz. Ind., 1905, iii., 26-9).

In recent agricultural statistics it is shown that the net area cropped in British India amounted, in 1905-6, to 207,683,741 acres. Of this, 73,400,522 acres were found to be under rice. In the Native States in the same year the net area cropped amounted to 12,015,009 acres, and the area under rice to 717,767 acres. Thus, out of a total area of 219,698,750 acres under crops, rice occupied 74,118,289 acres, or over one-third. But so large a percentage averaged for the whole of India is misleading. Rice is almost concentrated into Bengal. In fact, with the exception of Madras and Burm it is in the other provinces of India unimportant relatively. In the Agricultural Statistics (published by the Government of India) two sets of figures are given, viz. (a) the surveyed areas from which we obtain the total rice area of 73,400,522 acres; (b) estimates of area and yield framed by the local authorities (township officers, etc.). In the case of Burma, the local estimates are usually considerably below the surveyed areas (in fact, they do not deal with the whole of the province), but these estimates are instructive. The following are the figures (estimated) of the four chief rice areas for 1905-6:—Bengal, 25,150,600 acres; Eastern Bengal and Assam, 15,960,200 acres; Madras, 6,604,400 acres; Burma, 6,713,400 acres; giving a total of 54,428,600 acres and a yield of 433,138,300 cwt., and in 1906-7 a total of 54,521,600 acres and 430,258,600 cwt. In the case of Burma the surveyed area was 9,283,801 acres. The Final General Memorandum, issued by the Commercial Intelligence Department, estimates the total area in the four chief centres of production as having been in 1905-6, 54,428,600 acres, and the yield as 375,198,300 cwt. of cleared rice; and in 1906-7, 54,535,400 acres and 368,334,000 cwt.

Bengal (excluding Eastern Bengal and Assam).—Area.—The normal area cultivated with rice in the province of Bengal (according to the Season and Crop Report for 1905-6) has been estimated at 26,308,800 acres, and as the total area in Bengal under cultivation in that year amounted to 45,287,000 acres, it is thus seen that rice comprised over 58 per cent. of the actual cropped area of the province. The Final General Memorandum for 1906-7 stated the estimated area in Bengal as 24,506,200 acres, and the yield as 195,461,600 cwt. of cleaned rice. This represented 34:8 per cent. of the rice area of British India. The Season and Crop Report for 1906-7 gives the normal area as 25,919,600 acres, which would consist of 21,301,700 acres of winter rice and 4,617,900 acres of autumn rice. The forecast of the winter rice alone for 1905-6 shows a total of 20,043,400 acres, which represented 28:5 per cent. of the total area under this particular crop in British India. The corresponding estimate for 1906-7 was 19,845,300 acres of winter rice. The chief districts in 1905-6 were:—Midnapur, 1,365,300 acres; Ranchi, 1,240,900 acres; Gaya, 1,151,600 acres; Shahabad, 1,132,000 acres; Darbhanga, 961,400 acres; Cuttack, 952,200 acres; Hazaribagh, 950,400 acres; Manbhum, 929,100 acres; and Bardwan, 807,700 acres.

Eastern Bengal and Assam.—Area.—The Commercial Intelligence Department, Government of India, gives the extent of rice cultivation in 1906-7 (summer, autumn and winter crops together) as having been
THE RICE PLANT

ORYZA SATIVA
E. Bengal

16,105,800 acres as compared with 15,960,200 acres in the previous year. The total yield came to 122,476,700 cwt. This represents 23 per cent. of the total rice crop of India. The forecast of the winter rice for 1905–6 shows 12,226,200 acres, which represented 17·2 per cent. of the winter rice for the whole of British India. The chief districts were as follows: Bakarganj, 1,436,900 acres; Dinajpur, 1,160,000 acres; Maimensingh, 1,130,000 acres; Sylhet, 1,098,400 acres; Rangpur, 837,900 acres; Rajshahi, 636,900 acres; and Tippera, 614,300 acres.

Races Cultivated. — There are innumerable varieties of rice familiar to cultivators under various names, and possessing particular properties which make their cultivation suitable to particular localities. In the two provinces of Bengal, they may all be referred to three primary classes, according to the land on which they are grown, the season of year when reaped, and the period taken in coming to maturity. Thus:—

1. The Áman (or winter rice) crop, sown on low lands in May or June and reaped in December or January. This is by far the most important crop. (2) The ãus or bhadoi (in official statistics designated as autumn rice), or early rice crop, sown in April or May on comparatively high land and reaped in August or September. (3) The boro (or summer rice) crop, sown in swamps in January or February and reaped in April or May.

An important feature of the Bengal rice crop is the fact that a large portion of the area bears two or more crops a year, a circumstance that has led to the expression of a "vertical" as compared with a "horizontal" area. In fact, it has been pointed out that a proprietor of an estate with a fairly mixed soil might have three, four, or even five harvests of rice every twelve months:—(1) ãus, from July to August; (2) chaton áman, from October to November; (3) boran áman, from December to January; (4) boro, from April to May; and (5) raida, from September to October.

It has also been said that in many parts of Bengal, two crops are all but universal, hence it may be inferred how misleading a hard-and-fast percentage of rice area may be to the total cropped area. In the Indian Museum will be found a collection of rice made in 1872 and for some years subsequently. The collection finally brought together came to something like 5,000 forms. These are probably not all distinct, but even if halved, the number would still be sufficiently significant of the vast antiquity of the cultivation. A remarkable fact is that the ãus, Áman, and boro rice of one district are often so different from those of another, that if interchanged the one may not grow on the fields where the other has flourished for centuries. Here the European farmer is confronted with a problem scarcely known to scientific agriculture; for the rice-cultivator of India will detect the one from the other with a perfectly marvellous degree of certainty. In Burma a few forms only constitute the chief crop, and to these the milling apparatus now in use have been adapted, and to such an extent that it is believed the Burma machinery would be quite unsuited to Bengal, and, further, that milling in Bengal on the European method would be impossible, unless a particular rice could be guaranteed in sufficient quantity to justify the preparation of the required special machinery.

A. C. Sen gives an instructive account of the methods of cultivation in the Dacca district, and as that is more or less applicable to the whole of Bengal, as well as to Eastern Bengal and Assam, it may serve the purposes of this work better than a series of abstracts of the varying methods
in many districts. He divides the crops into three groups, subdividing each again into two sections. These are (1) áman, (a) long-stemmed and (b) transplanted; (2) aus, (a) ordinary and (b) lepi; (3) boro, (a) ordinary and (b) lepi.

**ÁMAN.**—Long-stemmed áman is extensively grown in Dacca. Low lands, the sides of jhils, and low plains on which 5 to 15 feet of water accumulate during the rains, are selected. The soil best suited is a stiff clay, deposited on the bottom and edges of jhils. At harvest-time only the ears with about 1½ feet of the straw are removed. The remainder of the straw is generally gathered in heaps and burnt, and immediately after the field is ploughed, generally in December. It is again ploughed once or twice and left exposed till March–April, when the larger clods are broken. One or two more ploughings and harrowings are given, and the field is ready for sowing in April–May. About 15 seers of seed are broadcasted over a *bigha* of land. In moist low-lying places, sowing takes place a month or even two months earlier, in February–March. Harvest is from 15th November to 15th January. When the seeds have germinated the field is rolled twice with the ladder, and when the plants are 5 to 6 inches high the soil is loosened by the rake. After this the only operation till harvest is a weeding, which may be dispensed with. The yield per *bigha* varies from 3 to 12 maunds.

Transplanted áman is grown on two different classes of land, in the upper reaches of the valleys of the Madhapur jungle and in the comparatively high land and old *dearahs* of the Brahmaputra and its branches. The *paddy* in the Madhapur valley is a special variety, known as *shaldan*; the transplanted paddy of other places goes by the general name of *rova*. Seedlings are prepared in a nursery close to the *rayia*’s homestead, or in a corner of the field. The nursery is ploughed four or five times in April–May, and the next month, when a little rain-water has collected on it, the surface is levelled and plastered. Meanwhile the necessary quantity of seed (6 seers for every *bigha*) is soaked in an earthen pot, drained, and kept covered with mats till it germinates; then it is sown broadcast so thickly that the grains overlap. When the seedlings are 12 to 18 inches high, they are fit for transplantation. In the case of jungle valleys, the first thing done before transplanting is to repair the embankments thrown across for collecting water. The field is prepared by ploughing in the mud two or three times. The seedlings are transplanted at the end of July about half a cubit apart either way, putting in three to four plants in the same place. The crop is harvested in November–December. In the case of *dearah* land, two ploughings are given in the dry field, as soon as the previous crop, generally *khesari*, is taken off. On such lands two rain-crops are sometimes grown in the same field in the same season. As early as possible the field is sown with jute or *aus* paddy. The jute or the paddy is harvested in July–August; then the field is ploughed and transplanted with the áman crop.

**ÁUS.**—This kind of paddy is grown (1) on the high grounds of the Madhapur jungle, where sufficient water cannot be collected for the cultivation of *shal* paddy; (2) on the comparatively high and sandy *dearah* lands. *Áus* paddy cannot be grown on land on which more than 2 feet of water accumulates during the early part of the rains. The land on which *aus* paddy grows is light and easily workable. It generally bears two crops in the year—*aus* paddy or jute during the rains and one
of the pulses or mustard during the cold weather. As soon as the rabi crop is off the field, it is ploughed and harrowed as rapidly as possible. Preparation must be hastened, especially on char lands, for here a late crop is sure to be lost by the rise of the rivers. Sowing time, therefore, varies. In the chars of Meghna, it may be sown as early as the middle of February; in the highlands of North Manikgunge it may be delayed till the middle of April. As soon as the plants appear the field is rolled with the ladder, and a week after harrowed with the rake. After this it must be carefully weeded. Harvest extends from the middle of July to the middle of August.

**Boro.**—The places in Dacca where this class of paddy is most extensively grown are (1) the sides of the jhils and streams of the Madhupur jungle; (2) the chars and edges of the Meghna and its branches; (3) in some of the chars of the Padma. The soil best suited is a mixture of clay and vegetable matter. As soon as the rains are over, a plot, from which the inundation water has just reeded, is chosen for a nursery, aquatic grasses, etc., are removed, and the place worked into a soft mud. The seed is made to germinate and then sown broadcast. Thirty seers of paddy sown on a quarter bigha of land give seedlings sufficient for transplanting two bighas. The time for sowing is usually about the middle of October, and for transplanting, December-January. No tillage is generally needed for boro paddy. The harvest time is April-May and the yield per bigha 5 to 12 maunds.

**Assam.**—By way of affording a comparison with the particulars already given regarding Bengal as a whole, the following brief statement of the Assam Valley may be furnished. Darrah (*Ann. Rept.*, 1887–8) discussed the Assam rices under two sections which practically correspond with the chief Bengal crops, viz. early or summer, and late or winter rices. He subdivided these into the two great sections of the province, the Brahmaputra valley—Assam—and the Surma valley—Sylhet and Cachar. Of the rices of the Brahmaputra valley, he enumerates three—sali, ahu, bao. Sali is the general term applied to all transplanted rice grown on land lower than that required for ahu and higher than needed for bao. It is sown about May and June, transplanted in July and August, and reaped in December and January. Ahu is the name given to the numerous kinds of rice which grow on high lands, require little rain, and are sown from March to June and reaped June to September. It is usually sown broadcast, but sometimes transplanted. Bao comprises the varieties grown on the lowest land which will support rice. It is sown in March–April, cut in November–December. When transplanted, the operation is performed in July and August. Of the Sylhet or Surma valley, there are
low-land and high-land āus, murali, sāil, low-land and high-land āman, kataria and sāil-bura. High-land āus is sown in the higher parts of Sylhet usually broadcast but occasionally transplanted. It is put down in March and April, harvested in August-September. Low-land āus is grown in the lower parts of the district, but is never transplanted. It is sown in January–February, cut in May–June. Murali is generally sown on lower land than in the case of āus of the high-land form, but on higher than the low-land. It is put down in February–March and cut in June–July. Sāil is always transplanted; sown in April–May, transplanted July–August, and reap ed November to January. It is grown on land almost as high as āus land. Āman, like āus, is referred to two sections, according as grown on high or low ground. In the higher parts it is transplanted like sāil, but sown and gathered about a month earlier than that crop. In the lower parts of the district one variety is always sown broadcast, viz. the long-stemmed kind. Kataria is a form of āman sown in April–May, transplanted in May–June, and reaped in October–November. Sāil bura is grown on the very lowest land and is generally irrigated; sown in October–November, transplanted in December–January, and cut in April–May. The lands used are those portions of the ḍoors, or large natural depressions in Sylhet, which are left dry by the receding of the water in the cold weather.

The Cachar rices enumerated are dumai, murali, asra and sāil. Dumai comprises the Cachar rices which correspond with the forms of āus sown broadcast on high-lands in April–May, never transplanted, and reaped in July–August. Murali is sown in March–April, sometimes transplanted about May and reaped in June–July. Asra is sown in March and April on low-lying lands, never transplanted, and reaped in December. Sāil is practically the same as the sāil of the Brahmaputra valley and the sāil of Sylhet. [Cf. Sen, Final Rept. Settl., Jaintia Parganas, 1892–7, 8–9; Banerjei, Final Rept. Settl., Cachar Dist., 1894–9, 65, 111.]

**United Provinces.**—The area in 1905–6 was 7,078,563 acres: 4,252,528 acres in Agra, and 2,826,035 acres in Oudh. In Agra the largest areas occur in Gorakhpur, 976,423 acres; Basti, 700,314 acres; Allahabad, 285,503 acres; and Azamgarh, 277,401 acres. In Oudh: Gonda, 565,895 acres; Bahraich, 236,399 acres; Sultanpur, 277,039 acres; and Barabanki, 262,225 acres; etc.

**Methods of Cultivation.**—Duthie and Fuller give a full and comprehensive account of the cultivation in these provinces; the races are very numerous, strongly-marked, and may be assorted under three groups:—(1) those with a tall habit of growth, with the ear protruded from the sheath, feathery and drooping, and with thin usually yellow-husked grain; (2) those with a shorter habit of growth and stouter stems, with the ear not so prominent and carried more erect than that of the preceding, and with thick yellow or red-husked grain; (3) those with short, strong stem, ear partially enclosed in the sheath and grain-husk, dark-coloured or black. The first are most highly prized, the commonest being known as naha, bānsmatti, bānsphal and jhima. Of the second, seondhi and sūmāhara are the principal, while sāthi is the most important of the third. Munji is a term of varying meaning, denoting in some places high-class rice, in others being merely a term for rice sown broadcast. Another classification is into transplanted from seed-beds or sown broadcast. As a rule, the finer
ORYZA SATIVA

United Provinces

Seasons.

varieties, falling under the first two classes named above, are raised in seed-beds and planted out, while the coarser kinds are broadcasted.

Rice is sown in all months from January to July, and harvested from May to November. The seasons in which the greater portion is grown are June to August for broadcast rice, and June to November for transplanted. Broadcasted rice is sown mostly on the break of the monsoon and is ready for cutting in August (bhadoi) or September (kuār), and hence often known as bhadoi and kuārī. A certain quantity is also sown two months before the monsoon rain can be expected, and in this case there are two methods of cultivation. Either the rice germination is promoted and its growth stimulated by frequent and copious irrigation till the rains break, or, taking advantage of a fall of rain in April and May, the ground is ploughed up and sown, but the seed allowed to lie unirrigated, and the young plants should not come up before the advent of the rain induces germination. Nearly the whole of the transplanted rice (jarhan) is sown in seed-beds at the beginning of the rains, planted out after a fortnight or three weeks, and cut in aghan or November, hence also called aghani. A small portion, boron, jethi or hot-water rice, is sown in January, planted out in February, and cut in May. This is only practised in slimy soils, along the edges of tanks or beds of rivers, which are planted with rice as the water becomes shallow from evaporation.

Much of the rice land in the Sub-Himalayan districts is prepared by being dug over by the mattock during the cold and hot weather months when the soil has been softened by a fall of rain. For land not dug in this way the number of ploughings varies according as the crop is to be sown broadcast or planted out, two or three in the first case, four or six in the second. For sowing, the soil must be thoroughly moist. If sown broadcast, 40 seers to the acre are held sufficient. If seedlings are to be raised in a nursery, the seed is sown more thickly. If the crop is to be transplanted, the nursery should be about one-twelfth the size of the field. The seedlings are taken up when about a foot high and planted in regular rows at distances of about 6 inches, 2 to 6 seedlings being planted together. For rice grown in the hot-weather months, frequent irrigation is necessary. Rice sown at the commencement of the rains and cut in August or September under ordinary circumstances needs no watering, but the transplanted varieties, which are not ripe till November, require two or three waterings when the rains cease. At least one weeding is given to broadcast rice. Planted rice in Cawnpore is said to be more frequently weeded than broadcast, but in Allahabad it requires no weeding at all. When ripe, the crop is cut with sickles in the same way as wheat or barley. [Cf. Dist. Sett. Repts., U. Prov.; Nevill, Dist. Gaz. U. Prov.; Dist. Repts. quoted in Dictionary, v., 605-12.]

Central Provinces and Berar.—The area in 1905-6 amounted in the Central Provinces to 4,178,430 acres. The largest areas occur in Raipur, 1,264,198 acres; Bilaspur, 1,005,941 acres; Bhandara, 433,186 acres; Balaghat, 254,029 acres; and Chanda, 221,465 acres. Of the area under rice in 1904-5, it has been stated that 712,824 acres consisted of transplanted rice (302,794 irrigated and 410,030 unirrigated) and 4,193,045 acres of broadcasted rice (305,492 acres irrigated and 3,887,553 acres unirrigated). In Berar, the total area in 1905-6 amounted to 28,457 acres, almost entirely unirrigated.

Methods of Cultivation.—Fuller (Note in Outturn of Land under Principal

832
Crops in C. Prov., 1894, 10) states that the rice-growing areas fall into three tracts. The first lies in the north, and comprises the southern portion of the Damoh district, the Jabalpur district, and part of Manilla. Rice is here grown from seed, sown broadcast, and the crop is rarely irrigated. In black-soil fields it is generally grown as a catch crop before wheat. On lighter land it forms the only crop of the year. The second tract may be described as the Wainganga valley from its origin in the Seoni district to its termination in Chanda, and includes the southern portion of Seoni, the low country of Balaghat below the hills, and the eastern portion of Bhandara and Chanda, with isolated patches at the northern and southern extremities of the Nagpur district. In these localities most of the crop is grown from transplanted seedlings, and a large proportion is irrigated from tanks. The third tract consists of the plain of Chattisgarh and the Sambalpur district, forming the valleys of the Seonath and Mahanadi rivers. The common method of cultivation in Chattisgarh is to sow thickly broadcast and then to plough up the seedlings when they have made some progress, leaving the land a mass of mud; weeds and rice plants, from which a proportion of the latter make good growth. This process is known as besi or bilura in Raipur and Bilaspur, and as bilura in Sambalpur. Transplantation of rice is almost unknown in Chattisgarh proper, i.e. in the Raipur and Bilaspur districts, and though tanks are numerous, the whole of the crop is practically unirrigated. [Cf. Dist. Settl. Repts., C. Prov.; Rept. Operat. Dept. Agr., C. Prov., 1894-5, 15; Craddock, Rept. Land Rev. Settl., Nagpur, 1899, 61-2; Rept. Dept. Land Rec. and Agr., C. Prov., 1902-3, 10-11.]

Panjab and North-West Frontier.—The area in the Panjab in 1905-6 was 493,062 acres, and in the North-West Frontier 29,647 acres. The largest areas in the former were:—Kangra, 96,938 acres; Gur-daspur, 52,361 acres; Sialkot, 38,151 acres; Amritsar, 33,217 acres; Dera Ghazi Khan, 32,152 acres, etc.; in the latter:—Hazara, 12,793 acres; Peshawar, 12,053 acres.

Methods of Cultivation.—In the Upper Kangra valleys, where abundance of water, high temperature and a peculiar soil which favours its growth, are found in combination, rice is the staple product. It is also grown in the irrigated parts of Dehra and Nurpur. Coarser kinds are grown without irrigation in the more elevated parts of the district. There are upwards of 60 cultivated forms, of which the most esteemed are begami, básmati, jhinua, nakanda, kamádh, and rangari. Each has its special locality, e.g. Rihú is famous for its begami, Pálam for its básmati. Of the coarser kinds, the best known are kathón and kolhena; of the inferior unirrigated rices, rora, kalína, dhákár. Where irrigation is possible, rice is not sown till June. In districts dependent on rain, the seed is sown as early as April. Harvest takes place in October.

There are three methods of cultivation. By the first, bitar, the seed is sown broadcast in its natural state and is the usual method on unirrigated land. In the second, macch or lunga, the seed is first steeped in water, forced under warm grass to germinate and then thrown into the soil, which has been previously flooded. By the third, ár, the young rice, about a month old, is planted out by hand at stated intervals in a well-flooded field. The growth of weeds in the rice-fields is rapid, and to check them the crop, weeds and all, are ploughed up. This practice is called holdma, and only the weeds suffer, as the rice springs up again more luxuriant than before.
THE RICE PLANT

In the Karnal districts, rice is divided into two well-defined classes—fine, known by the name of *ziri*, and coarse, of which the principal sorts are *munji* and *santhi*. Of *ziri*, the principal varieties are *ramali* and *rāmjamāni*. *Sunkar* and *ansari* are coarser and grown chiefly where there is fear of too much water. Rice is grown only on stiff soil. The seed-beds are ploughed four or five times and carefully prepared, manure is spread on them, and the seed sown broadcast. More manure is then spread over the seeds and the whole watered. Four days after they are again watered, and after the fifth or sixth day they must be kept wet till ready to plant out. The rice-field is ploughed twice, and such manure given as can be spared. It is then flushed with 3 inches of water, and, if there are weeds, a plough is driven about under water. When the plough has worked the mud to a fine pulp, operators take the seedlings (*pod*) in handfuls (*jūti*) and plant them one by one in the water. The field is weeded once at least and must at first be kept under water, but not more than about 6 inches deep. When the ears begin to form, the ground must be kept well wetted, but not too slushy. Reaping must be done directly the grain is ripe.

Coarse rice is of two kinds, mentioned above, viz. *munji* and *santhi*. The former is sown in spots liable to be flooded, since it cannot be drowned, the straw lengthening as the water deepens. The peculiarity of the latter (*santhi*) is that it ripens within an extraordinarily short time from sowing. It requires but little water, if the soil is thoroughly moist, after the shoots are once up. Both kinds are sown in their final positions. After two or three ploughings, cattle are sent into the water to walk about and stir up the mud or a plough is worked under water. The seed is sown broadcast. No manure is used nor is the crop irrigated. [Cf. Pb. Dist. Gaz.; Pb. Settl. Repts.]

Kashmir.—Lawrence (*Valley of Kashmir*, 1895, 326–36) gives a full and interesting account of rice cultivation. The varieties grown are very numerous but may be roughly divided into two classes, the white and the red, the latter being the more alpine form. As a food, the white is more esteemed, and the best are the *bāsmati* and the *kanyun*. Though of good quality, the white is less popular from the cultivator’s point of view, since it is a more delicate plant and suffers more from changes of temperature and from the chill of snow-water. If the cultivator can obtain water and manure, he will continue to grow rice, and no rotation takes place. Where, however, water is uncertain, the rice land is allowed a fallow, and in some cases may be followed by cotton, maize, wheat, barley and *mah* (*pulse*).

There are two systems pursued: either the rice is sown broadcast, or first sown in a nursery and then planted out. Results show that the broadcast system gives the best outturn per acre. Preparatory cultivation commences in March, when the fields are hard and stiff. Where the soil is dry ploughed, cultivation is known as *tao*; where wet, as *kenalu*. Previous to ploughing, all the village litter and farm-yard manure are carried to the fields and ploughed in, or heaped in a place through which the irrigation duct passes, and so reach the fields as liquid manure. In June and July the labour of weeding the rice begins. The process is known by the name of *khushába*, and consists in weeding the crop, placing the rice plants in their proper places, and kneading and pressing the soft mud round the green seedlings. Only experts can
perform this work successfully and detect the counterfeit grasses. Under the nursery system two khushibas are sufficient, while four are essential in broadcast sowing. Sometimes when the rice is 2 feet high the whole crop is ploughed up (sele). When the rice has bloomed, and the grain begun to form, the water is run off the fields, but a short time before harvest a final watering is given to swell the ears. Harvest takes place in the months of September and October. [Cf. Dist. Assess. Repts. Kashmir.]

**Bombay and Sind.**—In 1905-6 the total area was 1,512,261 acres in Bombay; 1,013,902 acres in Sind. The largest areas in the Presidency occur in the Konkan:—Thana, 304,872 acres; Kolába, 248,067 acres; Kanara, 185,873 acres; and in the Karnátak, Dharwar, 143,606 acres; Belgaum, 207,571 acres. Of Sind, the following may be mentioned:—Lárkhána, 336,019 acres; Hyderabad, 215,297 acres; Karachi, 189,273 acres; Thar and Párkar, 134,192 acres.

**Methods of Cultivation.**—Mollison tells us that rice is principally a kharif crop dependent on natural rainfall. In the Southern Collectorates, especially in Kanara, rabi rice, known as vaingan, which ripens in the hot weather, is grown. This rice is generally irrigated, usually by channel water drawn from a nullah or natural spring. As a rule the crop is grown on the same land year after year without rotation. This is the case in the Konkan, except in years of favourable late rainfall, when a second crop of vél, gram, castor, wheat, or of mixed vél and castor or mixed gram and castor may be preferred. This second crop, however, is more common in the tank irrigated rice-beds of Northern Gujarat and elsewhere in the Konkan rice-fields. In the southern tálukas of the Surat district it is common to grow a crop of sugar-cane once in four years or at longer intervals, and the same practice prevails in the laterite soils of Belgaum, Dharwar and the above Ghát parts of Kanara. In the Belgaum and Dharwar rice-beds a sprinkling of jiáar is sown with the rice. In Broach, in deep, black soil and in the tálukas, where the average rainfall exceeds 40 inches, rice is sown subordinate to cotton. Elsewhere in Gujarat, where the land is not true rice land and the produce uncertain, kodra and rice, with a sprinkling of tuver, are a common mixed crop.

The best soils are clays or clay loams with a substratum of other porous material. Embankments are formed, and the surface of the beds made level. Many fields on and under the Gháts are never manured, but the seed-beds invariably are, either by burning ráb material thereon or by direct application of manure. The rice-beds of Gujarat and those of the flat bottom-lands of the Konkan and elsewhere are regularly manured. In Gujarat tank-mud, 40 loads per acre, is a favourite application, and the practice of green manuring is also common. Castor cake may also be given as a top-dressing to supplement ordinary manure. Fish manure is similarly employed in the southern tálukas of Surat and parts of the Konkan. In Kanara and the forest tracts of Dharwar, leaves and twigs of certain forest trees are used as a green manure. Rice is sown broadcast, drilled, or broadcast in a seed-bed and thence transplanted. The first is seldom adopted except in the case of rice grown on marshy situations reclaimed from the sea. The second plan is very common in the western tálukas of Belgaum and Dharwar and above the Gháts in Kanara and in unembanked fields in Gujarat. The third method is most suitable in fields which are embanked and where the rainfall is over 80 inches, or

835
where deficient rainfall can easily be supplemented by irrigation. Broadcasted or drilled rice requires a higher seed-rate than the transplanted, viz. about 120 lb. per acre; the seed-rate of the transplanted varies per acre from 25 or 30 lb. to 90 or 100 lb. In the Konkan, Mollison estimates a full yield under favourable circumstances at less than 4,000 lb. per acre. A full average from transplanted rice ranges from 2,800 to 3,200 lb. of grain per acre, while broadcasted or drilled yields on an average 1,800 lb. per acre. The cost of cultivation is estimated at Rs. 52-15a. per acre. [Cf. Crop. Exper. Bomb. Pres.; Mollison, Textbook Ind. Agri., 1901, iii., 32-44.]

**Madras.**—The total area in 1905-6 was 7,561,611 acres, and distributed thus:—in Tanjore, 1,074,152 acres; Malabar, 831,545 acres; Kistna, 611,664 acres; South Arcot, 553,574 acres; South Kanara, 530,402 acres; Madura, 376,302 acres; Trichinopoly, 203,967 acres, etc. The Final General Memorandum for 1906-7 estimates the area for the year at 6,934,900 acres with a yield of 50,395,700 cwt., or 10·5 per cent. of the total rice area of British India.

**Methods of Cultivation.**—In Malabar the crop is sometimes sown broadcast, but usually transplanted. There are several crops in the year, the principal of which are the _kanny_, sown in April–May and cut in August–September, and the _makaram_ crop, sown in September–October, and reaped in January–February. These are the principal rice harvests, but there are intermediate crops in some places; and a third, known as _poonja_, sown in February and reaped in April–May. The greater portion of the land, however, bears only one crop.

In South Kanara, rice is the staple crop. The land is classified, according to its capacity for irrigation, into _byle_, or rich wet land; _majal_, or middling wet land; and _bettu_, or land watered only by rainfall. On _byle_ land of the best quality three rice crops can be raised in the year; on the best _majal_, two crops; while _bettu_ land produces only one crop. The earliest rice crop of the season, on whatever land it may be grown, is termed _zenelu_ or _carly_. The seed is usually sown in nurseries, highly manured, and the plants transplanted. In almost two months' time the crop comes to ear, and in about twenty-one days more is ready for reaping.

In Tanjore, rice is raised almost entirely by artificial irrigation. There are two chief kinds, viz. _kar_ and _pishanam_, each including minor varieties. In all cases of irrigated cultivation, transplantation is the rule. A few coarser sorts, grown in some places beyond the delta of the Kanveri, and on rain-fed land, are sown broadcast. _Kar_ is planted in June and reaped in October; _pishanam_ in July–August and reaped in January–February. In the Madura district, rice is stated to be grown on almost every description of soil, the only essential being a constant supply of water. The seed may be sown broadcast, but the rule is to sow in nurseries. Sometimes the young plants raised in the nursery are transplanted to a second nursery, and afterwards carried to the field. As a rule, ploughing is done in June or July, after the early rains have softened the ground, and the seed is sown in nurseries at the end of July or beginning of August. After thirty days the seedlings are fit for transplanting, and in January may be harvested. When re-transplanting takes place, the young plants are suffered to remain in the second nursery about 35 days. Weeding is done about a month after sowing or transplanting. During the whole time the plants are in the ground they must stand in about 2 inches of water,
which must not be allowed to stagnate. In lands well supplied with water, as soon as the January crop is reaped, preparations are made for a second crop (mdsi kódei) raised in the same way as the first, but which comes to maturity about May. If the season be unpropitious during January–February, the second sowing will be in March, April or May and the reaping in July or August. The second crop is then called adi-kódei. Sometimes there may be three crops of rice raised in succession in a period of 13 or 14 months. [Cf. Sturrock, Man. S. Canara, 1894, i., 21, 199–204; Cox, Man. N. Aroo, 1895, i., 160–2; Francis, Gaz. Anantapur, 1905, 39; A Root Parasite of Paddy in Malabar, in Agri. Journ. Ind., 1906, i., pt. ii., 169.]

**Mysore and Coorg.**—The only available figures are for 1903–4, when the area in Mysore was 792,754 acres, and Coorg, 79,763 acres. The largest areas in Mysore State occur in Shimoga, which grew 244,758 acres; Mysore, 117,749 acres; Hassan, 103,639 acres; Kadur, 97,905 acres, etc.

**Methods of Cultivation.**—In Mysore the bara batta or punaji seed is sown dry in the fields; the mole batta, germinated seed, in fields reduced to a puddle; and the ndi, seedlings transplanted from a nursery after having attained a foot in height. Rice (Mysore Gaz.) fully describes these methods. There are two crops, the hain (rainy season) and the karu (hot weather). In the first, dry-seed cultivation is managed as follows:—from February to May, plough twice a month, having previous to the first ploughing softened the soil with water. After the fourth ploughing the field must be manured with dung, and after the fifth, watered by rain or from the canal. Three days later, the seed is sown broadcast and covered by the sixth ploughing. Any rain that falls the first 30 days after sowing must be allowed to run off, but should there have been no rain, the field must be kept inundated till the crop is ripe. If there have been occasional showers, inundation should not commence till the 45th day. Weeding and loosening the soil about the roots of the young plants and placing them at proper distances must be done three times, first on the 45th or 50th day; secondly, 20 days later; and thirdly, 15 days after the second weeding. These periods refer to crops that require 7 months to ripen. Rice which ripens in 9½ months must be inundated on the 20th day: and the weedicings are on the 20th, 30th and 40th days. By the sprouted-seed method, ploughing takes place in June–July. During this time the field is inundated, ploughed four times, and at each ploughing turned over twice in two directions which cross each other at right angles. About the middle of July the field is manured, again ploughed, and the mud smoothed by foot. All water except 1 inch is left off, and the germinated seed sown broadcast. For 24 days the field must have some water every other day, and thereafter, till ripe, be constantly inundated.

In the method of transplanting rice, two distinctions are made, one called bara-vagi or dry plants, the other nitrági or wet plants. Low land is required for both. In bara-vagi the ground is worked in the same way as for the dry-seed crop. In May it is manured and the seed sown thickly and ploughed in. If no rain falls till the 8th day it is watered, and again on the 22nd. From the 45th till the 60th day, the plants continue to be removed. The field must be inundated for five days before plucking up the seedlings for transplantation. The ground in which the dry seedlings are to be ripened is ploughed four times in the course of 1904.
eight weeks commencing about 15th May, and all the while inundated. The manure is given before the fourth ploughing. The mud is then smoothed and the seedlings transplanted into it, about 3 to 5 being stuck together in the mud at about a span distant from the next clump. The water is let off for a day, but afterwards the field is constantly inundated till the grain is ripe. In 11rd, the ground is ploughed three times in February-March while it is dry. About the middle of May the field is inundated, and in the course of 15 days ploughed four times. After the fourth ploughing the mud is smoothed, the seed sown thickly and dung sprinkled over the surface, and the water let off. On the 3rd, 6th and 9th days water is again given, but must not stagnate. After the 12th day, inundation is commenced, and continued till the seedlings are fit for removal 30 days after sowing. The cultivation of the field into which the seedlings are transplanted is exactly the same as for dry seedlings. Various pulses are sown in the fields that are to ripen the transplanted crop, and are cut down immediately before ploughing for rice commences.

Kār (or karu) crops (hot weather) are divided into three kinds according to the time of sowing. When the farm is properly stocked, the seed is sown at the most favourable season, and is called kumbā kār; but if there be a want of hands or of cattle, part of the seed is sown earlier and part later than in the proper season. When sown too early it is called tula kār; when too late, mēśa kār. The three methods of cultivation described above for the hain crop, viz. by dry seed, germinated seed, and transplantation, are found here also, except that in the case of tula kār no dry seed is ever sown.

In Coorg there is annually but one rice crop, except in a few valleys in the north. The rice cultivated throughout Coorg and in general use is the large-grained dodda-batta. A finer kind is the small rice sanna-batta, and a red variety the kēsari. For parched rice the kalame is the kind used. The seed is sown in a nursery, and in 20 or 30 days the seedlings are ready for transplanting, which takes place in July and August, regulated by the monsoon. The crop is cut in November or December. [Cf. Rice, Mysore Gaz., 1897, i., 131–44, 217–8; ii., 317–8, 323, 563–4.]

Burma.—The area in 1905–6 was 9,283,801 acres. The districts of importance are, in Upper Burma:—Shwébo, 365,107 acres; Yamethin, 225,170 acres; Upper Chindwin, 160,783 acres; and Kathu, 159,596 acres. In Lower Burma:—Hanthawaddy, 1,114,359 acres; Thongwa, 843,840 acres; Pegu, 778,372 acres; Akyab, 599,880 acres; Thaton, 563,973 acres; Bassein, 536,720 acres; and Myanmarma, 518,508 acres. The crop is divided into three main classes: kaukkyi or late-rain paddy; kaukkyin or early-rain paddy; and mayin or dry-weather paddy. Kaukkyi is said to occupy the largest area, viz. in 1904–5, 8,833,716 acres; kaukkyin next with 332,117 acres; then mayin with 99,631 acres. The Final General Memorandum of the Commercial Intelligence Department estimates the area in 1906–7 at 6,988,600 acres. The yield was given as 96 per cent. of normal, and the surplus available for export was 2,374,000 tons cargo rice, equivalent to 40,237,000 cwt. cleaned rice.

Methods of Cultivation.—The most fertile land, where the largest amount and the best quality is grown, is found in the delta of the Irrawaddy. There are five methods of raising the crop, practised in different parts of the country:—(1) On the ordinary swamp land in low-lying plains where the rainfall is sufficient; (2) on level land from which the
rain-water runs off too quickly and irrigation has to be resorted to; (3) on land near the river-bank which is submerged and cannot be planted till after the highest rise; (4) in hill clearings; (5) a hot-weather crop obtained by irrigation either by means of dams or by water-wheels.

For the first three methods, ploughing commences in June, when the rains have softened the soil and rendered the use of the plough possible. Meantime nurseries have been prepared on higher ground and seed sown broadcast. By July or August the fields for the first two classes and the plants in the nursery are ready and the young plants are dibbled in, two together at intervals. In the case of riparian lands, the plants cannot be put out till about September; the harvest begins in November and is over by January. The hot-weather crop is planted in January–March, and is reaped about three months afterwards. The water necessary is usually obtained by throwing a dam across a stream, but at Meng-doon in the Thayet district a self-acting wheel is used.

In cultivating rice in hill-clearings, a site is first selected, thickly covered with bamboos and forest, which is all felled in April. After two months' drying, the fallen trees and scrub are set on fire, the ashes fertilising the ground. After the first fall of rain, the surface is slightly broken with a hoe, the ashes mixed with the soil, and the seed, usually rice and cotton or sesame and cotton, sown broadcast. The rice and sesame are reaped in September or October, and the cotton bolls picked in December to April. After this the hill-clearing is abandoned. [Cf. Dist. Sett. Oper. Repts.; Upper Burma Gaz., 1900, ii., pt. 1, 337–41; Max and Bertha Ferrars, Burma, 1900, 48–56; Nisbet, Burma under Brit. Rule and Before, 1901, i., 330–43.]

**MANUFACTURE.**

*Mills and Milling.*—An important feature of the Indian rice trade is the rise and present position of the Burma power-mills. These mills had their origin in the very high cost of labour in that province and the disinclination of the Burman agriculturist to undertake any work he can avoid. In Bengal the rice crop is as a rule husked by the growers; in Burma it is conveyed to the market as paddy. It thus soon became evident that if rice was to become an important article of export, it must be husked at Rangoon. This gave rise to the important rice-milling industry of Burma. But these mills were for a long time greatly handicapped by the cost of coal imported from England. Moreover, the question of the disposal of the husk became a serious one. The discovery soon followed that the husk, previously wasted, might be utilised as the fuel to drive the mills. The husk is accordingly conveyed by special contrivances to the furnaces and there consumed, while a stream of water flowing below carries off the ash. By these and other inventions so great economies were effected that it soon became evident that not only was a great export trade possible, but that it would no longer pay to carry rice in husk to be milled at localities remote from the areas of production. To the skill and energy of the European inventors and owners of these mills, therefore, is due the credit of this great and prosperous industry.

According to the *Financial and Commercial Statistics*, there were 127 rice mills in India in 1904 employing 17,814 persons (mostly Madras coolies). The industry, however, is of importance only in Burma, which had of the above totals 114 mills and 17,016 employees. According to the statistical tables, the remainder were distributed as follows:
Panjáb 1 mill, with 33 employees; Bombay 1 mill, with 80 employees; Madras 11 mills, with 685 employees.

Revenue Duty.—In the Imperial Gazetteer (iv., 257–8) it is stated that the "revenue derived from rice and millet beer amounted in 1902–3 to about 6 lakhs in Bengal and 11 lakhs in Burma; elsewhere it is insignificant. In Bengal, pachwai brewed from rice or millet is consumed by aboriginal tribes, and by the lower orders in general, in certain districts. It is valued both as a stimulant and as food. The bulk of the revenue which it yields is derived from licenses for manufacture and retail sale, which are put up to annual auction, the number and sites of the shops having been previously fixed. Licenses for the home-brewing of pachwai for domestic purposes are granted in certain districts to the headmen of villages inhabited by aboriginal races, on payment of a fixed fee for each household. In Burma the Native beer is brewed from rice. When consumed by certain hill tribes, mostly in Upper Burma, it is exempted from taxation, otherwise the excise system is similar to that in Bengal. It is almost as easy to brew this beer as to make a pot of tea, and as the main ingredient is a staple article of food, it is almost impossible to check private manufacture." In the Moral and Material Progress of India the excise revenue from fermented local liquors, amounted in 1905–6 to £113,234 in Bengal and to £151,402 in Burma (see pp. 757, 760). The preparation of vinegar from rice is almost peculiar to Burma (see p. 111). As regards Customs Revenue, rice and rice flour are the only articles on the export tariff schedule, the duty on which is levied at the rate of 3 annas per maund of 82½ lb. The revenue thus obtained during the years 1900–6 amounted to the following sums:—In 1900–1, Rs. 84,89,433; 1901–2, Rs. 90,87,957; 1902–3, Rs. 1,26,06,624; 1903–4, Rs. 1,20,31,363; 1904–5, Rs. 1,31,75,772; 1905–6, Rs. 1,15,11,257 (£767,417). The increase in recent years is doubtless to some extent the direct expression of the economies effected by the Burma milling industry.

It was said some time ago that India held a practical monopoly of the world's supply of rice and accordingly was justified in placing an export duty on the quantities sent to foreign countries. The duty above mentioned was first imposed in 1875, when oil, rice, indigo and lac were subjected to an export duty. In 1880 the duties on the other articles were remitted, and that on rice alone retained. But the exports of rice from the Southern States of America, from Madagascar, from Cochin-China, from Siam, from Japan, etc., have given a new conception of the trade. In fact, it might almost be said that but for the economies effected by Burmese milling, the exports would have by now been lost to India.

TRADE.

The foreign rice trade of India may be said to be very ancient. So long age as 1503 Vertomannus (Travels, in Hakl. Voy., 1811, iv., 577) made special mention of the exports from Mangalore. In present-day traffic almost the entire supplies of the cereal sent to foreign countries are drawn from Burma. It is employed as food, for distillation, and in the manufacture of starch. "Formerly the bulk of the rice exported from Burma consisted of 'cargo' rice, of which five-sixths was unhusked (or 'paddy') and only one-sixth husked. Gradually, with the extension of rice-mills, the proportion of cargo rice has diminished, this description being replaced by husked and cleaned rice, to the great advantage of the

840
trad. For the husk is used as fuel in the mills, the bran lying between the husk and the grain is exported at a good profit for pig-feeding, and a saving in freight is thus effected." "Rice is exported to every quarter of the globe, not more than half of the total exports being consumed in Europe. Large quantities are sent to the Straits and Ceylon, to other parts of Asia, to East Africa, to the West Indies and South America. Indian rice penetrates to every region to which the Indian or Chinese coolie finds his way. It is to be noted that other countries, such as Siam, Cochin-China and Java, are already competing with India in these markets."

Again, "The rice trade is conducted under conditions as regards the effects of the seasons which are unknown in other parts of India, for as yet no failure of the monsoon in Lower Burma has been recorded. The fluctuations of the export trade from Burma depend, however, upon conditions in other parts of India, since bad seasons cause the diversion to India of rice which would ordinarily be exported to foreign markets" (Imp. Gaz., 1907, iii., 284-5). Burma has thus very properly been described as the granary of India, and it plays an important part in securing the balance of food supplies of the East generally.

Staple of Burmese Commerce.—The importance of the rice crop may be seen by the fact that the Exports often constitute the highest valued commodity and have often disputed the first position with raw cotton. Thus in 1904-5 the Rice exports (all kinds) were valued at Rs. 19,62,04,232; Wheat, Rs. 18,59,82,302; Cotton (raw), Rs. 17,43,46,872; Jute, Rs. 11,96,66,402; Opium, Rs. 10,62,04,442; Hides and Skins, Rs. 9,90,58,538; Tea, Rs. 8,46,54,867; Coffee, Rs. 1,66,09,757; and Indigo, Rs. 83,46,073. But in 1906-7 these positions were seriously changed: jute headed the list, followed by cotton, then rice, hides, tea, opium, wheat, coffee and indigo. Other raw products and partially manufactured products might be added to the above enumeration, but enough has been said to show the great importance of the rice traffic—the exports in that cereal being the staple of Burmese commerce.

Internal.—The total recorded internal trade transactions by rail and river amounted in 1906-7 to 35,038,390 cwt., of which 8,039,211 cwt. consisted of unhusked rice (paddy) and 26,999,179 cwt. of husked rice. The chief exporting centres were Bengal, 10,364,281 cwt.; Madras, 4,290,216 cwt.; E. Bengal and Assam, 1,228,575 cwt.; Sind, 2,905,816 cwt.; Bombay port, 949,010 cwt.; Calcutta, 6,755,856 cwt.; and Madras ports, 916,575 cwt. The chief imports were Calcutta, 9,470,405 cwt.; Bengal, 3,733,778 cwt.; Madras ports, 3,128,178 cwt.; Bombay, 1,754,606 cwt.; Madras, 1,195,222 cwt.; United Provinces, 460,072 cwt.; Karachi, 2,631,258 cwt.

The total coastwise external traffic by sea in the same year amounted to 19,582,791 cwt. (5,085,681 cwt. unhusked and 14,497,110 cwt. husked). Of this Burma exported 16,259,498 cwt.; Bombay, 900,618 cwt.; Bengal, 309,708 cwt.; Madras, 463,487 cwt.; Sind, 1,684,085 cwt. The chief importing centres by coast were Bombay, 3,755,193 cwt.; Madras, 5,132,772 cwt.; and Bengal 5,848,337 cwt.

Foreign.—The exports of husked rice during the five years 1902-7 were as follows:—1902-3, 47,033,137 cwt., valued at Rs. 18,73,73,780; 1903-4, 44,441,186 cwt., valued at Rs. 18,95,42,429; 1904-5, 48,573,297 cwt., valued at Rs. 19,47,22,505; 1905-6, 42,211,869 cwt., valued at Rs. 18,41,06,407; and 1906-7, 38,054,054 cwt., valued at Rs. 18,32,55,332.
In addition to this, a considerable quantity of unhusked rice (rice in husk) or paddy, amounting in 1906-7 to 655,132 cwt., valued at Rs. 19,98,886, and smaller quantities of rice-flour, viz. in 1906-7, 6,165 cwt., valued at Rs. 44,484, are annually exported. Robertson (Rev. Trade Ind., 1904-5, 23-4) states that both in regard to quantity and value the trade of 1904-5 was the largest known, and that the average price was 7 per cent. lower than in 1903-4. The bulk of the exports of husked rice is always from Burma, which, out of the totals above mentioned, contributed as follows:—1902-3, 36,791,543 cwt.; 1903-4, 33,346,351; 1904-5, 37,514,518; 1905-6, 31,067,895; and 1906-7, 28,105,443 cwt. Bengal comes second with, in 1903-6, 8,995,237; and in 1906-7, 4,736,786 cwt. Madras in 1905-6 supplied 1,500,945, and in 1906-7, 3,333,774 cwt. Sind in 1905-6 gave 303,354 and in 1906-7, 1,344,529 cwt. Lastly, Bombay in 1905-6 furnished 584,440 and in 1906-7, 533,443 cwt. According to Robertson, unhusked rice goes entirely to Ceylon, except as a constituent of husked rice to prevent its heating. Of cleaned rice the principal destinations west of Suez are Germany, which, in 1906-7, took 4,968,851 cwt., valued at Rs. 1,97,42,006; United Kingdom, 3,473,883 cwt., valued at Rs. 1,48,95,995; Holland, 2,513,425 cwt., valued at Rs. 89,00,902; Austria-Hungary, 2,442,632 cwt., valued at Rs. 87,55,678.

Of the Eastern section of the trade, the most remarkable feature is the development in the export to Japan, which amounted in 1904-5 to 9,277,293 cwt., valued at Rs. 3,52,13,937, an increase of 33 per cent. over the quantity for 1903-4, though it fell in 1905-6 to 6,593,531 cwt. After Japan in 1905-6 comes Ceylon with 5,976,582 cwt., valued at Rs. 3,21,23,634; then the Straits Settlements with 5,028,694 cwt., valued at Rs. 2,05,89,495.

The imports into British India do not amount to much, viz. in 1905-6, 965 cwt. unhusked rice, valued at Rs. 3,263, and 7,230 cwt. husked rice, valued at Rs. 40,018, the bulk of which comes from the Straits Settlements.

Of the trade by land (Trans-frontier) the latest available figures are for 1906-7. In that year the quantity of husked rice exported amounted to 69,050 cwt., valued at Rs. 4,31,739, and unhusked rice to 29,682 cwt., valued at Rs. 1,64,542. The Trans-frontier import trade is considerable. In the year under review, imports of husked rice amounted to 1,739,026 cwt., valued at Rs. 76,08,888, and of unhusked rice to 1,349,532 cwt., valued at Rs. 49,84,420. Almost the whole of this, husked and un-husked, comes from Nepal, viz., in 1906-7, the former, 945,640 cwt., and the latter, 1,215,852 cwt.
SPECIES OF MILLET

P. crus-galli, Linn.; var. frumentaceum, Trimen; Prain, l.c. 1177; P. frumentaceum, Rozb.; Duthie and Fuller, Field and Garden Crops, 1882, ii., 3-4, t. xxiv.; Duthie, Fodd. Grass, N. Ind., 8; Lisbon, l.c. 11. The shanula, shama, aide, sanai, hingaru, mandura, bani, chamatu, etc. A tufted annual, extensively cultivated as a rainy-season crop over the greater part of India and on the Himalayas up to 5,500 feet. In The Bower Manuscript (Hoernle, trans.), 151 mention is made of "gruel made of suamaka," and this has been regarded as denoting the present millet. The MS. in question was found at Kucha near Khotoan, and is of the 5th century.

This is the quickest-growing of all the millets, and in some localities can be harvested within six weeks of being sown. It thrives best on bright sandy soil. Banerjea (Agri. Cuttack, 1893, 76) says it often follows kanju (setaria italica). The soil is ploughed twice, and the seed sown broadcast in the middle of May to the middle of June. In about a month and a half the land is thoroughly weeded. Rain is required till about the middle of August, when the crop is cut. Of the United Provinces, Duthie and Fuller state that it is sown at the commencement of the rainy season and a spring crop usually follows it. The seed is sown at the rate of 10 lb. to the acre, and the young plants require at least two weedicings. In the drier regions of the Doab it is frequently grown as a subordinate crop with judr (sorghum vulgare). The yield varies from 8 to 10 maunds grain to the acre. In Bombay the area devoted to it in 1905-6 was 43,586 acres. Mollison (Textbook Ind. Agri., 1901, iii., 61) states that the land is prepared as for bįja (Pennisetum typhoides). The seed is drilled with a four-toothed plough in June-early July at the rate of 6 to 8 lb. to the acre. The rows are about 12 inches apart, and the plants should be thinned out where the seed is sown too thickly. The crop is weeded and intercultured with the bullockhoe as with bįja. It ripens in September-October. In the Deccan it is usually grown on poor, light upland soil where the rainfall is moderately heavy, and on such land a yield of 400 to 500 lb. grain and 1,500 lb. straw is a full average crop.

The grain is consumed chiefly by the poorer classes, with whom it has the special merit of ripening early. It is eaten boiled in milk or is parched. Leather (Agri. Legd., 1901, No. 10, 368; 1903, No. 7, 150, 178) gives the following analysis:—moisture, 7-75; oil, 4-39; albuminoids, 7-06; soluble carbohydrates, 67-56; woody fibre, 7-44; soluble mineral matter, 1-70; sand and silica, 4-13; and total nitrogen, 1-15; albuminoid nitrogen, 1-13. In the Madras Presidency and in Mysore the straw is much used as a cattle fodder, and in the Meerut district it is sometimes grown as a fodder crop. [Cf. The Bower Manuscript (Hoernle, trans.), 1890-91, 137; Church, l.c. 49; Basu, Agri. Lohardaga, 1890, pt. ii., 29; Rice, Mysore Gaz., 1897, i., 114-6; Mukerji, Handbook Ind., Agri., 1901, 250.]

P. maximum, Linn.; Prain, Bent. Plants, ii. 1179; P. junctorum, Pers.; Duthie, l.c. 9; Lisbon, l.c. 18-22. Guinea Grass, ginir gauv, geneo-pulu, gin huulu, nauka-thau-hau, etc. A tall perennial native of Africa, and now cultivated in India.

Is best propagated by root cuttings. A sandy soil is most suitable. After the ground has been prepared in the ordinary way, the roots should be planted out 2 feet apart on the flat, at the commencement of the rains, care being taken to arrange them so as to form lines at right angles in both directions. If planted at any other time, the field should be inundated with water immediately after planting. When the crop is established the rows should be ridged up in the direction of the slope. Subsequently, according to Mollison, Guinea Grass can hardly get too much water or manure, but the water must not be allowed to stagnate. The best manure is well-rotted farm-yard, and it should be applied in dressings of at least 5 tons per acre every fourth time the crop is cut. Crops are cut about eight times in the year, and plantations should be renewed every three years. Of the Poona and Surat Farms, Mollison says that it has been known to give outturns of 20,000 to 35,000 lb. per acre according to season. [Cf. Dept. Land Rec. and Agri. U. Prov. Bull., 1897, No. 6; Mollison, l.c. 233-6; Leather, Agri. Legd., 1901, No. 10, 368; 1903, No. 7, 156, 170.]

P. milaceum, Linn.; Duthie and Fuller, Field and Garden Crops, ii., 1-2, t. xxiii.; Duthie, Fodd. Grass, l.c. 9; Lisbon, l.c. 16. Common Millet, chena (or chens), chin phikai, sàvan-chaitava, anne, sülun, tse-dze, wàdi, varti, kataka-nai, varugh, bili baragh, etc. This grass is supposed to have been introduced from Egypt or Arabia. It is grown in various parts of the

**PANICUM MILIACEUM**

country up to 10,000 feet on the Himalaya, but nowhere to any great extent. Stein (Ancient Khotan, 376) says he found at the Niya site (3rd century) some ancient straw among which the husk of this species had been recognised by the authorities of Kew.

**Bengal.**—Roy (Crops of Beng., 1906, 58–60) states that this millet does best on a heavy loam and luxuriates on newly formed char lands. The land is ploughed after the 15th December, up to January or even to 15th February, and harrowed two to four times after each ploughing. By the time of the fifth or sixth ploughing the cloths are broken with the hammer and the seed sown broadcast about the 15th February, at the rate of 5 seers to the acre, then ploughed in; but to cover the seed, the land is again harrowed. When the plants are 6 inches high, the field is weeded if necessary. The crop is harvested about the 15th March to the 15th May. The average yield is about 24 maunds per acre, valued at Rs. 48.

**U. Prov. United Provinces.**—It is grown as a hot-weather crop, irrigated from wells. Sown in March at the rate of 10 lb. to the acre, and ripens towards the end of May. Yield, six to eight maunds of grain per acre. In Bandelkhand there are two varieties, phikai and rali. The former is sown a little earlier than the latter, and yields a heavier outturn.

**Bombay.**—The area under this crop and under *P. miliaceum* are returned together. They are generally distinguished by the names of *vari* and *sāra* respectively. In 1905–6 they occupied 231,948 acres in Bombay and 2,140 acres in Sind, and are said to take the sixth place among the cereals of Bombay. Their cultivation is almost limited to the Konkan and the Ghāt parts of Nāsik, Poona, Sātara, Belgaum and Dhārwār. In these districts *P. miliaceum* is a *kharif* crop, depending on natural rainfall, and is never irrigated. According to Mollison, it is raised like *nāglī* (Eleusine coracana) from rābed seedlings transplanted. When the seedlings are growing, the field is ploughed three or four times during the first three weeks of the rains. About 1 lb. of seed per guntha (one-fortieth acre) is sown broadcast on the seed-bed. It is grown without manure, and is commonly hand-weeded once in August. If transplanted early in July, the late varieties of the crop ripen towards the end of October. A full average crop on good vārkas land (i.e. upland soils of the Konkan) will yield 700 to 750 lb. grain per acre, worth 40 to 45 lb. per rupee. In Gujarat the crop grown is known as *cheno*, and according to Mollison is agriculturally very different from the crop of the Konkan and Ghāt districts. It is grown in garden lands as a hot-weather irrigated crop. When ginger or other garden crop is removed in December–January, the land is ploughed several times and beds formed for irrigation. The seed is sown broadcast, 10 lb. per acre, and lightly covered. Light irrigation is given as required, and the crop is hand-weeded once. If sown at the end of January it comes into flower in March and is fully ripe in April. A good crop yields about 2 tons straw and 1,000 to 1,200 lb. grain per acre.

**Uses.**—The grain is considered digestible and nutritious, and in many places is eaten whole, being cooked like rice. In Bihar, when boiled and parched, it is called *marha, manhra* or *mār*. Prepared with milk and sugar it is a favourite food at marriage ceremonies. Near Simla it is sometimes used as bread in the form of *chapatties*, called chinatti (pancakes). Leather gives the following average analysis of three samples
of grain:—moisture, 8·34 per cent.; oil, 4·57; albuminoids, 8·04; soluble carbohydrates, 65·20; woody fibre, 7·39; soluble mineral matter, 2·16; sand and silica, 3·79; total nitrogen, 1·36; albuminoid nitrogen, 1·29.

[ Cf. Agri. Ledg., 1903, No. 7, 179.]

In the green state it affords excellent Fodder for cattle and horses, and in parts of the Panjab is sometimes grown for this purpose only. The dry straw, called pra! or prad! in the Montgomery district, is sometimes given to cattle.

[ Cf. Church, l.c. 42; Basu, Agri. Lohardaga, 1890, pt. ii., 33; Banerjeal, Agri. Cuttack, 1893, 75-6; Lawrence, Valley of Kashmir, 1895, 337-8: Rice, Mysore Gaz., 1897, i., 117; Mukerji, Handbook Ind. Agri., 1901, 259; Mollison, l.c. iii., 61-4; Crop Exper., Bomb. Pres.; Joret, Les Pl. dans L'Antiq., etc., 1904, ii., 245.]

P. millare, Lamk.; Duthie, l.c. 10; Lisboa, l.c. 17; Little Millet, kungta, kutki, gondula, mirhri, chika, varai, suda, shamai, nalla-shama, etc. One of the minor millets, smaller in all its parts than the former.

Of Bengal, Roy (Crops of Bengal, 62) states that this millet is largely cultivated in the Lower Province. No manure is used, and it may be followed in rotation by a rabi crop. The land is ploughed and harrowed from January to March and the seed sown from March to May, at the rate of 18 seers per acre. No further operations are necessary till August or September, when the crop is cut and threshed like dus paddy. The yield is stated to be 24 maunds per acre. In the United Provinces its cultivation is confined chiefly to the southern hills districts. It is sown in June and reaped in October, forming, together with kodon (Paspalum scrobiculatum), the crop generally taken from the poorest land in the village. In Bombay, the description from Mollison given under P. miliaceum applies equally to the present crop.

PAPAVER AND OPIUM: Papaveraceae. Opium is an inspissated juice obtained by scratching the unripe capsules of Papaver somniferum, Linn., and allowing the milky sap, which exudes therewith, to dry spontaneously. There may be said to be two chief kinds of opium, that used for medicine (produced chiefly in Asia Minor), and that smoked, eaten, etc. (grown in India and China).

History.—Various species of poppy are mentioned by the early Greek writers (Homer, etc.) as ornamental garden plants or as attractive-looking weeds of the fields; the merits of the seed as an article of food and as affording oil were extolled before the discovery had been made of the somniferous property of the capsules, and certainly long anterior to the recognition of the value of the milky sap. The capsules, stems and leaves were employed by the Greeks in the preparation of an extract called meconium (cf. Hippocrates, Theophrastus, etc.), which was employed as a soporific drug and used in the fabrication of a soothing beverage exactly corresponding to the post of the Panjab to-day and the kuknir of Akbar's time. Lastly came the discovery of the more potent nature of the inspissated sap, the opion of the Greeks, a word that may be spoken of as the diminutive of óya—the juice. Papaver somniferum was grown in Asia Minor for its capsules, which the Arabs carried all over the East, even to China, sometime before the Greek discovery of the value of the juice.

The discovery of opium began to attract attention about the 3rd century B.C. Theophrastus was acquainted with it, and describes the method of obtaining it by scratching the green pods. Virgil (Georg., iv., 545) speaks of the lesthian virtue of the plant. Pliny pays special attention to the medicinal value of...
PAPAVER
SOMNIFERUM

History

opium, while Dioscorides narrates with the minutest detail the process of extracting and manufacturing the drug, and is careful to distinguish it from the older preparation meconium. In his time the drug would seem to have come mainly from Asia Minor. Indeed, during the Roman Empire, as also the early Middle Ages, the only sort of opium known was that of Asia Minor. And even in the 13th century Simon Janensis (physician to Pope Nicholas IV.) spoke of Opium thebacum.

But if the Greeks discovered the potent juice—opium—the Arabs were chiefly concerned in disseminating the knowledge of the plant and its uses. The Arab medical writers from about the 9th to 12th centuries give a full account of it derived almost exclusively from Dioscorides and Galen. That the followers of the faith of Islam proclaimed the properties of opium to the people of India and China there can be no doubt, since the Sanskrit and all the vernacular names in use to-day are clearly traceable to the Semitic corruption of opos or option into afyun. Thus the Hindi afim points to afyun as the transitional stage from opion. In the same way the Arabs carried the poppy capsules and opium to China, hence the name ya-pien, also a-fou-yong, in the Chinese language. Previous to the T'ang dynasty the opium poppy was apparently not known to the Chinese.

According to one writer the Sanskrit name is akhipha, and, explained as meaning "snake venom," would thus not be derived from the Greek. But it is more often written ahipan, a word which most authors speak of as being quite modern and derived directly from the Arabic. Sir George Birdwood (E.I.C. First Letter Book, liv.), for example, says, "It does not occur anywhere until it appears in a Sanskrit dictionary published in Calcutta about seventy years ago." Mr. R. M. Dane (Hist. Mem., in Rept. Roy. Comm. on Opium, vii., app., 28–63) says that evidence was placed before the Commission to the effect that it is mentioned in the Bhavaprakasha and other Ayur-Vedic medical works supposed to have been written not less than 800 years ago. He then adds that the history of the production and use of opium in India before the commencement of the 16th century is, however, obscure.

On the other hand, Grierson (Bihar Peasant Life) gives a complete vocabulary of words for the plant, its varieties, every part of it, as also every product it affords and every feature and stage in its cultivation and manufacture. Still there can be no possible doubt that the poppy cultivation of Bihar does not date further back than a couple of centuries or so. While that view is doubtless correct, and extreme caution is necessary, still there are words, such as post or pust (already mentioned), that seem quite unconnected with Greek literature, and which indicate, as has been suggested, a more ancient knowledge of the plant than in its special sap—opium. The word post usually denotes the capsules, and in South India it becomes postaka-tol. Dutt tells us that in Benares the poppy capsules are khatka, and the seeds khasha, but that there is no classical name for opium. The seeds are kashkhud in India generally, and in South India gashagasha. So also in China there are names for the poppy that carry the knowledge of the plant back to the 7th century. Dr. Edkins (Hist. Notes on the Poppy in China, in Rept. Roy. Comm. on Opium, 1894, i., app., 146–58) points out that in the 10th century the Emperor Sung T'ai-tsu directed the first great medical work to be written; in that, the names given to the poppy are minang (=millet vessel) and ying-ru (=jar-millet). Both names of necessity denote the poppy capsule and its seeds, and involve most probably a knowledge in their respective properties prior to the discovery of opium. Su Sung compiled the second great medical work (which appeared in 1057 A.D.), and it is there stated that "the poppy is found everywhere. Many persons cultivate it as an ornamental flower. There are two kinds, one with red flowers and another with white." This, therefore, implied that though the name that more aptly denotes opium had not come into use, the forms of the opium-yielding plant were well known in China at the period mentioned. Lin Hung, in the 12th century, alludes to the milk from poppy heads. A poem written during the Sung dynasty speaks of the poppy fields resembling snow. Thus there can be no doubt the opium poppy was extensively cultivated in China long anterior to the importation of India opium. Wang Shih, in the 13th century, speaks of the prepared drug as simply magical in the treatment of dysentery.

At the beginning of the 16th century the opium imports into China from India had not only been fully established, but the cultivation of the poppy plant and the manufacture of opium at Malwa had become regular industries, thus
EARLY INDIAN TRAFFIC

fully two centuries prior to the conquest of Bengal by Clive. And there can be no manner of doubt that prior to the British, the Portuguese controlled the Chinese opium exports from India. It is significant that while Baber (Memoirs, 1519, 334) makes no mention of opium in connection with his discussion of the revenue of Bihar, his grandson, the great Emperor Akbar, on the subjection of Malwa and Cambay, found the opium traffic a distinctive and important feature of these new dominions. Moreover, Abul Fazl specially mentions Fatehpur, Allahabad, Ghazipur, Lahore, etc., as concerned in poppy culture, and lays stress on the excellence of the crop in Malwa. Sir J. B. Lyall (Hist. Sketch in Rept. Roy. Comm. on Opium, vii., app., 5-29) says that it seems certain the Mughal monopoly began a little later than Akbar's time. He, moreover, came to the conclusion that it probably was confined to Bihar. The right to manufacture and sell the drug was finally placed by the Muhammadans under direct supervision; it was farmed out, and land devoted to this cultivation subjected to a higher tax than that for other produce. But as bearing on the probable date of the State monopoly, it may be mentioned that in the Mirat-i-Ahmedi we learn of the systems of taxing and the revenue realised from opium by the city of Ahmadabad in the time of Sultan Musoffar and other Gujarat kings, before the overthrow of the dynasty by Akbar in 1573 A.D.

The antiquity of the opium traffic may be judged of by the fact that Giovanni da Empoli (in 1611) mentions that Alboquerque had captured eight "Guzzarate" ships that contained, among other merchandise, "arjun, for so they call opio debaco." In 1616 Barbosa tells us that this drug was among the articles brought to Malacca by the Arab and Gentile merchants to exchange for the cargoes of the Chinese junk. He also informs us that opium was carried from Arabia to Calicut, and from Cambay to Calicut, the Arabian being one-third higher priced than that of Cambay. Garcia de Orta, in 1563, published a full account of the Indian habit of eating opium, and Frederick speaks of going (1568) to Cambay, where he purchased sixty parcels of opium. Shortly after, Acosta (Traict. de las Drogas, etc., 1578, 408) and Linchoten (1598) amplified very greatly the particulars made known by Garcia regarding the Indian habit of eating opium. Bocarro (1644) laid stress on the importance of the three great products of Cambay, viz. opium, indigo and cotton. Thevenot (Travels in Levant, Indo- stan, etcc., 1687, pt. ii., 97) mentions the use of opium in Persia. In the Tusuk, reference is made to the Governor of Bihar being much given to kuknar (opium-hemp), and his consequent neglect of his duties. If this can be accepted as denoting a Bihar cultivation, it would be the earliest known. The first direct mention of Patna opium appears to be given by Ralph Fitch, an Englishman who travelled in the East from 1583-91 A.D., and who visited Agra, Benares, Patna (Patenaw), He describes the last town very correctly, "as a very long and great town," which had a large trade in cotton, sugar and opium. The Abbé Raynal (Hist. Philosoph. des deux Indes, 1770, a work translated into English in 1777, i., 424) says that "Patna is the most celebrated place in the world for the cultivation of opium. Besides what is carried into the inland parts there are annually 3,000 to 4,000 chests exported, each weighing 300 lb." Alexander Hamilton. (New Acc. E. Ind., 1727, i., 315; ii., 22) speaks of the chiefs of Calicut vending from 500 to 1,000 chests of Bengal opium yearly, up in the inland countries where it is very much used. Mr. J. F. Finlay (Rept. Roy. Comm. on Opium, ii., 371-99) furnishes particulars of the proposals to abolish the Government monopoly. He gives the early history and fixes the present arrangements as dating from 1797.

Thus then the opium monopoly was a direct legacy from the Muhammadan rulers of India and from the early Portuguese traders, that had to be assumed by the British shortly after the battle of Plassey (1757). Mention, for example, is repeatedly made of the traffic having expanded so inordinately as to have forced the East India Company to assume its control and supervision in 1781. But prior even to the advent of the Portuguese, the Chinese had become possessed of a full knowledge of the drug. Wang Hsi (who died in 1488 A.D.) speaks of opium being obtained from Arabia and being the produce of a poppy with red flowers. He died thus ten years before the arrival in India of Vasco da Gama, and not only describes the use of opium, but the methods pursued in the cultivation of the poppy and the extraction of the narcotic. There can, therefore, be no sort of doubt that the cultivation of the poppy plant, as a source of opium, was fully established in China by the middle of the 15th century. The prohibition against foreigners trading with China, issued in 1523, was a
THE OPIUM POPPY

PAPAVER SOMNIFERUM

History

Opium Smoking.

The consequence of Japanese raids, but its immediate effect was to lessen the supply of foreign opium, and in consequence regulations were issued with the view to improve and extend Chinese home production.

Dr. Edkins, from whom most of the above historic facts regarding China have been derived, says that towards the end of the Ming dynasty the legitimate practice of taking opium medicinally was destined soon to change into that of smoking it. The new phase, he affirms, was intimately associated with the introduction of tobacco-smoking from the Philippine Islands. Tobacco reached China about 1620 A.D., or just about the time that King James I. published in England his Counterblast to Tobacco, and the last of the Ming Emperors prohibited the smoking of tobacco. But the habit nevertheless spread rapidly, and unfortunately various substances came to be mixed with the tobacco, such as opium, arsenic and the like. These were for some years used as flavouring ingredients, but in time they became the chief materials smoked. It may thus truly be said that tobacco was a lesser evil than the early Chinese reformers supposed, while opium-smoking proved a far greater danger than they feared. The Emperor Ch'eng Taung was much to be respected for his strong moral convictions. He made great efforts to cope with the evil of narcotic indulgence, but in vain. According to Bretschneider, opium-smoking is a Chinese invention and quite modern. Nothing, he adds, proves that the Chinese smoked opium before the middle of the 18th century. Dr. Edkins regards the connivance of the Chinese authorities (during 1729-96), from the highest to the lowest, as having served to render repressive measures futile, both against local production and foreign importation. Opium-smoking originated, moreover, in a lawless locality, at a great distance from Peking, and (as observed by Holmes) "while the Court at Peking was endeavouring to suppress the foreign trade in opium, from 1733 to 1840, it did not or could not put a stop to the home cultivation of the drug, since a Chinese Censor in 1830 represented to the throne, that the poppy was grown over one-half of the province of Ch'okoang, and in 1836 another (Cho Tsum) stated that the annual production of opium in Yumnn could not be less than the several thousand piculs " (Encyc. Brit.).

This state of affairs culminated, and naturally so, in a conflict of interests as represented by local production on the one hand (an item of provincial revenue) and foreign importation on the other (an item of Imperial revenue). While the British and Indian Governments were in treaty with the Emperor of China, with regard to the enforcement of such restrictions on the foreign traffic as the Imperial Government of China deemed desirable, the provincial authorities of China, as represented by the Commissioner Lin Tse-hsu, demonstrated their desire for the complete discontinuance of the foreign supply by destroying £2,000,000 worth of opium, the property of British traders. Had the Chinese Government taken the course open to it, and that, too, without arbitrary injury to a trade of large proportions (the growth of several centuries), namely to impose a gradually increasing taxation on imported opium; had it exercised also the power, and if it should have of restricting or prohibiting the cultivation of the poppy within its own territory, little would have been heard of the perplexing Opium Question of the present day.

By the middle of the 18th century Bihar had become the province in which opium of the best quality and greatest quantity was produced. In the anarchy of the period, the Government monopoly had fallen into abeyance. The system under which, in the early part of the century, business in opium was conducted, in that part of India, is described by Ram Chand Pandit. In the first year of the British monopoly he was one of the joint contractors of the opium provision. There was, he tells us, a body of "Native" merchants, then resident at Patna, known as the opium-dealers, who made advances to the cultivators and received in return the opium produced, took it to their houses, and made it up in the form required by the exporters. After the growers had delivered as much as liquidated the advances received, they disposed of the surplus as they thought fit, and the price rose accordingly. In October, the opium being prepared in the required form, the merchants used first to offer it for sale to the Dutch, having previously agreed among themselves as to the rate they would accept. A dealer owning, say, 500 maunds would dispose of 200 to the Dutch. After such preliminary sales, the dealers would then go to the English merchants and offer a further quantity, at a higher rate, and finally they would go to the French and dispose of some more at a still higher rate. Thereafter, say in November, the Dutch would make a second contract with the opium merchants, but at a higher price.
than their first agreement, and usually by this time the pykars or small traders, who had picked up here and there odd parcels, brought their much adulterated article to market and thus lowered the price of the closing sales. The usual price averaged from 100 to 150 rupees per maund, but might rise to Rs. 200 or, during the wars among the Europeans, would fall to ruinous rates—Rs. 70 to Rs. 75.

With such a state of affairs it can be no matter for surprise that corruption became universal with the growers, the traders, and the exporters, nor that misunderstandings should have threatened both internal and external peace and thus rendered imperative some system of supervision. An end, as it was thought, was put to all disputes in 1773 by the Governor of Bengal, Warren Hastings, assuming supreme control, on behalf of the East India Company, an agreement having been entered into to supply the Danes, Dutch and French with fixed amounts annually. From 1773 to 1797, in virtue of this new arrangement, the right to the exclusive manufacture of opium, on account of the Company, was sold annually in the first instance, and from 1781, by four-year contracts, on private bargain. In 1785 the contracts were opened to public competition and assigned to the highest bidder. Definite stipulations were thenceforward exacted from the contractors with a view to protecting the cultivators from being compelled to grow the poppy; for securing to them freedom from vexations imposts and ensuring a fair price for their produce. The cultivators, on the other hand, were made liable to penalties for keeping back the opium produced, and to a deduction of *batta* (assessed by arbitrators) upon opium adulterated. Dealing in opium contrary to the conditions of the monopoly was made criminal by whomever conducted. But in spite of all the regulations that could be framed, the system of farming became oppressive. Cultivators were often compelled by the contractors to grow the poppy when they had no desire to do so. The contention was advanced that the contractors must have an assured production, and hence, they said, once land came under opium, it had throughout the period of contract to continue to produce it. If the owner or cultivator of opium land objected, he should, they said, be compelled to vacate it and allow some one willing to grow poppy to be placed in charge. Instances of such high-handedness and abuse became so rife and flagrant that the Board of Directors were forced to seek some other plan of operation than that of farming out the right to produce a drug of such potency.

It had been early resolved by the Company that the profits of opium traffic should be credited to Revenue, not to Commerce. The country, and not the shareholders, thus participated in the profits. The vested interests of the Indian people were thus early recognised as demanding efficient control. Ram Chand Pandit, who could contrast the free-trade system, in which he had, in fact, participated, with the subsequent contract system and its grievances, bribery, corruption and dishonest weights, etc., admitted that the carrying on of the opium traffic as a State monopoly was the best mode "as well for the *raiyat* as for the preservation of the quality and the good of the country at large." After discussing the many recommendations of the new system, viz. constant market, liberal advances, freedom from all compulsion, etc., he added that the *raiyats* should be punished whenever detected either delivering adulterated juice or disposing of the produce other than to the Company, and that after receipt into warehouse it should be made up with the greatest care so that its good quality might redound to the honour of the agent.

It will thus be seen that in the growth of the present Indian opium traffic, free trade was tried and found wanting; that the contract system proved defective and pernicious; hence that direct control was hailed by the people of India as a greatly needed and much valued reform.

The Government of India, in a Dispatch issued during the Marquis of Ripon's administration, stated their case fully. One passage from that dispatch gives the key-note to the whole controversy—"The economic objections to the manner in which opium revenue is raised, whether in Bengal or Bombay, may be admitted to be considerable. In the former case, the Government itself engages in private trade, a course which is open to obvious objections. In the second, a very heavy export duty is imposed. In both cases the course adopted interferes with and restricts the free production of the trade in opium. It cannot be doubted that it would be highly profitable to any private trader to pay for crude opium a very much higher sum than is paid now by the Government to the cultivators of Bengal. If, therefore, supposing such a thing to be possible, no restrictions were placed upon the cultivation of the poppy, and if, at the

849 54
same time, the export duty were taken off, it is certain that an immense stimulus would be given to the production of opium, and that China would be flooded with the Indian drug. Thus, in direct proportion to the removal of the economic objections, the moral objections would be intensified in degree." "If, therefore, the policy is to be not merely theoretical, but is to be productive of some practical good, it must aim, not only at the disconnection of the Indian Government with the opium trade, but at the total suppression of the trade itself."

China produces locally the major portion (some writers say nine-tenths) of the opium it consumes. The province of Yunnan, which the indulgence is carried to the greatest extent, is self-supporting in the matter of opium, that is to say, it exports opium but imports none. But Yunnan does not stand alone. Mr. A. Hosie, Consul-General, says that with the province of Su'ch'uan (Report, 1904) the greater profit of opium as a crop has driven wheat very largely from the list of surplus products exported from the province. Out of a population of 45 millions, nearly 3 millions are opium smokers. The locally produced article is gradually displacing the imported, and the province even now exports to other parts of China 20,000 piculs of opium a year. There would thus seem no manner of doubt that the exclusion of Indian opium from China would not affect materially the indulgence of the peoples concerned. The earnest words of the Hon. the Maharaja Bahadur of Durbhanga should be read by all persons interested in this subject (Rept. Roy. Comm. on Opium, 1895, vii., suppl.) and its bearings on India and the Indian and the peoples. Export of Yunnan opium into Upper Burma was a source of much annoyance that led to special regulations. Col. Manifold has published a vivid account of the effects of opium-smoking in Yunnan.

The Royal Commission on opium showed that the trade was simply legalised by the Treaty of Tientsin (1858). Prior to then the traffic was irregular, and disturbances were almost of constant occurrence that greatly interfered with ordinary trade. In the instructions given by the British Government to Lord Elgin there occurs the following:—"There would be obvious advantages in placing the trade (opium) upon a legal footing by the imposition of a duty instead of its being carried on in the present irregular manner." The Treaty of Tientsin was to regulate general commercial relations between China and Great Britain, and opium was only a side issue. Mr. H. N. Lay (Rept. Roy. Comm. on Opium, i., 54), in fact, says that in framing the Treaty, opium was not so much as mentioned, either by the Chinese or the British Commissioners. The terms of the Treaty are such that the duty by constitutional methods might be increased indefinitely or the imports prohibited. By the authorities subsequently appointed to frame regulations based on the Treaty, opium was of their own free will accepted by the Chinese as a foreign drug, that might be imported and upon which a duty was to be levied (l.c. app., 137).

Sir James Fergusson, in a debate in the House of Commons (April 10, 1891), remarked, "The Chinese at any time may terminate the Treaty on giving twelve months' notice, and to protect themselves they may increase the duty to any extent they please or they may exclude it altogether." Sir Joseph Pease, commenting on that view (l.c. 4), amended the interpretation of the Treaty by saying that while the Convention of Chefoo might be recast every twelve months, the Treaty of Tientsin could only be modified every ten years. The Convention of Chefoo simply consolidated the likin (provincial) taxes on imported opium into one common Imperial import duty, thus doing away with a source of much trouble and confusion. This was of great advantage to the Imperial Government, no doubt, and checked materially the smuggling of foreign opium through the country (l.c. app., 137). A duty levied on imports was, in other words, a simpler and more effective tax than fiscal duties on the drug being carried across provincial boundaries.

**CULTIVATION AND AREA OF INDIAN PRODUCTION.**

There can be no doubt that much still remains to be done in selecting stock, toward the production of desired qualities of the drug. In Bengal (Patna and Benares agencies) the plant chiefly grown is one or other of the many white-flowered races, especially that with a pale-coloured capsule (sdjed dherri). In Malwa, on the other hand, the poppy most frequently seen has purple flowers. In the Himalaya a parti-coloured form is occasionally met with. No one, subsequent to Scott (Manual of
Opium Husbandry, 1877), appears to have given the subject serious attention, and the merits of the opium of India have become an accepted axiom, without the endeavour having been made to trace out how much depends on climate, soil, stock of plant, system of agriculture or purity of manufacture. Even when cultivated side by side in the garden, Scott noted that the various races which he found in the hands of the cultivators, or which he was able to select and perpetuate, yielded materially different results in quantity and quality of the drug. Nevertheless it is freely admitted that the highly valued medicinal form of opium obtained from Asia Minor is the produce of a special variety known to botanists as *glabra*. At present we possess no evidence as to whether that particular plant exists in India or could even be cultivated there. While the opium used medicinally in Europe is obtained to-day, as it appears to have been centuries ago, from Asia Minor, the opium used medicinally in India is the Indian grown and specially prepared drug obtained from *var. alba*. While in many respects the chemical nature of the two would seem widely different, Indian medical men claim that, given in the same doses, the Indian is in no way inferior to the European. [Cf. Heuze, *Les Pl. Indust.*, 1895, iv., 91-105, 357-60; *Kew Mus. Guide*, 1907, 13.]

**Area and Yield.**—In modern language, "Bengal Opium" means opium manufactured at the factories of Patna and Ghazipur, and therefore grown in the provinces of Bengal, Agra and Oudh. Then again, "Malwa Opium" means opium grown in Central India, Rajputana and certain other Native States. The former class of opium is exported from Calcutta and the latter from Bombay. The area devoted to Bengal opium is accurately known; that devoted to Malwa can be ascertained only approximately, namely by estimates based on the annual exports to foreign countries. In the former, the cultivation is directly controlled by Government—a State monopoly; in the latter, by export duties only.

During the years 1872 to 1892 the area under the poppy in the British districts (Bengal opium) averaged 515,000 acres. The following were the areas returned officially as devoted to the crop for the five years ending 1901-2:—British districts, in 1897-8, 592,232 acres; in 1898-9, 602,975; in 1899-1900, 640,263; in 1900-1, 621,891; in 1901-2, 607,418. Since 1902 the net area in the Ganges valley, excluding areas on which the crop was sown but failed, has been:—1902-3, 582,807 acres; 1903-4, 642,831; 1904-5, 587,140; 1905-6, 654,928. In 1906-7 it is stated that the Government of India have decided to reduce the area to about 562,500 acres. [Cf. *Moral and Med. Prog. Ind.*, 1905-6, 75.] In the Native States for which agricultural returns are available, the average has been about 70,000 acres. Of the British districts, approximately 200,000 acres are in Bengal, the same in Agra, and a little less in Oudh. The cultivation beyond these provinces is insignificant, and can be described as a concession practically to ancient usage or aboriginal tribes. In the Panjáb, Ajmir-Merwara and Upper Burma, for example, there have been on an average about 6,000 to 7,000 acres between them under the crop, mostly in the hill districts (Karnal, Ambala, Kangra, Shahpur, etc.). Of the Malwa production, the Native States of Gwalior, 36,378 acres; Tonk, 9,733 acres; Kotah, 31,166 acres; and Jaipur, 3,077 acres, are the published returns for 1904-5. Others, such as Baroda, Indore, etc., do not furnish particulars.

**Production and Profit.**—The cultivator of opium, in the monopoly
districts, is licensed and money advances made to him (if he so desires) to enable him to prepare the land for the crop in accordance with the somewhat expensive system recommended. As the advances on opium are made at the very time the rent has to be paid, they are much valued, and the profits may pay the rent of the entire holding. The cultivator is next required to deliver the whole produce at a fixed price to the Government local agents, by whom it is dispatched to the factories. The fields are surveyed when under the crop and a fairly accurate forecast of production obtained as a check on deliveries.

The price paid had for some years been fixed at Rs. 5 per two pounds, but it was raised recently to Rs. 6. Still, at the former figure the value to the Bengal and United Provinces cultivators may be judged of by the fact that the average payments for some years have exceeded £1,500,000, and occasionally as much as £2,000,000. The opium is specially prepared both for the home and foreign markets in accordance with long-established custom at the Government factories. The foreign supply is sold by public auction at monthly sales which take place at Calcutta; but, in order to check speculation and steady prices, the exact amount to be offered at each sale is previously notified for twelve months. The amount to be manufactured each year is also determined beforehand, the area necessary for the production fixed, and permits issued accordingly. The opium used up in India is technically designated "Excise Opium," that which is exported being called "Provision Opium." In 1888 and some time subsequently, the estimate of required production was 57,000 chests of provision opium per annum. In 1896 the standard was reduced to 54,000 chests; and at present it is 48,000 chests. The excise opium fluctuates considerably; during the past thirty years the minimum has been 2,243 chests, and the maximum 5,554 chests. This represents the total Indian consumption, less the supplies produced within the Native States.

Most of the Native States assimilate their internal opium arrangements to those prevalent in the British districts, and, moreover, make strenuous efforts to prevent contraband dealings. Still, there must be a considerable personal traffic from the Native States into British territory. Were greater restrictions placed on the production and supply within British territory than presently prevail, illicit traffic would assume political importance and become a danger of no ordinary magnitude. As now administered, the Native States levy heavy dues on opium exported from their territories for the China market, and such opium, moreover, pays to the Indian Treasury a transit duty which in 1894 was £43 3/4 per chest of 140 lb., in 1896 became £40, and in 1897 £33 3/4 per chest. The decline stated in the exports of Malwa opium is attributed to Chinese production directly competing, and successfully so, with all inferior grades, none but the finest and purest Bengal opium finding a steady market. Thus at every stage the Government directly controls production and manufacture. There can be no doubt that with a commodity that bears such heavy taxation, an infinitely higher price could easily be paid to the cultivator than the amount actually received from Government, were the traffic free from all restraints and regulations. Here the first check is given by the prevention of the profits of production becoming an incentive to illicit traffic. The yield per acre may be put at from 6 to 8 seers, so that the profits of the cultivators are not materially greater than with other crops. It has been pointed out that the consumption locally of Govern-
ADVANTAGES OF THE CROP

Opium cultivation.

Opium is much lower in opium-growing than in non-opium-growing districts—a circumstance explained on the supposition that the cultivators always retain a portion of their produce for their own consumption and that of their friends. This deduction has therefore seemed to justify the belief that an average yield of 9 seers (18 lb.) to the acre would perhaps be more like that actually attained in good seasons. Mr. W. B. Johnson of Patna, who wrote an account of the cultivation of the poppy, given as an appendix to Sir W. O'Shaughnessy's Bengal Dispensatory (1841, app., 749), puts, however, the yield still higher, viz. 15 seers per bigha, and the total value of the crop at Rs. 80. The great advantages of the crop are advances made free of interest; the wells or other permanent improvements that become possible; an absolutely certain market; no fear of sudden changes in price or demand and prompt payment for produce; while in times of scarcity and famine it is an invaluable source of income.

Cultivation in Bengal and the United Provinces.—The opium year is considered to commence in September. It is customary to follow poppy after Indian corn or other kharif crops, the soil being at once taken in hand after the removal of the corn. It is ploughed at an interval of every ten days till the middle of October, when the sowing commences and may be extended to the middle of November. Land in the immediate vicinity of the village or homestead is selected for the crop on account of its being higher, usually more richly manured and more easily supervised. It requires a rich dark, sandy loam. The soil is often specially manured to the limits of the cultivator's resources—frequently 150 to 200 maunds of farm-yard manure. Penning sheep and goats on the field is regarded as one of the most satisfactory methods. Nitrate of potash is highly commended as a mineral manure. When top-dressed to the extent desired or possible, it is next partitioned off into oblong plots 6 or 8 by 4 feet for convenience of weeding and irrigation. The seed is usually specially selected from extra large or highly productive capsules. The advantage of the exchange of seed is also fully recognised, and the seed from certain localities is regarded as specially good. Still, there are no expert seed-producers, and much therefore depends on the integrity of the person with whom the exchange is made.

The day the seed is sown the land is well watered, and the next the clods on the surface are carefully broken. Six pounds are considered sufficient for a bigha of land (3,025 sq. yards). The seed is often soaked in water the night before sowing, and for this purpose some cultivators use a liquid manure. About a week after the plants shoot up, and when about 6 inches high the plots are weeded and thinned. Vigorous plants only are retained, and in the final condition these should not be closer than 7 to 8 inches each way.

Irrigation commences as soon as the plants appear, and resowing made in places where failure seems indicated. At regular intervals right up to the maturing of the fruit, flooding of the plots must be continued; but care has to be taken that the plants are never submerged or kept in stagnant water. Where subsoil moisture exists, watering may be delayed until December, and with certain soils may not be necessary at all.

Flowering and Collection.—The plants take from 75 to 80 days until full flowering can be said to have been attained. The petals, which are four in number, are removed the third day after expansion. These are carefully preserved and are the "Flower Leaves" of the casing employed with the
THE OPIUM POPPY

PAPAVER OPIUM Malwa

Malwa, Panjab, etc.—Of Malwa, for example, it has been said a mild climate, plentiful irrigation, rich soil and diligent husbandry are indispensable. The black cotton soils from which annual crops of wheat may be obtained without any manure are useless for poppy unless richly fertilised. In Baroda, poppy follows a crop of bajra. The following are the centres of production of Malwa opium:—In Central India—Indore, Gwalior, Bhopal, Bandelkhand, Baghelkhand, Malwa and Bhopawar: in Rajputana—Mewar, Jaipur, Haraot and Tonk, Eastern Rajputana States, Kotah, Alwar, Bikanir and Western Rajputana States. An interesting account of Opium in Malwa was prepared by Mr. H. Hastings in 1895. Shahpur is the chief opium-growing district in the Panjab, the supplies going mainly to the chief Sikh centres of Lahore and Amritsar.

[ Cf. Mollison, Textbook Ind. Agri., 1901, iii., 245-7.]

EXTRACTION AND MANUFACTURE OF OPIUM.

The cultivation of the poppy yields several distinct and paying substances. There are (1) the inspissated sap of the green capsules—crude opium; (2) the moisture and soluble substances that drain from the opium, known as paseva; (3) the poppy petals; (4) the “trash” or powder prepared from the leaves, dried stems, etc.; (5) the capsules; and (6) the oil-seed. The first-named three substances are those alone with which the Opium Department are concerned, and these, therefore, have to be dealt with here in some detail.

1. Crude Opium.—The green capsules are scratched in the afternoon with an instrument called the nashtar. This consists of four sharp blades tied together with cotton, passed between the blades so as to keep them one-thirtieth of an inch apart and allow of scratchings being made to a certain depth through the wall of the capsule and no farther. It is important that the wall of the capsule be never completely severed, but at the same time a purely superficial scratching is useless. The exact degree of penetration to ensure the best possible flow of milk requires great skill. The padding of cotton between the blades is intended to assist in this matter, since the blades can but cut up to that point when drawn at a certain angle. The incisions are usually made from below upwards, more or less perpendicularly. By modern usage this is done in the afternoon, but according to Johnson, “in the hottest part of the day, the juice as it exudes in the night may be protected by the pellicle formed in the day; the wound ought to be diagonal to prevent the juice from falling off in the night when the dews are heavy.”

Each capsule is usually lanced in this manner three or four times at
CRUDE OPIUM AND PASEWA

intervals of two or three days, but sometimes a single scratching may exhaust the drug, while occasionally an extra fine capsule may afford eight or even ten discharges. The opium from early sowings is thin but plentiful, and that from later sowings scanty but of a high consistence. The field is usually divided into certain portions, each taken in hand and scratched in one day, the others in succession and rotation until the entire crop has been collected. This ensures regular and systematic scratching which would not be attained by promiscuous work.

The drug formed is collected in the early morning on the day following the scratching. The juice adhering to the incisions is scraped off with a small trowel-shaped scoop of thin iron called the setwah. On the scoop being filled the drug is transferred to a metal or earthen vessel and conveyed to the farmer’s house for further manipulation. It is stored in an earthen pan tilted to one side so as to allow the liquid pasewa to drain from the more solid extract. In Benares the standard of good-quality crude opium is 70 per cent. opium, 30 per cent. fluid. The pasewa is decanted from time to time into another vessel, and the opium turned over as occasion arises to facilitate the draining off of the pasewa. In the Bengal agency the standard is a little higher, viz. 75 per cent. opium, and to obtain this condition the opium is dried by being placed on a cloth tied over the mouth of an earthen pot. The required further draining away of the pasewa takes place, but as the cloth gets impregnated with opium it comes to possess a money value, and is purchased at the factory under the name of kaffá (kaphá). The average yield for each scarification is about 10 grains, and a healthy plant after five to eight scratchings may yield 75 grains in all.

2. Pasewa.—This is the dark coffee-coloured fluid (as mentioned above) that drains from the crude opium in the process of drying. The chief purpose in removing this substance is to prevent the physical depreciation which its presence effects on the drug, viz. it turns it black and makes it liquid. Pasewa, however, consists of the most soluble of the opium principles dissolved in dew or moisture absorbed from the atmosphere. It has a peculiar smell, is strongly acid, and contains meconic acid, resin, morphia and narcotin. It is less abundant during westerly winds or in the absence of dews at night.

3. Leaves (Petals).—As already mentioned, the flowering season is January to March. But here again considerable skill is required, since if plucked off before they are ripe, the capsule afterwards contains much less opium than if the petals be allowed to fully mature. The hand is made to gently encircle the base of the flower, then drawn upwards, when, if properly matured, the petals will come away naturally. A day is selected for collection of petals when they are not moist, as otherwise they would get discoloured. The petals are then made into what is technically called “leaves.” For this purpose an earthen plate is placed over a slow fire, and over it is spread a handful of petals. These are then covered over with a damp cloth and pad until the steam from the cloth causes the petals to adhere together. The thin cake thus formed is turned over and the damp pressure repeated to ensure the union of the petals on both surfaces. When fresh they have a pleasant aroma, said to be imparted to the opium for which they are subsequently employed as the packing material. There are various grades or qualities of these petal cakes recognised and sold, separately packed in specially prepared baskets. These realise Rs. 10, Rs. 7 and Rs. 5 a maund according to quality.
4. "Trash."—This is the pounded poppy stalks and leaves. It is employed in packing opium.

5. Lewa.—This is the paste used in consolidating the "leaves" in the formation of the casing employed with provision opium. It is formed of all the inferior opium and paseva.

6. Seed and Oil.—The best seed is obtained from capsules that have not been lanced. They yield a sweet edible oil absolutely devoid, of course, of any trace of opium, though in preparing the excise opium it is the sweet oil employed to prevent the opium adhering to the paper in which it is packed.

Malwa Manufacture.—The systems of collection pursued in other parts of India differ almost wholly in the number of blades formed into the nashtar, the direction of the incisions, the method of collection and drying. The work of adulteration begins with the act of scraping off the drug from the capsules. If honestly done, the pure extract alone is removed; but if adulteration be desired, a portion of the superficial tissue of the capsule may be carried away with the drug. In Malwa the system prevails of depositing the collection of crude drug (known as chick) into a vessel containing linseed oil, in the proportion of one of chick to two of oil. This is justified from the desire to prevent evaporation. It is in reality a mode of adulteration, and the dealers refuse to purchase any opium that is thinner than half-dried glue. One acre of land well cultivated yields 70 to 100 lb. of chick which fetches 3 to 6 rupees a pound, so that the total crop will realise from 200 to 600 rupees to the acre.

The traders place the oil-adulterated drug in double bags suspended from the ceiling of a close and dark room, to allow of the excess oil draining off. In a month's time all the oil that can be separated is drained away. By June or July the opium is removed from the bags and thrown into large vats, where it is worked up until it attains a uniform colour and consistency. It is now made into balls of 8 to 10 oz. each, which are thrown into baskets full of a chaff prepared from the dried poppy capsules. It is then spread out on a floor covered with the "trash" or powder of the poppy leaves and stems, and there it remains until it has dried sufficiently to allow of packing, when about 150 of the cakes go to each chest. It is ready for the export market by October or November.

Bengal Manufacture.—It may now be desirable to describe the stages of manipulation pursued at the Government factories in contrast with that mentioned above with the Malwa drug. The opium, as purchased from the cultivators, is first tested for purity and quality. It is then stored in large wooden boxes capable of containing 10 cwt. Whilst thus stored it deepens in colour by exposure to air and light. From this is taken the quantity that is daily to be manufactured. This is sampled, assorted, kneaded up together and thrown into boxes, certain ones being again assayed. The opium is next placed in troughs and kneaded and thoroughly mixed by men wading knee-deep in it. When uniformity by these various stages of separating, sampling, mixing and kneading has been attained, it is next day made up in cakes. For this purpose the "leaves" required, having been weighed out and damped over-night, are given to each operator along with a supply of lewa. The leaves, lewa and opium required for each cake are accurately weighed out. The operator, taking a brass cup in his hand, places the leaves within it layer upon layer, moistened with the lewa, until
he thus builds up the shul (a structure half an inch thick). The cake of opium, brought direct from the scales, is now inserted within, and leaf after leaf moistened in the lewu is inserted until the space around the cake is filled up. The layers of leaves are now brought up over the opium and compacted together until the finished cake looks like a Dutch cheese in size and shape. It is now removed from the cup and rolled in a fine powder of "trash." It is then placed in earthen cups of the size to hold it comfortably, and carried out to be dried through exposure to the sun. In this position it is retained for three days, the cakes, or balls rather, being occasionally turned round. The weight of an average cake is about 4 lb. 3½ oz., but of that fully half consists of the shul that surrounds it.

Excise opium (known as Abkari opium) is inspissated by direct exposure to the sun until it attains the standard of 90 per cent., when its consistence resembles wax. It is then moulded into square bricks weighing about 2 lb. These are wrapped in oiled Nepal paper and packed in boxes furnished with compartments for the bricks.

**REVENUE AND TRADE IN OPIUM.**

*Consumption in India.*—The excise systems of the local Governments are framed in accordance with the Opium Act of 1878. To review even briefly the various enactments and methods of fiscal administration that prevail in the various provinces of India would, however, occupy many pages. For a concise statement, mention may be made of the *Moral and Material Progress and Condition of India* (1903, 171–6). Briefly, the consumption of opium is highest in the damp malarial tracts of India, where its use is universally believed to be beneficial. It is nowhere consumed to an extent to occasion anxiety; in fact, the use of opium by the people of India, as a rule, is distinctly moderate, excess being very exceptional and condemned by popular opinion. No physical or moral degradation can be regarded as occasioned by the Indian habit, at all comparable with the use of alcohol in Europe. The mean consumption expressed to head of population in British India (including the high rate prevalent in Assam) comes to 38 grains per head per annum, and if Assam be excluded it is under 30 grains. [Of. Papers relating to Consumption of Opium in Brit. Burma, Rangoon Press, 1881.]

In India, opium is eaten, drunk or smoked, opium-smoking being by no means uncommon. *Madak* is the special Indian preparation smoked by the lower classes. *Chandu* is a smoking mixture made after the Chinese method, and in India is used mainly by the Chinese. Opium is, as already remarked, almost a necessity of life with certain communities, and so much faith do the people place in the drug that they by no means infrequently give it to their horses when an exceptionally heavy task has to be performed. Moreover, with the people of India the danger of accumulative action or the establishment of a craving does not seem to exist. A very large number of persons take a daily allowance throughout life, and never show any tendency to increase the amount consumed. And some of the strongest and most healthy communities, such as the Sikhs, have to be placed in this category.

*Internal Traffic.*—The returns of traffic by the railways were, in 1904–5, 127,509 cwt.; in 1905–6, 130,412 cwt.; and in 1906–7, 144,255 cwt. The distribution from the provinces of production to those of consumption and to the ports of export were in 1906–7 as follows:—United Provinces, 69,574 cwt.; of which 54,057 cwt. went to Calcutta, 13,830 cwt. to Bengal, 13,830 cwt. to Bengal, 857

Revenue

THE OPIUM POPPY

1,416 cwt. to the Central Provinces and Berar, and 271 cwt. to the Panjab. The next important centre is Bengal, which exported 50,171 cwt., mainly to Calcutta. Then come Rajputana and Central India, which exported 18,500 cwt., mainly to Bombay town; and lastly the Bombay Presidency exported 2,983 cwt. to Bombay town, and these two items of Bombay town supply constitute the Malwa opium of commerce.

Opium Revenue.—The following statement of the opium revenue for five years may be instructive:

* Approximates.

The excise revenue on opium is composed of duty and vend fees. The former varies with local conditions, being highest where smuggling is most difficult. The average per seer in Assam is Rs. 23'5; in Bengal, Rs. 20'5; in Central Provinces, Rs. 13'5; in Madras and Bombay, Rs. 10; in the United Provinces, Rs. 8'8; and in the Panjab, Rs. 3'6. Adding vend fees the average ranges from Rs. 34'9 in Assam to Rs. 11'5 in the Panjab.

Foreign Sales.—The number of chests of Bengal opium sold (Fin. and Comm. Stat. Br. Ind., 1906, 50), and the average prices realised during the six years 1897-8 to 1903-4, were as follows:

Canton is the chief market for the Indian opium. According to the Consul-General's Report for 1905, 75 per cent. of the drug there used comes from India. The annual average imports by Canton are about 12,000 chests, or, say, about one-fourth of the total Chinese imports. But it is ascertained that about an equal quantity of local opium is smuggled into Canton via Pose and the West River from Su's'ch'uan, Yunnan and Kwei-chou provinces. The Chinese drug is 40 per cent. lower priced than the Indian, and can thus easily sustain all the risks incurred. According to Hosie (Opium Trade of China, in Pharm. Journ., Nov. 10, 1906, 512-3), the average import of foreign opium into China for the ten years ending 1904 was 52,127 piculs, and in the previous decade 72,298 piculs, so that for the twenty years since 1885 the average annual decline has exceeded 1,000 piculs. The import in 1905 was 51,890 piculs, or 2,876 piculs less than in 1904. That decline, says Hosie, is due not to a decrease in opium-smoking, but to an increased consumption of the Native drug. The greatest decline occurs in Northern China, where the import has fallen from 1,735 piculs in 1895 to 690 piculs in 1905. In Central China, the decrease in 1905 was 3,740 piculs as compared with 1904. In Southern China, on the other hand, the figures show an apparent increase. In 1895 the imports amounted to 18,708 piculs, in 1905 to 25,209 piculs. It is stated, however, that these figures must not be taken to indicate an increase in consumption of the drug by the people. They are due chiefly to the fact that with the final absorption of the Native Customs in 1901 the carrying trade for opium passed to steamers and entered and paid件
duty at the maritime customs. The imports, in short, are believed to have remained stationary, and that there has only been a transfer from the Native to the Maritime Customs.

The Persian production of opium and traffic with China is seemingly assuming considerable proportions. It is grown in the central provinces and carried via Bokhara, Khokan and Kashgar, and also, more recently, by sea. The Kermanshah opium is in consequence being frequently alluded to in Consular Reports. The shipments in 1895 were 2,440 chests, and in 1903 they had become 4,859 chests. While often much adulterated, Persian opium has a good name in Hongkong.

**Poppy Seed and Oil.**—Buchanan-Hamilton (Journ. Mysore, etc., 1807, i., 296-6) observes: "The poppy (Papaver somniferum) is plentifully cultivated both for making opium and on account of the seed, which is much used in the sweet cakes that are eaten by the higher ranks of the Natives." The seeds form a valuable article of food in the districts where poppy cultivation occurs. They have no intoxicating properties, but are better flavoured and richer in oil when taken from capsules that have not been tapped. The seeds are exported from the districts of production all over India, and are extensively employed by the sweetmeat makers or in the manufacture of certain curries. The oil obtained from the seeds is largely used for culinary purposes, the lowest grades being employed for lubrication or burning. The cake is said to be a wholesome food often resorted to by the poor, and is remarkably sweet and nutritious, and accordingly is greedily eaten by cattle. In India the oil is expressed by the cold process, the yield being about 30 per cent. In France three stages are observed:—1st, cold expression—a very superior oil used for table purposes and in the manufacture of very high-class paints; 2nd, cold expression—a lower-grade edible oil used also for paints and in illumination; and 3rd, hot expression—a much inferior oil to either of the others used chiefly in soap-making. The oil is rendered perfectly colourless by exposure to the sun. It is accordingly peculiarly suitable for mixing with paints; with white lead, for example, it forms a paint that does not readily tarnish. The price of the oil is the chief reason of its not being more extensively used in paint-making, as it is moreover a good drying oil. It is largely used by artists. Mixed with strong sulphuric acid, the rise in temperature is from 88° to 90° C. It takes about 19 per cent. of caustic potash to saponify it, and absorbs about 134 to 137 per cent. iodine.

**Trade in Seed and Oil.**—Perhaps the most significant feature of the foreign
trade in poppy seed (though an unimportant one relatively) is the fact that India imports this seed. The supply comes mainly from Persia, but during the five years 1901-6 has steadily declined from 3,858 cwt. in 1901-2 to 151 cwt. in 1905-6, nearly the whole quantity being taken by Bombay. In 1906-7 there was a slight increase on the previous year to 193 cwt. The exports are very considerable:—In 1900-1 they were 802,186 cwt., valued at Rs. 68,65,266; in 1904-5 they had expanded to 1,362,599 cwt., valued at Rs. 78,43,018; though in 1906-7 they declined to 802,615 cwt., valued at Rs. 65,77,231. The price seems to fluctuate very greatly, for while the quantity exported in 1902-3 was only 966,220 cwt., it realised Rs. 82,45,096. These exports go very largely to France, Belgium and Germany, only a very insignificant quantity to Great Britain. During 1906-7, out of the total indicated, the following were the shares taken:—France, 387,252 cwt.; Belgium, 326,038 cwt.; Germany, 88,260 cwt.; and the United Kingdom, 2 cwt.; all other countries the balance of the total. The shares supplied by the chief exporting provinces were Bombay, 526,262 cwt., and Bengal, 276,348 cwt. No figures are available for the exports of poppy-oil. The cake is chiefly employed as manure (see p. 771).

**PAPER AND PAPER MATERIALS.**—The word paper is derived from *papyrus*, the name of the Egyptian reed which afforded the material chiefly used to write upon in the classic times of Europe. On this subject Prof. E. Rapson of Cambridge writes me—"There is no ancient paper (in our sense of the word) in Egypt. When people speak of Egyptian paper they mean *papyrus*."

In other parts of the world various substances have similarly been employed as paper substitutes; for example, in classic India and Central Asia, more especially with the Sanskrit people, the birch-bark (*bhujpattra*) was, and to this day is still used for most of the purposes of paper (see p. 131). But in the moist climate of the plains of India, birch manuscripts would of necessity be very perishable, hence as a rule they are hardly more than 300 years old. As they exist they are copies of copies of copies. In Chinese Turkestan, however, manuscripts of the 3rd or 4th centuries A.D. have been found. On the plains of India, and from fairly ancient times, the leaves of certain palms have been employed for writing on. The oldest of all known Indian manuscripts are the palm-leaves found in Nepal, which belong to the 9th century A.D. The leaves most largely used are those of *Corypha umbraculifera* (*ola*, see p. 429) and *Borassus flabellifer* (see p. 170). While being written upon, the specially prepared strips of leaf are held in the left hand and the words scratched on the surface with a sharp style, the scratchings being sometimes loaded with pigment. In Assam the aboriginal tribes have for several centuries past used the inner bark of *Aquilaria Agallocha* (see p. 73) as a natural writing material, a substance that not inaptly compares with the thin boards of beech-wood (the material upon which the Teutons first wrote, and from which have come the words *bece, boe, buche, book*). It has been said that the ancient history of China was written on finely prepared strips of bamboo, and that these were destroyed during one of the dynastic wars. It is often, in fact, affirmed that bamboo as a writing material is even more ancient than the papyrus.

**History.**—Stein (*Ancient Khotan, 1907, 345*) furnishes much interesting information regarding the official documents, letters, etc., found by him during his excavations.
tions of the Niy and other sites. These MSS. consist, for the most part, of two sets; (a) those written in Khotan State itself, and (b) those in China. The materials used were specially prepared strips of wood (presumed by Stein to be *Populus alba*), the older ones being in imitation of bamboo slips; next, neatly folded pages of leather; and various kinds of paper; also, more rarely, birch-bark. Bamboo slips, according to Chavannes (Les lires Chinoises avant l'invention du papier, in As. Journ., 1905, 5–75), were used in China before the discovery of paper in 105 A.D. [Cf. Raynal, Hist. Phil. et Polit., 1782, iii., 146.] In fact, wood had come into use to displace bamboo, but was invariably cut to the size and shape of the older bamboo stationery. The Chinese wooden letters discovered by Stein bear out completely the tradition of the early Chinese letters. Why paper should not have reached Khotan until at least a century and a half after its discovery in China is hard to say. Whatever the cause may have been, wood was undoubtedly continued as the stationery of distant Khotan till the latter half of the 3rd century. Moreover, the early wooden letters found at Khotan are of two kinds: long, narrow and pointed (kilamudras), and rectangular tablets (likitakas), both being neatly tied up and furnished with seals. The pointed wooden letters were apparently of purely local manufacture, hence deal with local affairs, reports, official orders. The Chinese bamboo-like letters were not pointed nor furnished with seals, but they also convey official orders, and it has been established that they date from the Han epoch; in fact, one bears the actual date of 265 A.D., and is connected with the Wu-ti Emperor, the founder of the Western dynasty of China. While the imperial control of China was thus placed on the Khotan administration, it is quite clear that local self-government was to a large extent retained.

The letters on paper are all of a later date than those on wood. One picked up at Endere (Stein, i.e. 426) has been examined by Prof. J. Wiesner and determined to be made of *Daphne*-bark, and hence it is surmised the letter in question came from Tibet. Moreover, it was ascertained to date from early in the 8th century, and was noted to have had the surface sized and dressed with rice-water in order to render it suitable for writing purposes. It may thus be regarded as marking an important advance in the knowledge of paper-making accomplished by the people of Tibet. In passing, it may be added that the further advance of sizing with gluten was not made until the 14th century. So again it may be added that a dressing with rice-water was and still is the universal practice in the manufacture of the once famed Kashmir paper, an article greatly in demand some centuries ago for making copies of the Koran. Sir Walter Lawrence points out, moreover, that this dressing allowed of passages being readily obliterated with water, and was thus objectionable. Another paper mentioned by Stein (i.e. 307–8) dates from 718 A.D., and has been found to be written in Judaeo-Persian. This is, in fact, the oldest actual example of that language known. It was written in Persia, and was addressed to a Khotan official. Wiesner, who apparently examined the paper of this document also, has not determined the material used—except that it was different both from the Tibetan letter and from the numerous other examples of paper presumed to be of Khotan manufacture. Stein, commenting on the absence of paper from all the other ruins explored by him, adds, "The fact itself must be considered as certain, for rich though the ruins explored by me at the Niy river site were in rubbish remains of all kinds, not one of them yielded the smallest scrap of paper. This total absence of records on paper is all the more curious in view of the political connection with China, which did not cease, as our Chinese documents plainly prove, even after the close of the Han dynasty. Nor can it be attributed to the possible want of the paper-mulberry tree (*Broussonetia papyrifera*), from the bark of which the modern paper of Khotan is extensively manufactured, seeing that the alternative use of rags, hemp and other substances was known in China from the very time of the first invention of paper (105 A.D.)." The MS. found at Dunjan-Ullig (8th century) has been identified as very possibly of Khotan manufacture, and so also those found at Kucha, which, though a little earlier (5th century), are also regarded as made of *Broussonetia* fibre. But as opposed to the idea of an ancient local industry in paper-making, there are two circumstances that seem worthy of mention in this place:—

(a) None of the botanists who have collected plants in Turkestan, Mongolia, Yarkhand, Gilgit, Ladakh, Kashmir, Afghanistan, etc., appear to have seen *Brouss-
INDIAN KNOWLEDGE

while locally made paper is sometimes spoken of as procured from other indigenous plants, such as a species of Desmodium.

(b) The material of the Bower, Macartney and Godfrey Manuscripts was found by Wiesner (Denkschr. Akad. Wiss. Wien. Math.-Nat., 1902, lxxii., 1–50) to be usually a mixture of fibres in which Bobkewaria (ramie) and Brassaexenia (paper-mulberry) were the chief. These MSS., being for the most part in Sanskrit, were not likely to have been written in China, while the presence of ramie fibres in their fabrication precludes all idea of having been made in Khotan or anywhere in East Turkestan.

Wiesner, reviewing the information to hand regarding the paper-mulberry tree, says that in Japan the fibre has been used for the manufacture of paper since the 6th century of our era, but earlier still in China. The Chinese use the young shoots of the bamboo in paper-making. [Cf. Karabacek, Das Arabische Papier, 29.] Prof. Giles (in a letter to Wiesner) remarks: “The earliest paper (in China) was made from tow, old linen, fishing-nets, etc. Modern paper is made from bamboo fibre, the bark of the Brassaeckia papryacea and rice straw. I can find no record of different papers at different periods. It is expressly stated that in Sau'ch'uan hemp was used for making paper, in Fukien bamboo, in the north mulberry bark, in Kiangsu rattan, on the sea coast lichen, in Chahkiang husk of grain, in Central China silk and in Hupeh Brassaeckia papryacea and rice straw.” The MSS. discovered by Stein at Khotan thus prove that paper manufacture was very possibly known and practised in Persia, Central Asia, Tibet and China many centuries before the art was known in Europe.

There is no very certain knowledge when the art of paper-making came to India. It is not mentioned by any trustworthy writer until the 14th or 15th century. Recently it has been affirmed in the Indian public press that paper-making was practised at Sialkot 620 years ago. Marco Polo, towards the close of the 13th century, was one of the earliest authors who made known the fact that the Chinese issued paper money, the paper being prepared from the bark of the mulberry. [Cf. Travels (ed. Yule), i., 378.] Kublai Khan had paper-money made in Pekin about 1200 A.D., and thus about the time when paper, as we now understand it, was first made known in Europe. Polo, therefore, expresses no astonishment at the material paper, but simply as the fact of its being accepted in place of gold and silver. John Ray (Hist. Pl., 1688, ii., 1302) mentions that the art of paper-making was introduced into Germany from Galicia in 1470 A.D., and he gives a description which is interesting from the fact of being supposed to have been new and instructive at the time when penned.

Nicolo Conti, who visited India in the early part of the 15th century, says, “The inhabitants of Cambay alone use paper; all other Indians write on leaves of trees, of which they make very beautiful books. But they do not write as we, or the Jews do, from left to right or right to left, but perpendicularly, carrying the line from the top to the bottom of the page” (Winter Jones, transl.; also in ed. Hakl. Soc., 1857, 31). A little later Abd-er-Razzak, Ambassador from Shah Rukh, visited India in 1442 A.D., and, like Nicolo Conti, went to Bidjanagar (Vijajanagar), the capital then, as he says, of the mightiest kingdom on earth. To-day that great city is a vast ruin, no part of it inhabited, and public buildings which were in process of erection are left as if the stone-workers had but gone for their midday meal.

“The writing of this people, says Abd-er-Razzak, is of two kinds: in one they write their letters with a kalam of iron upon a leaf of the Indian nut (the cocoa-nut tree).” “These characters have no colour and the writing lasts but a short time. In the second kind of writing they blacken a white surface; they then take a soft stone, which they cut like a kalam and which they use to form the letters; this stone leaves on the black surface a white colour, which lasts a very long time, and this kind of writing is held in high estimation.”

It is customary to read that paper-making was introduced into Hindustan from Kashmir in the 16th century about the time of the Emperor Akbar. Lawrence (Valley of Kashmir, 379) tells us that Kashmir was once famous for its paper, which was in much request in India. It was made from rags and hemp fibre sized with rice-water. He then adds that it is believed the art was introduced from Samarkand. It is often said the Arabs learned the art on the capture of that city and thence in due time carried it to Spain. So also Gibbon mentions that the knowledge of paper-making from linen rags was diffused from Samarkand, and Cassire is of opinion that it reached Mecca in the year 710 A.D. It is,
Nepalese Paper.

however, highly likely that Nepal was possessed of the same knowledge, and that both States may have derived their skill from Tibet or China; and it is certain (from Nicolo Conti and others) that paper was used in India at least a century prior to Akbar’s time. Pietro della Valle (Travels, etc., 1623 (ed. Hakl. Soc.), ii., 291) speaks of books being written on palm-leaves at Mangalore, “not on paper,” and Thevenot (Travels in Levant, Indostan, etc., 1657, pt. iii., 90) also mentions that palm-leaves were used by the Malabars as a writing material. But Ovington (Voy. to Suratt, 1689, 249), less than a century after Akbar’s time, gives such vivid a picture of the merchant’s account books that it is difficult to realise that he is speaking of fully two centuries ago. “The paper-books,” he says, “in which the Inhabitants of India, on which they write, are long Schrolls of Paper, sometimes Ten Foot in length, and a Foot broad, sewed together at the upper end, as many long Sheets as the occasion of the Writing requires. The Pen they write with is the ancient Colamus or Reed, about the thickness of a large Goose Quill. And some of their Standishes are made long and square and above an Inch broad and of sufficient length to contain both Pens, and a place for Ink.” He then describes the manner of writing obliquely and down the long pages in such a fashion as to explain Nicolo Conti’s statement of the Indians writing from the top to the bottom of the page. Ovington expresses says that the Indian writing is not like the Chinese, in straight lines downwards, but “from the uppermost corner of the left to the lowermost corner of the right.” The long page of the books, however, was doubtless the idea that inspired Nicolo Conti. But Ovington goes on to say that the paper used in India “by its Slickness and Smoothness appears shining, which is of ordinary use, but such as which they write upon, either to the Bee or to Persons of consequence is gilt all over the surface, as ours is on the Edges.”

San Hemp Paper.

Nitroside published in 1774 (Phil. Trans., iv., 99; abridg. ed., xii., 506) an interesting account of the Indian paper manufacture practised in his day. The material was san hemp (Crotalaria juncea), but for paper-making “old ropes, clothes and nets, made from the san plant” were preferred to fresh fibre, presumably because of their cheapness. These san rags were cut up into small pieces, macerated in water for a few days (generally five), washed in the river in a basket, and thrown into a jar of water lodged in the ground; the water being strongly impregnated with a lixivium of “sedgi-mutti” (crude carbonate of soda) six parts, and quicklime seven parts. “After remaining in this state eight or ten days, they are again washed, and while wet broken into fibres, by a stamping lever, and then exposed to the sun, on a clean terrace, built for this purpose; after which they are again steeped in a fresh lixivium as before. When they have undergone three operations of this kind they are fit for making coarse brown paper; after seven or eight operations, they are prepared for making paper of a tolerable whiteness.” The pulp thus produced is taken up on a fine-wire frame just as in the English manner.

Burmese Paper.

Nisbet (Burm on under Brit. Rule and Before, 1901, i., 386) says the Native manufacture is now confined mainly to “the preparation of parabaik or paper-slates used at the monasteries, and of umbrellas.” The inner fibre of soft bamboo shoots or the bark of the maulaing or paper-mulberry (Broussonetia papyrifera) being pounded into a pulp with water, and half its weight of lime being then added, it is boiled with water until nothing but the pulp is left. This is pounded and spread thinly over a coarse cotton muslin framework, and allowed to dry in the sun. It now forms a rough grey parchement, about a cubit in breadth, which is folded up in alternating folds of about nine inches wide. When coated with finely powdered charcoal dust mixed in glutinous rice-water it is ready for being written upon with pencils of steatite or soap-stone.” The use of paper in the manufacture of Burmese umbrellas is an important branch of the local industry, but unfortunately the artistic indigenous paper umbrella is rapidly being displaced by the cheap European article, and the making of the special umbrella paper is accordingly rapidly becoming a thing of the past. The Burmese system of writing on black-coloured pasteboards (parabaik) recalls Abd-er-Razzak’s story of the people of the now lost empire of Vijajanagar (see above), who wrote on black surfaces with a soft stone. The supposed close affinity of the Telugu people to certain of the Burmese races gives an interest to this curious circumstance that it might not otherwise be supposed to possess. In Japan, paper-making is very ancient and the plant chiefly used is (as in Burma) the paper-mulberry. The reader will find Rein’s account of Japanese paper-making most instructive (Industry of Japan, 1889, 393-419).
THE TWO CHIEF INDIAN GRASSES

Paper Manufacture.—The Native art of paper-making in India to-day is very much like that of glass-blowing; it consists in re-making waste paper. In a country teeming with fibres, it is surprising that the question of a good paper material has not been satisfactorily determined. And this theme seems to be constantly revived by residents in Europe who overlook the immense size of India. A few hundred miles are of little concern in most questions, but with paper-making transit freights soon kill the prospects of supplies. Then again the cost of land near the centres of trade where paper mills are usually built, precludes the special cultivation of paper stuffs. Moreover, as paper fibre, like esparto, must be fit for almost immediate immersion in the vats, paper-making can never pay the cost of separation and preparation, however simple and inexpensive. No fibre known to commerce can compete with jute in point of cheapness, yet the paper-makers can afford to purchase jute waste and jute cuttings only, so that but for the demand for an altogether different purpose the paper-maker could never procure jute at all.

The two most important paper grasses in India are bhabar (Ischemium, p. 694) and munj (Steccharum, pp. 929–30). These are now being largely used by the Indian steam-power paper mills, the supply at a remunerative price being the chief obstacle to their further utilisation. It has been demonstrated that bamboo (pp. 108–10) affords an excellent paper, but practical difficulties exist such as the cost of the chemicals required, and the fact that the wholesale removal of the young shoots, which alone are serviceable, injures the stock. It accordingly has to be added that, at present, the most valuable paper materials in India after bhabar and munj are old rags, waste gunny bags, waste jute and san ropes, old paper, etc.

Whatever may be the source of the cellulose, it has to be reduced to pulp, and in most cases bleached. If rags are used, a preliminary dusting is essential. The material is then boiled with alkalies; in the case of grasses, such as esparto, a 10-per-cent. solution of caustic soda under a pressure of 10 to 50 lb. of steam is required. The pulp thus obtained is then washed to free it from the residuary alkalies, thoroughly pulped mechanically, then loaded with the mineral sizing material and coloured as desired. This is known as the magma, and to convert it into paper a fine wire cloth is passed through the trough containing liquefied pulp, when a film of the required thickness is made to adhere and is removed. This is then compressed by being passed between rollers and, if so desired, is sized with gelatine, and lastly dried off by being passed between heated rollers or colanders.

[ Cf. Morris, Cantor Lect., Soc. Arts, 1895; Cross and Bevan, Textbook of Paper-making, 1900; Blount and Bloxam, Chem. for Engin. and Manuf., 1900, 344–7; Julius Habner, Cantor Lect., 1902-3; Chem. Appl. to Arts and Manuf. i., 513-42; Clayton Beadle, Chapters on Paper-making, 1904, i.; 1906, ii.; Hänauers, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 92-4; Stuhlmann, Halfa-Gras oder Esparto für Deutsch-Ostafrika, Der Pflanzer, 1907, No. 15-7.]

Paper Mills.—The first works for the manufacture of paper organised in England date from 1588, and these were established at Dartford in Kent by a German jeweller, John Spielman, who was knighted by Queen Elizabeth. A century previously similar works had been erected in Spain. So late as 1690 coarse brown paper only was made in England, the supplies of the finer white papers being obtained from France and Holland. The war with France occasioned such a rise in duty that a stimulus was given for the improvement of home production. But an

Jute Paper.  

1840.  

"Serampore Paper."  

Capital Engaged.  

Indian Mills at Work.  

Act of Parliament had to be passed before the desired improvement became possible. The first white paper made in England was produced by a Mr. James Whatman of Maidstone. Soon, however, England made rapid progress, but so late even as 1801 English paper was entirely hand-made.

The first occasion on which cotton was used in England was in the manufacture of paper. Cotton paper superseded the more expensive parchment of previous dates. Mention is made of cotton paper in 1102 (Macpherson, Ann. Comm., 1805, i., 315 (many passages)). It is often affirmed that linen paper appeared before that from cotton, but there is no very satisfactory proof of that opinion, though it is quite likely that the discovery of pulping fibrous materials may have led to the use of linen and cotton almost simultaneously. [Cf. Yates, Text. Antiq., app. A., 383–8.] One of the earliest detailed accounts of the Native methods of paper-making in India is perhaps that given by Buchanan-Hamilton (Stat. Acc. Dinaj., 272–3), the material used being jute. Prior to 1840 India obtained a large share of its paper supplies from China. About that date interest was aroused in the subject, and both Hindu and Muhammadan factories for hand-made papers were established all over the country. During Sir Charles Wood's tenure of the office of Secretary of State for India, an order was issued for the purchase of all the supplies required by the Government of India in Great Britain, and this threw back very seriously the growing Indian production.

It is not very certain when paper mills were established in India. The expression "Serampore Paper" is used all over India for a particular class of Native-made white paper. Mr. D. M. Traill wrote, some years ago, an interesting account of paper-making in which he reviews briefly some of the historic facts, especially the chief grades of paper and firms concerned in their production (Ind. For., 1891, xvii., 322–30). He there tells us that the capital engaged in the paper trade is nearly fifty million pounds, of which three-fourths represent plant and one-fourth working capital. He then concludes with a brief notice of the Indian mills, in which he refers to the fact that a paper mill in Serampore was the pioneer, and adds, "we well recollect seeing the silent and rusty machinery as far back as 1864."

"There are eight paper mills in operation—three in the Bombay Presidency, four in Bengal, and one at Lucknow. Of the eight, two are private concerns in the Bombay Presidency, one of which has stated the capital invested. So far as information is obtainable, the total capital invested amounts to Rs. 67,33,000 (of which Rs. 57,63,000 are paid up), besides Rs. 11,07,650 debentures, and shows a decrease of 6 lakhs, compared with 1902, owing to the reconstitution of the Imperial Paper Mill at Kankinara as a branch of the Titagarh Paper Mills Company, Ltd. Most of the white and blue foolscap and much of the blotting paper, note-paper, and envelopes used in the Government offices are now obtained from the Indian mills. The total quantity of paper made in 1904 was 45 million pounds, and its reported value Rs. 61,49,446. The mills employ 4,266 persons. The capital employed has been doubled in twenty years since 1885, and the production and number of persons employed have increased about fourfold. Two of the larger mills in Bengal have paid no dividends for five years, as they have been unable to compete successfully with the cheap wood-pulp paper of attractive appearance which is
largely imported from Europe” (Fin. and Comm. Stat. Br. Ind., 1906, lix.).

Trade.—Internal.—The total transactions by rail and river in paper and pasteboard amounted in 1906–7 to 457,355 cwt. The chief exporting centres were the Province of Bengal, 214,137 cwt.; Bombay sea-port, 87,116 cwt.; Calcutta, 61,121 cwt.; Madras ports, 31,530 cwt.; the United Provinces, 26,109 cwt. The chief importing centres were Calcutta, 160,162 cwt.; the Panjāb, 80,559 cwt.; United Provinces, 40,530 cwt.; Bombay, 37,916 cwt.; Bengal, 21,936 cwt. By coast, the returns are given in rupee values. In 1906–7 the exports were valued at Rs. 11,69,758 and the imports at Rs. 9,05,237. Bengal exported paper to the value of Rs. 11,56,510; while Madras imported to the value of Rs. 6,50,297, Bombay, Rs. 2,09,866, and Burma, Rs. 20,124.

External.—The Exports from India of manufactured paper amount to little. For the period 1900–7 the total value of manufactured papers of all sorts, including pasteboard, was as follows:—1900–1, Rs. 78,227; 1901–2, Rs. 53,638; 1902–3, Rs. 42,903; 1903–4, Rs. 26,781; 1904–5, Rs. 28,350; 1905–6, Rs. 13,703; 1906–7, Rs. 6,607. In 1906–7 the total was made up thus:—printing paper, Rs. 5,885; writing paper and envelopes, Rs. 167; other kinds, Rs. 507; pasteboard, Rs. 50. Almost the whole of the printing paper, writing paper and pasteboard go from Bengal, and ordinarily of other sorts also, but in 1904–5 Bombay supplied the largest share of writing paper. During the same period the export of rags and other materials for paper manufacture showed the following returns:—1900–1, 21,683 cwt., valued at Rs. 70,833; 1901–2, 26,321 cwt., valued at Rs. 67,840; 1902–3, 13,431 cwt., valued at Rs. 46,490; 1903–4, 9,077 cwt., valued at Rs. 34,705; 1904–5, 10,248 cwt., valued at Rs. 29,543; 1905–6, 19,831 cwt., valued at Rs. 83,870; and 1906–7, 12,581 cwt., valued at Rs. 67,412. India also re-exports quantities of manufactured paper, and in 1906–7 these were valued at Rs. 76,614.

The Imports of paper, on the other hand, are large, and in late years show a slight increase. For the period 1900–7 they were valued as follows:—1900–1, Rs. 45,29,996; 1901–2, Rs. 52,71,634; 1902–3, Rs. 52,48,058; 1903–4, Rs. 52,18,396; 1904–5, Rs. 64,37,288; 1905–6, Rs. 70,48,978; and in 1906–7, Rs. 80,11,105. In 1906–7 the total was made up thus:—printing paper, Rs. 28,33,632; writing paper and envelopes, Rs. 22,66,714; other kinds of paper, Rs. 25,75,366; pasteboard, Rs. 3,35,393. The largest quantities come from the United Kingdom, and in 1906–7 these were valued at Rs. 44,06,312; from Germany, Rs. 15,82,445; Austria-Hungary, Rs. 7,04,525; and Belgium, Rs. 6,66,638. In the same year the imports of rags and paper materials were valued at Rs. 86,173.

As showing the value of esparto grass as a paper-making material, it may be mentioned that Messrs. Ide & Christie, in their monthly circular of September 16, 1907, show that for the years ending August the imports received by Great Britain of that grass were in 1905, 198,508 tons; in 1906, 186,242 tons; and in 1907, 192,809 tons. Needless to say, India imports no esparto. The British supply is mainly Spanish, Algerian, Tunisian and Tripoli, and the prices shown range from £3 2s. 6d. to £5 2s. 6d. per ton.

Paper Materials.—As already set forth, the chief considerations in the selection of paper materials are cost at the mill and constancy of

867
supply. The chief materials are accordingly rags of linen or cotton; esparto, munj and habar grasses; flax in the form of spinners' waste; hemp in the form of fragments of used rope; wood; straw; jute waste and old paper remade. Hanusek (Micro. Tech. Prod. (Winton and Barber, trans.), 1907, 100-2) gives the following paper fibres:—linen rags, hemp, cotton rags, jute, straw, esparto, maize, júār, wood, etc.

Paper (as may have been inferred from the brief account of manufacture given above) is literally a felted fabric composed of vegetable cellulose fibrils. When the fibrils, of which it is proposed to be made, are cemented together as in wood, they must be liberated and the raw material thus reduced to the condition known as "half stuff," and finally "pulp." In this condition, when floated out in water, allowed to settle over a frame and the water drained away, the felting of the fibrils takes place and paper is formed. Obviously, therefore, the less bulky the raw material the cheaper its transport to the mill. From this point of view, the advantages are entirely on the side of wood; it is compact, can be transported easily, more especially if a waterway connects the forest with the mill, and requires no expensive storage. But the pulp obtained from wood is of a very different nature from that of cotton rags, so that the purpose for which the paper is to be used comes in as a governing factor in the selection of the crude material.

The following are some of the chief materials used in the manufacture of paper in India:—

<table>
<thead>
<tr>
<th>Native Name (Paspalum Scrobiculatum)</th>
<th>Scientific Name</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adansonia digitata</td>
<td>Helicteres Isora</td>
</tr>
<tr>
<td>Agave sp.</td>
<td>Hibiscus cannabinus</td>
</tr>
<tr>
<td>Antiaris toxicaria</td>
<td>Ischaemum angustifolium</td>
</tr>
<tr>
<td>Bambuseae</td>
<td>Musa sp.</td>
</tr>
<tr>
<td>Broussonetia papyrifera</td>
<td>Opuntia Dillenii</td>
</tr>
<tr>
<td>Corchorus sp.</td>
<td>Phénix paludosa</td>

<tr>
<td>Crotalaria juncea</td>
<td>Saccharum arundinaceum</td>
</tr>
<tr>
<td>Daphne cannabina</td>
<td>Sansevieria zeylanica</td>
</tr>
<tr>
<td>Edgeworthia Gardneri</td>
<td></td>
</tr>
</tbody>
</table>

Several of these will be found discussed in their respective places in this work; for the others the reader is referred to the Dictionary (vi., pt. i., 107-9). The chief ones are Ischaemum and Saccharum, but with the Native paper-makers of the plains of India, the san hemp (Crotalaria) and the hemp-leaved Hibiscus are the most important, and on the hills, Daphne and Edgeworthia afford the so-called Nepal paper. Sir W. Thistleton-Dyer (Kew Bull., 1888, 81-4) was instrumental in drawing attention to the fact that in Siam the bark of the tree Strybicus asper is employed in the fabrication of Native paper. The tree is plentiful in many parts of India. (See Alkaline Earths (pp. 55-6, 58); Acacia Jacquemontii (p. 15); Agave (p. 43); Aquilaria (pp. 73-4); Alpinia (p. 60); Caryota (p. 286).)

**Area.**—Returns under this crop are available only for Bombay, where in 1905-6 there were 204,022 acres, chiefly in Gujarat, Katnágiri, the Uplands of the...

**Pennisetum typhoideum**

Bulrush Millet

Konkan and the Ghāt parts of the Deccan. In the Central Provinces the area occupied is believed to be greater than in any other part of India, but it is not returned separately. Together with *kalā* (*Eleusine indica*) it occupied, in 1904-5, an area of 2,039,345 acres. In the same year in the United Provinces, *Paspalum* and other small millets covered 1,933,753 acres. In *Field and Garden Crops* it is stated to be grown more extensively than any other millet in the United Provinces, and over a large portion of these provinces it is the favourite crop for inferior outlying lands. This is chiefly on account of the readiness with which it grows on the poorest of soils, not on account of the quality of the grain. Sowing takes place at the commencement of the rains, at the rate of 12 to 20 lb. seed to the acre, and the crop is cut in October. It is either grown alone or (in the Doāb) mixed with cotton, and in the Benares Division with *dal* (*Cajanus*). Careful weeding is required to secure a good outturn, which is estimated at 10 to 12 maunds per acre.

**Cultivation.—** Of Bombay, Mallison (*Textbook Ind. Agri.*, 1901, iii., 64-7) observes that the crop is important in the *poydū* soils of the Kaira district and similar alluvial soils in Baroda. It is never grown alone in Gujarat, the usual mixture being *tāver* (*Cajanus indicus*), *tal* (*Semionapus indicus*), and *ambādī* (*Ambardia ambardi*). If properly manured, the mixture may be sown about 3-4 weeks after year in the same field. In low-lying damp fields rice and *krodā* are grown together, the mixture being known as *vagadū*. In preparatory tillage the bladed harrow (*kařab*) is used to loosen the surface soil and prepare a friable, shallow seed-bed. The seed is furrowed with the three-coultoured drill (*łařn*), and the seed is mixed before sowing in about the following proportions:—12 lb. *krodā* : 2 lb. *tāver* ; ½ to ¾ lb. *tal* ; ¼ lb. *ambādī*. After sowing, the field is levelled, and the crop should subsequently be weeded once in about a month or six weeks and bullock-hoed two or three times. It is ripe early in October, and reaped with a sickle, tied into bundles, and threshed by bullocks in the usual way. Mallison gives the outturn of a good Kaira crop as follows:—

<table>
<thead>
<tr>
<th>Grain &amp; Straw</th>
<th>Yield</th>
<th>Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>Krodā</em> (12 lb. seed), 985 lb. grain per acre, 1,304 lb. straw</td>
<td>869</td>
<td>23 per acre</td>
</tr>
<tr>
<td><em>Tāver</em> (4 lb. seed), 265 lb. grain per acre, 232 lb. straw</td>
<td>277</td>
<td>22 per acre</td>
</tr>
<tr>
<td><em>Tal</em> (½ lb. seed), 130 lb. grain per acre</td>
<td>152</td>
<td>22 per acre</td>
</tr>
</tbody>
</table>

The crop is of great value in the poor season, required during the critical months of July and August, and though not of marked nutritive value, its fibre content is of great importance in affording a check to the spread of rickets and scurvy.

Though used as Food by a large number of people in India, the grain cannot be considered a wholesome article of diet, and in some seasons contains a poisonous narcotic principle. In Gujarat the poisonous and non-poisonous grain are known in the beāzas as *mitha* and *minā* respectively. Damp cloudy weather towards harvest time, a damp season and damp soil are said to produce poisonous *krodā*. Leather (*Agri. Ledg.*, 1901, No. 10, 370; 1903, No. 7, 151, 180) gives the following analysis of the grain:—moisture, 8.01 ; oil, 3.38 ; albuminoids, 5.81 ; soluble carbohydrates 70.06 ; woody fibre, 8.47 ; soluble mineral matter, 1.34 ; sand and silica, 2.95 ; total nitrogen, 1.00 ; albuminoid nitrogen, .93. [ Cf. Church, *Food-Grains of Ind.*, 1886, 39-40 ; Basu, *Agri. Lohardaga*, 1890, pt. 2, 29 ; *Pharmacog. Ind.*, 1893, iii., 619-20 ; Rice, *Mysoor Gaz.*, 1897, i., 117-8 ; Mukerji, *Handbook Ind. The Bulrush, Cumboo or Spiked Millet, *bājra*, *lahra*, *kasa-jonar*, *jōndhariya*, *lendha*, *kambū*, *gantelū*, *sajja-tū*, *sajje*, *mattari*, etc. A tall erect grass, 5 to 6 feet high, probably of African origin.

**CULTIVATION.—** Though grown to a less extent than *juār* (*Sorghum vulgare*), its cultivation is geographically very similar and comprises extensive tracts in Northern, Western and Southern India. The following were the acreages in British India during the three years ending 1905-6:—14,157,482 in 1903-4 ; 10,369,765 in 1904-5 ; and 11,630,710 in 1905-6. In the Native States:—1,382,473 in 1903-4 ; 1,305,446 in 1904-5 ; and 893,949 in 1905-6.

**Bengal.—** This crop may be described as unimportant, the area fluctu-
THE BÁJRA MILLET

Cumboo

The bájra millet, sometimes used as manure, but no irrigation is required. It is sown at the end of July at a rate of 6 to 10 lb. seed per acre. Harvesting takes place in October and November, and the outturn of grain amounts to from 300 to 500 lb. per acre.

**United Provinces.**—The area in 1905–6 amounted to 1,792,526 acres in Agra and 372,848 in Oudh. In Agra the largest areas occur in Budaun, 200,643 acres; Agra, 166,787 acres; Moradabad, 160,014 acres; Etah, 113,936 acres; Allahabad, 95,903 acres; Shahjahânpur, 99,049 acres; Bareli, 87,746 acres. In Oudh, Hardoi, 130,771 acres; Unaô, 59,738 acres; Sitapur, 47,884 acres; Lucknow, 36,588, acres. According to Duthie and Fuller it is a kharif crop, sown a little later and reaped a little earlier than juâr; is accordingly a useful substitute when sowing has been delayed through floods or failure of the rains until juâr is impossible. It is rarely sown alone, but generally mixed with the same minor crops as are grown with juâr, except that mung (Phaseolus radiatus, Linn.) is usually replaced by moth (P. aconitifolius). It generally occupies poor, light soil, and requires less rainfall than juâr. It is never manured and rarely irrigated. The land is ploughed one to four times and the seed (mixed with that of the subordinate crops) sown at the rate of 2½ to 3 seers per acre. There should be at least one weeding. The grain ripens towards November, when the heads are cut off and carried to the threshing-floor. The cost of cultivation is estimated at Rs. 9–8a. per acre, and the outturn varies in different localities from about 5½ maunds of grain to 7 maunds, and the outturn of dry fodder about 30 maunds. [Cf. Agri. Led., 1895, No. 17, 233; Nevill, Dist. Gaz. U. Prov.; Cawnpore Exper. Farm Repts.]

**Central Provinces and Berar.**—The area in 1905–6 was 40,608 acres in the Central Provinces and 55,188 acres in Berar. In the former:—Nimar, 22,146 acres, and Narsinghpur, 11,470 acres; and in the latter cultivation is almost entirely in Budaun with 46,080 acres.

**Rajputana and Central India.**—The crop is grown largely in the Native states, especially in Alwar, where in 1905–6 the area was 221,604 acres; Bharatpur, 193,465 acres; Gwalior, 184,426 acres; Marwar, 165,692 acres; Jaipur, 79,093 acres; Mysore, 39,944 acres. In Ajmir-Merwara the area was 32,043 acres. The crop is sown at the same season as barley (June–July), and on dry lands only. The average yield is stated to be 1–73 cwt. per acre. [Cf. Watson, Rajputana Dist. Gaz., 1904, 1., 46, 56.]

**Panjâb and North-West Frontier.**—Bájra is largely grown in the districts of the Panjâb, and in the dry elevated tracts south of Rawalpindi it constitutes the principal kharif crop. In 1905–6 the area was 829,269 acres. The largest shares are as follows:—Jhelum, 108,684 acres; Gujrât, 103,624 acres; Rawalpindi, 94,766 acres; Attock, 68,357 acres; Gurgâon, 66,091 acres; Hissar, 64,345 acres; Shahpur, 55,746 acres; Delhi, 21,016 acres; Rohtak, 13,219 acres. In the North-West Frontier the area was 71,355 acres, mainly in Kohât. During the year under review the area seriously declined. In the districts of Hissar, Rohtak, Gurgâon, Delhi and Karnâl it fell from 1,135,674 in 1904–5 to 169,116 acres in 1905–6. The average yield for the year 1901–2 was 407 lb. per acre in the Panjâb, 402 lb. in the North-West Frontier. In Dera Ghâzî Khan it is the most important crop after wheat, and in the Rawalpindi district is the staple of the autumn harvest. It thrives everywhere in the plains at the base of the Salt Range, and in untoward years is usefully replaced by til
THE SPIKED MILLET

(Sesamum indicum) or some of the pulses. In the Karnál district it thrives best on a sandy soil, and is thinly sown after the first rainfall, mixed with the seed of some small pulse. In Kohat it is sown between April and August, and is the principal kharif crop on the barani (i.e. unirrigated) lands of the district. The crop is generally cut in October. In the Banni district it is largely grown on the stiffer than soils. It is sown at the rate of 2 to 5 seeds per acre from the middle of March to end of July. The first-sown crops ripen about the middle of August, and ears are plucked as they ripen till early in December. [Cf. Dist. Gaz. Panjāb; See. Repts. Panjāb.]

Bombay and Sind.—The area in 1905–6 was 4,354,437 acres in Bombay and 567,406 acres in Sind. In Bombay the largest areas were:—Ahmadnagar, 904,590 acres; Nasik, 803,469 acres; Poona, 681,413 acres; Khandesh, 583,686 acres; Satara, 366,940 acres; Bijapur, 340,560 acres; Kaira, 218,159 acres. In Sind, Thar and Parkar, with 406,033 acres, and Hyderabad with 338,221 acres, are the chief localities.

Mollison says it is entirely a rain crop, occupying the lighter description of soils in all districts of moderate rainfall. The crop does best when the climate is moderately dry and when the monsoon comes in downpours, with plenty of sunshine between the showers. Except in parts of Khandesh it is always a mixed crop, and as such may be grown continuously on the same land. But rotation is also frequent. In the lighter soils of Khandesh it is considered a good preparation for varodi cotton. In the sandy soils of Kaira, Ahmadabad, etc., it is rotated with kodra (Paspalum scrobiculatum), sundhia (Sorghum bicolor), juar (Sorghum vulgare), etc. In the light soils of the Deccan it is rotated with juar, niger-seed, etc. In the Deccan the subordinate crops with bajri (= bajri in Bombay) are, separate rows of tur (Cajanus indicus) and a sprinkling of udid (Phaseolus Mungo, Linn.), math (P. aconitifolius), kulkhi (Dolichos biflorus), ambadi (Hibiscus cannabinus), etc. In Gujarat the most common subordinate mixture is perennial rozi cotton in rows and math in amongst the bajri, but two or more of the following may also form subordinate crops, viz. mag (Phaseolus radiatus, Linn.), chola (Vigna Catjang), gur, tur or tucer (Cajanus indicus), sesamum and shiera (Hibiscus cannabinus).

In Gujarat the land should be ploughed two or three times after the first fall of rain, then left for some time. The field should again be ploughed shortly before sowing. Sowing takes place between 1st and 10th of July. The seed-rate mixture recommended is as follows:—bajri, 6 lb. per acre; gur, 1 lb.; math, 1 lb.; mag, ½ lb.; sesamum, ½ lb.; ambadi or shiera, ½ lb.; turor, 1½ to 2 lb. All are mixed together before sowing, except turor, which is sown separately in every fourth row. The seed is drilled in rows about 15 inches apart, and the surface then levelled. When the seedlings are about 6 inches high, the crop is bullock-hoed and hand-weeded, and again when 2 feet high. A crop sown in early July will be ripe the beginning of October. It is reaped with a sickle close to the ground, left lying in the field for several days, and then stacked.

Mollison gives the following outturn (grain, seed or by-product) from a well-managed field in the Kaira district:—bajri, 900 lb.; math, 120 lb.; gur, 80 lb.; sesamum, 60 lb.; shiera, fibre. The cost of cultivation he estimates at Rs. 26–1a. per acre. [Cf. Crop. Exper. Bomb. Pres.; Mollison, Textbook Ind. Agri., 1901, iii., 18–23.]
PETROLEUM

THE BÁJRA MILLET

Madras. Areas.

*Madras and Mysore.*—The total area in 1905–6 was 3,004,717 acres in Madras and 39,943 acres in Mysore. In Madras the largest areas occur in Coimbatore, 580,299 acres; Salem, 376,257 acres; Cuddapah, 341,311 acres; South Arcot, 276,284 acres; Guntur, 255,511 acres; Trichinopoly, 173,721 acres; North Arcot, 133,643 acres; Madura, 164,194, etc. In Mysore, Chitaldrug had 33,448 acres.

In the Godavari district it is grown on *regada, lanka* and sandy soils. The ground is manured in March by penning cattle or sheep on it, and in May it is ploughed twice every six days for three weeks. The ground, both then and at the time of sowing, should be moist. The seed, which should be the previous year’s produce, is sown in June, 4 seers to the acre. In Coimbatore it is cultivated on dry lands, except black. It is often grown as a mixed crop with cotton, castor-oil, pulses, etc. The land is ploughed in April, during the heavy rains, after having been manured. In July–August it is again ploughed, and the seed, mixed with various pulses, is sown broadcast, with *dál* or beans in rows a few feet apart. After six weeks the crop is interploughed and occasionally weeded. In November–December it is reaped by cutting off the ears as they ripen. The pulses are gathered gradually up to February, when the *kambu* stalks, beans, etc., are all pulled up together, leaving the cotton and castor only.

*Burma.*—In 1905–6 the area was 74,802 acres, all in Upper Burma, and chiefly in Myingyan, 42,958 acres, and Magwe, 26,526 acres.

Diseases.—An interesting account of the disease known as *Sclerospora gymminicola* is given by Butler in the *Memoirs of the Department of Agriculture, India* (1907, ii., No. 1). As Butler points out, however, it is not usually of sufficient intensity to attract much attention. [Cf. Maxwell-Leifroy, *Mem. Dept. Agri. Ind.*, 1908, ii., 9.]

**FOOD AND FODDER.**—The grain is used chiefly by the lower classes of Natives, and in many parts of India is their staple Food. The flour, made into cakes or bread with butter-milk, is considered more nutritious than rice. In Khandesh it is often eaten with butter and various condiments. The following is the analysis published by Leather (Agri. Ledg., 1901, No. 10, 370; 1903, No. 7, 151, 154, 181):—moisture, 8.77 per cent.; oil, 5.83; albuminoids, 9.52; soluble carbohydrates 73.52; woody fibre, 7.8; soluble mineral matter, 1.73; sand and silica, .35; total nitrogen, 1.61; albuminoid nitrogen, 1.51.

In the Panjáb, *bájra* is occasionally grown for Fodder and in unfavourable seasons may be given to cattle in the green condition, especially if the crop has proved a failure. The stalks, after the grain has ripened, are more or less utilised in all the provinces where available. In the Kurnāl district it is said that in some of the higher villages the stalks, called *dándar*, are even stacked and preserved until required, when they are chopped up and given to cattle along with green fodder. *Bájra* straw is much more generally employed as a cattle fodder in the Madras Presidency than in most other provinces. [Cf. Church, *Food-Grains of Ind.*, 1886, 56–9.]

**PERFUMERY** (see Oils, p. 820).

MINERAL OIL

pt. 1, 69–77; 1906, xxxiii., pt. 1, 15; 1907, xxxvi., pt. 2, 77. The mitti-ka-tél, kala salajit, minak tanah, manyenney, manti-tayilam, ye-nd, etc. Petroleum, otherwise known as mineral or rock oil or naphtha, is essentially a mixture of hydrocarbons of the paraffin and olefine series. It occurs stored in loose-textured conglomerates and sandstones, in which its distribution is similar to that of water in porous strata; being retained by impervious beds of clay. It may exude through any accidental fissure at the surface of the earth and thus form natural oil-springs, but is chiefly obtained by boring through the impervious covering strata into the oil-sands below, from which the oil may be raised by pumping; or it sometimes "gushes" out by pressure of the associated gaseous hydrocarbons. As to its origin, various theories have been advanced, such as that it is derived from the action of water on strongly heated iron carbide contained in the interior of the earth; and that it has been formed by the decomposition of the remains of animal matter at a high temperature or in contact with saline deposits, and the subsequent resolution of the more permanent fatty constituents into hydrocarbons and free carbon dioxide. Ball remarked on this subject, "There can be little doubt that the formation of petroleum is intimately, though obscurely, connected with the presence of salt, otherwise it would be difficult to account for the simultaneous occurrence of petroleum and brine-springs, which have been observed in India, as well as in Pennsylvania and Virginia."

Although much progress has been made in developing the petroleum resources of India, at the present day, according to Holland, these afford little more than 1 1/2 per cent. of the world's supply. The chief sources are the United States and Russia, which together produce about 90 per cent. [Cf. Redwood, A Treatise on Petroleum, 1906, for an account of the chief occurrences and a full bibliography.] The following figures show the huge increase in the Indian production within recent years:—1890, 4,132,287 gallons; 1895, 13,003,748 gallons; 1900, 37,720,211 gallons; 1904, 118,491,382 gallons; 1906, 140,553,122 gallons. The traffic of 1906 on 1905 represents an expansion of 22.6 per cent.—mainly in the new Singu field, of which it is believed a large portion is still held in reserve.

OCCURRENCE.—According to Holland, petroleum in India is confined to the two systems of folded rocks at either extremity of the Himalaya—
(1) the Iranian on the west, including the Panjáb and Baluchistan, and continued beyond British limits to Persia, and (2) the Arakan system on the east, including Assam and Burma, and continued to the oil-fields of Sumatra, Java and Borneo. In both areas the oil is associated with tertiary strata.

Panjáb and United Provinces.—The districts from which oil has been reported are Shahpur, Jhelum, Bannu, Kohát, Rawalpindi, Hazará and Kumaon. The output, however, is small, ranging between 1,000 to 2,000 gallons a year. In 1903 it amounted to 1,793 gallons, and in 1906 stood at 871 gallons.

Baluchistan.—The early efforts made to develop the oil resources in different parts of Baluchistan have been described in the Dictionary. The most prominent of these are near Khotan in the Marri hills and Moghal Kot in the Shiráni country, where springs examined in 1891 were found to yield oil of a high quality. Holland says that the oil-spring in the neighbourhood of Moghal Kot affords a good illustration of the way in which a country, well endowed with the conditions necessary for the
production of petroleum, may lose its resources by destruction of the natural reservoirs. "The Moghal Kot oil-bearing beds form a very open anticlinal fold, whose axis pitches to E.N.E., and if the dome possessed the necessary plastic, impervious envelope, the oil rising up from below would have become concentrated in the porous beds which form the saddle, but for the fact that along this line the rocks are more easily eroded by surface water, and the anticline thus forms the gorge of a river by which the rocks have been opened to permit the waste of oil for an indefinite time" (Holland).

Assam.—In 1865 the springs in the Assam oil-fields were visited by Medlicott, who stated that, though the discharge was small, they were the most promising he had seen. In 1867 a Calcutta firm obtained permission to prospect and struck a promising oil-spring at a depth of 118 feet near Makum, but nothing more was done till 1883, and very little development occurred in the following sixteen years. These oil-fields were first systematically reported on by Mallet (Mem. Geol. Surv. Ind., 1876, xii., 356), and were again examined by Mr. R. A. Townsend, Superintendent Petroleum Works, Baluchistan. According to Mallet, the oil-springs may be classified for commercial or leasing purposes into the following districts—(1) those of the Tipam Hill, north of the Dihing; (2) those of the range between the Dihing and Disang; (3) those of the Makum coal-field, south of the Dihing between the Dirack and Tirap rivers; (4) those to the east of the Tirap. The chief locality is that of the Makum coal-field, the best wells being at Digboi. In 1899 the Assam Oil Company was formed with a nominal capital of £310,000 (Holland, Rev. Min. Prod. Ind., Lc. 75). The result was that the output rose from 623,372 gallons in 1899 to 1,756,759 gallons in 1902; 2,585,920 gallons in 1904; and 2,733,110 gallons in 1905.

Holland observes that "the belt of tertiary rocks extending from the north-eastern corner of Assam for about 180 miles south and west shows frequent signs of oil, nearly always in association with coal and sometimes associated with brine-springs and gas-jets. The series of earth-folds in which this corner of Assam occurs stretches southwards to Cachar, where oil-springs are also known, through the little-known Lushai hills into Arakan, and in the same system of parallel folds occur the oil-fields of the Arakan coast on one side of the Yoma, and those of the Irrawaddy valley on the other." [Cf. Repts. of Assam Oil Coy., Ltd., 1900-3.]

Burma.—Holland furnishes the following brief account of the areas of Burma that are actually worked at the present day. "The most productive oil-fields of Burma are those on the eastern side of the Arakan Yoma, in the Irrawaddy valley, forming a belt stretching from the Magwe district, in which the well-known field of Yenangyaung occurs, through Myingyan, in which Singu occurs, across the Irrawaddy into Pakokku, where Yenangyat is situated. Oil is, however, known further south in Minbu, Thayetmyo and Prome, and further north in the Chindwin valley, but these areas have not so far been thoroughly prospected, and the great development which has recently taken place has been the direct outcome of work in the three fields, Yenangyaung, Yenangyat, and Singu."
"Yenangyaung, the best known and most developed of the fields, still holds the lead as producer. The oil in this area has been worked by Native wells on both sides of the dome for well over one hundred years, and before 1886 the annual yield was generally over two million gallons, but soon after systematic drilling was introduced in the central Kodaung tract in 1887, the output gradually rose to over 10 million gallons in 1894, and last year, 1903, reached a record of 56,920,662 gallons." In 1904 the output of Yenangyaung was 73,428,960 gallons, and in 1905, 85,648,749 gallons.

"Yenangyat yielded very small supplies of petroleum before 1891, when drilling was started by the Burma Oil Company. The expansion was slow until 1894, when 324,086 gallons were produced, but rose rapidly to 6,036,088 gallons in 1898, to 22,665,518 in 1903." It has since, however, dropped to about 18½ million gallons a year.

"Singu has suddenly come into prominence. Petroleum was first struck by the Burma Oil Company in this area on October 30, 1901, and arrangements were then made to provide tanks for its reception. Production did not consequently begin till 1902, when only 174,880 gallons were turned out, with the opening of the new wells, but the output jumped up to 5,617,381 gallons in 1903; 23,677,450 gallons in 1904; and 37,541,177 gallons in 1905. The crude oil first obtained had a specific gravity of 0.8247 and flash-point under 40° F., in consequence of which primary stills were erected on the field to remove the light naphthas before transport to the Rangoon refineries."

"Besides the Upper Burma oil-fields, the islands off the Arakan coasts, noted for their mud volcanoes, have also been known for many years to contain oil deposits of uncertain value. The chief operations have been carried on in the Eastern Barongo Island near Akyab and on Ramri Island in the Kyaukphyu district. During the past six years the average output of the former area has been 42,926 gallons, whilst in Kyaukphyu the output in the same period has averaged about 100,000 gallons, with a distinct tendency to decline," but the output from these islands is now rapidly diminishing.

The total production of oil in Burma in 1905 amounted to 142,063,846 gallons. The output of the various oil-fields was as follows:—Akyab, 53,455 gallons; Kyaukphyu, 60,647; Yenangyaung, Magwe, 85,648,749; Singu, Myingyan, 37,541,177; Yenangyat, Pakokku, 18,759,818.

**Properties and Uses.**—For particulars regarding the introduction and expansion of the demand for kerosene oil for illuminating purposes in India, the reader is referred to the particulars given under Oils (see p. 812). The following information on the composition and uses of petroleum is abstracted mainly from the account published by Mr. Edmond O'Neill (Develop. of Petrol. Indust., 1901). Chemically considered, petroleum is a liquid of varying composition. The colour ranges from clear water, white through shades of yellow, amber, and brown to black. Its viscosity varies from great mobility to a thick tar-like mass, and its specific gravity from 0.771 to 1.020. The refractive index and coefficient of expansion are high and the specific heat is low, but both vary in oil from different places. Oils from the same locality usually resemble one another, but not always.

Crude petroleum is used to a very slight extent otherwise than as a fuel, a mixture for insecticides and for coarse lubrication. A quantity is also used in gas-making. For other purposes it must be refined, and this is effected by distillation. The crude oil is made up of a number of products of different boiling-points, some gaseous, some liquid, some solid. On boiling the oil and condensing the vapours, first the gaseous, then the liquid, and then the solid pass over, leaving a non-volatile residue. These distillates and the residue are themselves made up of a number of different bodies that may to a certain extent be separated. The most valuable of these is the illuminating oil, known also as Kerosene, coal oil, burning naphtha and by various other names. The portions of the distillate boiling at lower temperatures than the illuminating oils are also of commercial value. They are known as gasolines, rhigolenes, ligroines, benzenes, petroleum spirits, etc. Their principal use is as solvents for fats, oils, varnishes, paints, and as fuel for gas engines, gas machines, ice-making machines, and other purposes. The higher boiling portions of the distillate are employed chiefly as lubricants. Still higher boiling portions that condense to solids and semi-solids are known as vaselines and paraffins.

Simple distillation is not sufficient to prepare the above substances, so that they can be satisfactorily used. They must be purified. This usually consists in distilling, washing with acid (mostly sulphuric), alkali (usually soda or ammonia), and water. Sometimes the distillates are sprayed through air to remove malodorous constituents. Some of the oils are bleached either by the sun or by chemical reagents, or they may be filtered through charcoal or bone-black. In the case of solids, recrystallisation is ordinarily resorted to, i.e. the body, such as paraffin, is dissolved in some of the low-boiling constituents, usually naphtha, and the solution cooled in ice and salt. The paraffin thus crystallises out.

**Legislation.**

Tests and Legislative Measures.—The term "Flashing-point" is technically employed to designate the temperature at which any sample of petroleum or its products begins to give off sensible quantities of inflammable vapour. To prevent accidents it was enacted by the American Petroleum Act, and by the British Petroleum Act of 1871, that no petroleum oil should be used for burning in lamps which gave off inflammable vapours at any temperature below 100° F. (38° C.) when tested in an open cup described in the schedule of the Act. The increase in the consumption of the article, however, between 1871 and 1877 necessitated the adoption of a system of testing less liable to vary. The question was referred to the late Prof. Sir F. Abel, who proposed the use of a closed vessel to be heated in hot water, with a standard flashing-point of 73° F., equivalent to 100° on the open-cup system. This proposal was eventually adopted as the basis of the English Petroleum Act of 1879. The law under which petroleum is tested in India is Act XII. (1886), in which the testing apparatus prescribed is an improved form of Abel's. Several other modifications, based on the special conditions attendant on the application of the test in a warm climate, have also been incorporated in the schedule of the Act. As changes of pressure influence the flash-point, a table showing the corrections to be applied for variations in barometric pressure is also

appendix. Dangerous petroleum is defined as petroleum having a flash-point below 76° F., but a consignment guaranteed uniform is not to be considered dangerous if it has an average flash-point of 73° and no sample flashes below 70° F.

Revenue.—In 1888 an import duty of half an anna a gallon was levied by the Government of India on petroleum, and in 1899-90 the revenue obtained amounted to Rs. 1,62,392. In 1894-5 this tax was doubled, as part of the means adopted to reduce the large deficit which then existed. The revenue from petroleum in that year was Rs. 3,17,995. Since 1894 the tax has remained at 1 anna per gallon, and the revenue thus obtained during the five years 1900-6 amounted to the following figures:—1900-1, Rs. 49,29,332; 1901-2, Rs. 53,03,104; 1902-3, Rs. 53,79,857; 1903-4, Rs. 43,99,912; 1904-5, Rs. 45,88,289; 1905-6, Rs. 36,64,723 (= £244,314).

TRADE.—Internal.—The movements within India itself are instructive. Thus the total recorded Exports of internal trade transactions by rail and river in 1904-5 amounted to 4,366,522 cwt.; in 1905-6, 4,458,541 cwt.; and in 1906-7, 6,194,699 cwt. Of that amount Bengal exported 2,592,587 cwt.; Bombay port, 1,531,394 cwt.; Madras ports, 983,133 cwt. The chief importing provinces were Eastern Bengal and Assam, 1,294,710 cwt.; Madras, 892,290 cwt.; United Provinces, 851,335 cwt.; Bombay, 678,944 cwt.; Calcutta, 462,135 cwt.; Central Provinces and Berar, 587,547 cwt. The total coastwise transactions may be represented by the following quotations:—IMPORTS, 1901-2, 17,187,223 gallons, valued at Rs. 70,97,587; in 1903-4, 40,469,364 gallons, valued at Rs. 1,62,72,273; and in 1906-7, 66,065,365 gallons, valued at Rs. 2,40,54,011. Of EXPORTS, Burma supplied in 1906-7, 58,372,648 gallons, and Bengal, 1,231,537 gallons. Of that supply Bengal took 33,074,834 gallons; Bombay, 9,226,720 gallons; Sind, 2,428,796 gallons; and Madras, 8,896,029 gallons. But in addition to Indian petroleum, foreign oil is carried along the coast. In 1901-2 this came to 6,069,534 gallons, and by 1906-7 had decreased to 2,304,032 gallons, the major portion being from Bombay to Madras, Kathiawar and Goa.

The Trans-frontier export trade in petroleum shows in recent years a steady increase. In 1904-5 the figures were 160,559 cwt., valued at Rs. 10,65,506; 1905-6, 180,748 cwt., valued at Rs. 11,15,212; 1906-7, 178,533 cwt., valued at Rs. 11,81,921. The largest quantities go to Nepal, viz., in 1906-7, 100,938 cwt., while considerable quantities are also conveyed to the Shan States and Kashmir. The imports during the same period are unimportant, amounting in 1906-7 to only 66 cwt.

External (Foreign) Exports.—The foreign EXPORT trade in petroleum has sprung into eminence within the last two or three years. The following are the exports of kerosene and paraffin wax for the period 1900-7:—1900-1, 258,752 gallons kerosene, valued at Rs. 1,29,376, and 37,943 cwt. wax, valued at Rs. 7,94,551; 1901-2, 16 gallons kerosene, valued at Rs. 8, and 54,097 cwt. wax, valued at Rs. 9,45,443; 1902-3, 2,085 gallons kerosene, valued at Rs. 1,050, and 56,464 cwt. wax, valued at Rs. 10,43,149; 1903-4, 913,908 gallons kerosene, valued at Rs. 4,27,692, and 43,894 cwt. wax, valued at Rs. 8,13,128; 1904-5, 4,076,139 gallons kerosene, valued at Rs. 19,99,413, and 54,707 cwt. wax, valued at Rs. 11,13,777; 1905-6, 1,766,566 gallons kerosene, valued at Rs. 8,83,151, and 56,795 cwt. wax, valued at Rs. 11,58,394; and in 1906-7, 24,684 gallons kerosene, valued at Rs. 10,928, and 60,208 cwt. wax, valued at 877
MINERAL OIL

PETROLEUM TRADE

Rs. 12,42,601. Exports of mineral oils, other than kerosene, amounted in 1904-5 to 164,253 gallons; 1905-6, 12,962 gallons; and 1906-7, 881,452 gallons. India also re-exports large quantities, amounting in 1904-5 to 2,097,472 gallons; 1905-6, 1,161,012 gallons; and in 1906-7, 486,676 gallons.

Imports. — The Imports of mineral oils are large and important. According to Holland, during the years 1897-1903 they averaged nearly 83 1/2 million gallons, valued at £2,314,801. Of the two great producing countries, Russia and the United States, which during the years in question supplied between them about 93.5 per cent. of the imported foreign oil, Russia has been gradually increasing its predominance over the States. In 1897-8 Russia contributed 58.1 per cent. of the imports and the States 29.7, but in 1901-2 the former had secured 85.5 and the latter only 9.5 per cent. of the Indian custom, though a slight reversal occurred in 1902-3 (Holland). In the Imperial Gazetteer of India (iii., 139) later particulars are given. Of the imports, it is said of the foreign oil that “about 75 per cent., amounting to 64 million gallons a year, comes from Russia, and 19 per cent. from the United States, while large quantities are now being obtained from the productive fields in the Dutch East Indies.”

In the Review of the Trade of India (1905-6, 15-6) the total value of all mineral oils imported in that year into India is stated to have been Rs. 222.9 lakhs, or 32 per cent. less than in 1904-5. Of this total, Rs. 178.3 lakhs, or just 80 per cent., had reference to kerosene. During the years 1900-6 the imports of kerosene (omitting last three figures) are quoted as follows:—1900-1, 72,602 gallons, valued at Rs. 3,10,34; 1901-2, 91,467 gallons, valued at Rs. 3,51,57; 1902-3, 81,451 gallons, valued at Rs. 3,14,61; 1903-4, 71,559 gallons, valued at Rs. 3,07,58; 1904-5, 76,190 gallons, valued at Rs. 2,97,56; 1905-6, 50,949 gallons, valued at Rs. 1,78,32. During the same period, it is interesting to note that the exports from Burma (omitting last three figures) rose from 8,269 gallons, valued at Rs. 33,53, in 1900-1 to 47,600 gallons, valued at Rs. 1,62,34, in 1905-6, and that while in 1905-6 the imports of foreign kerosene declined by 33 per cent. in quantity and 40 per cent. in value on the imports of the previous year, the exports from Burma to India are stated to have increased by 10 per cent. in both respects.

Analysing the figures of supply, we learn that Russia gave to India (omitting last three figures) in 1901-2, 84,478 gallons, and in 1905-6, 7,617 gallons; the United States, 5,768 and 22,332; the Straits Settlements, 1,023 and 10,391; and Sumatra, nil and 5,401 gallons. As a parallel to these records, it may be here added that Burma supplied India in 1901-2 with 13,463 gallons, and in 1905-6 with 47,160 gallons. It is also stated that “case oil” is giving place to “bulk oil” importation, and that “more than half of the above decline in total imports is to be traced to the falling off of 11 1/2 million gallons in arrivals of case oil from Russia alone, this being due to the destruction and anarchy that prevailed in the Russian oil region.”

Prices. — The following average prices in Calcutta, during 1905-6, of various classes of kerosene are quoted in the Review (I.c. 16):—American, Chester, per case, Rs. 4-2-9; Russian, Rising Sun, per case, Rs. 3-10-6; Anchor, per case, Rs. 3-6-8; Ram, per case, 3-9-7; Burma, Victoria, per 2 tins, Rs. 2-11-5; Gold Mohar, per 2 tins, Rs. 2-14-6; Borneo, Cobra, per 2 tins, Rs. 2-11-9; Sumatra, Silver Light, per 2 tins, Rs. 2-11-9.
ACONITE-LEAVED KIDNEY BEAN

**PHASEOLUS ACONITIFOLIUS**

Sumatra, Silver Light, per case, Rs. 4–13–8. The prices of American Chester Oil, the standard illuminant, are shown to have been very steady for the last ten years. In 1896–7 the average price per case was Rs. 4–3–3, and in 1905–6, Rs. 4–2–9.

A glabrous herb found throughout tropical and sub-tropical India, and often cultivated for use as a Vegetable and for its Essential Oil. The fruit yields on distillation with water 3 to 4 per cent. of an essential oil, which has well-known medicinal properties and is also employed for perfuming soap. Both fruit and leaves are used to impart a flavour to curries. [Cf. The Bower Manuscript (Hocornl., transl.), 1893–7, 170; *Pharmacog. Ind.*, ii., 128–9; iii., app., 159; Woodrow, *Gard. in Ind.*, 1903, 344.]

**P. aconitifolius, Jacq.;** Duthie and Fuller, *Field and Garden Crops,* 1882, i., 41–2, t. xi. The Aconite-leaved Kidney Bean, *moth (math), bhringya, banumuga kheri, bir mung, matti-kalai, tulka-pyre, kunctma-pesali, madki,* etc. A perennial or annual herb, found throughout India from the Himalaya to Ceylon, ascending the hills to 4,000 feet in altitude, especially in the north-west.

Generally cultivated in the plains as a hot-weather crop (June–July) and reaped in autumn (*kharif,* October–November), and specially suited to dry, light sandy soils and for green-manuring (*Watt, Pests and Blights of the Tea Plant,* 1898, 175, 177). In some localities it is an important crop, as in the United Provinces, where in 1904–5, together with *urd (P. Mungo, Linn.), mung (P. radiatus, Linn.),* and *lobia (Vigna Catjang),* it occupied an area of 1,062,783 acres; and in Bombay (including Sind), where it alone occupied in 1905–6, 299,701 acres. Of the United Provinces, Duthie and Fuller state that it grows on the worst land that can be made to bear a crop. It is sometimes sown alone, but more often in millet fields, especially of the spiked or bulrush millet (*bajra*). Its cultivation is very haphazard. Two or three ploughings are held sufficient, and the seed is sown broadcast at the rate of 4 seers to the acre. The highest outturn which could be taken as an average is 8 maunds to the acre with rather less than double that amount of fodder. Of Bombay, Mollison (*Textbook Ind. Agri.,* 1901, iii., 85–6) states that this pulse is fourth in importance, and is grown to a considerable extent in all districts except the Konkan. It is rarely sown alone, and is a common subordinate crop with *bajra.* The best outturn is obtained on the deep alluvium sands or sandy loams of Ahmadabad and Kaira. Heavy rain is harmful, and it is most successfully grown with a well-distributed rainfall of about 30 inches. It ripens after the *bajra* and is reaped in November–December. A fair yield in an average season may be 120 lb. pulse per acre from a seed-rate of 1½ lb. with the value of the pulse at 40 to 45 lb. per rupee.

The beans are used to a considerable extent in certain parts of India,
especially in Bombay, as a Vegetable. The pulse is split and eaten as dali, also cooked in various ways. It is considered a useful medicinal diet in cases of flatulence, and as a food in fever. The whole plant is a valuable fodder and is frequently grown, either alone or mixed with some millet, for this purpose exclusively. [Cf. Church, Food-Grains of Ind., 1886, 152; Leather, Agri. Ledg., 1903, No. 7, 152, 156, 181.]

**P. lunatus, Linn.; Kev Mus. Guide, 1907, 68. Lima or Duffin Bean, kursumbulle-pullie, bunbur-butt, tik-bit-zim, kerow-simbi, kataridadboa mah, udadyaweli, pegyi, etc.** A tall biennial, with long scimitar-shaped pods and large seeds of variable colour. According to De Candolle, this is a native of Brazil. In India it is very generally cultivated, especially in Assam, Burma, Bengal, the United Provinces, the Panjâb, etc.

According to Fîrminger (Man. Gard. Ind. (ed. Cameron), 180), the seed should be sown in the plains during October (or just when the rains are over) and in rows about 4 inches apart; on the hills the sowing season is from March to June. The ripe seeds of the best kinds are pure ivory-white, and, when cooked in a similar way to haricot or broad beans, are used as a Vegetable and said to have the flavour of roasted chestnuts. Duthie says the young pods are sliced and cooked like French beans.

Interest has recently been aroused in this bean owing to the poisonous properties which the species sometimes exhibits. A report was issued by Dunstan on its chemical composition (Proc. Roy. Soc., 1903, 72, 285; also Agri. Ledg., 1905, No. 2). The first specimens examined came from Mauritius, where the plant is raised in a practically wild state and used as a green manure. Chemical examination showed the presence of a cyanogenic glucoside (phaseolustinat) and an enzyme. When these two were brought into intimate contact, the glucoside was decomposed by the enzyme, yielding, amongst other substances, about 0·04 to 0·09 per cent. by weight of prussic acid, the largest quantity being found in seeds with dark, purple-coloured testa, and the smallest in seeds with almost white testa. In partially or wholly cultivated forms, the testa is either pink with a few purplish spots, pale cream-coloured or even white. Dunstan states that these are undoubtedly less poisonous than the almost wild type grown in Mauritius. While the Mauritius beans were being investigated there were imported into England from India quantities of beans described as Rangoon, Burma or Paaiya beans, which were intended to be used in preparing food-stuffs for cattle. Plants were grown from some of them, and identified as *P. lunatus*. [Cf. Bull. Imp. Inst., 1903, i., 16, 115.] Subsequently authentic samples of the beans were procured from Pakokku district, Burma, and these were found to contain 0·009 per cent. of prussic acid, a quantity quite sufficient to render them undesirable for consumption, at any rate in the raw state. Dunstan concludes by advising the cultivating of this particular bean to grow perfectly white forms rather than coloured varieties. Leather (Agri. Journ. Ind., 1906, i., pt. iii., 224), in a paper on Cyanogenesis in Plants, alludes to the poisonous property. "I have obtained prussic acid," he says, "from Rangoon beans (Phaseolus lunatus) and wâl (Dolichos lablab) by simply allowing the crushed seeds to remain in cold water for a few hours" (see p. 767). More recently, Dunstan and Henry (Journ. Board Agri., 1908, xiv., 722–31) have given additional particulars and reviewed the results obtained by other investigators. They then conclude that "it is undesirable that any further definite advice should be given to discontinue the use of Rangoon beans, since in spite of the fact that both the red and white varieties have now been shown to yield prussic acid, there is at present no evidence that this is formed in quantity sufficient to be injurious, and although these beans have been used as a feeding stuff now for some years, no poisonous cases have been traced to them so far as is known. At the same time, since the beans yield prussic acid in varying quantity, it is clearly not permissible to recommend them for use as a feeding material. All that can fairly be done at the moment is to place the facts on record." [Cf. Church, Food-Grains of Ind., 1886, 155.]

**P. Mungo, Linn., Mant., 101; Prain, in Journ. As. Soc. Beng., 1898, lxvi., 423; var. Roxburghii, Prain, Beng. Plants, i., 387; P. Mungo, var. radiatus, Fl. Br. Ind., ii., 203 (in part); Duthie and Fuller, Field and Garden 880**
HIGHLY PRIZED PULSE

Crops, 1882, i., 39–40, t. x. The urud (or urd), dord, tircorai-kalai, másh-kulái, ramra, udíd, adad, patchay-pyre, mini-nulu, hasari, etc. There has been some confusion regarding the nomenclature of *P. Mungo* and the species which follows — *P. radiatus*, — due chiefly to Roxburgh having transposed the original Linnaean names. *P. Mungo, Linn.,* is the present plant, *uddid* or *urd*; while *P. radiatus*, *Linn.,* is the plant known in the vernacular as *mung*. There are two varieties of *uddid*, one with large black seeds, the other with smaller greenish seeds, and these correspond very possibly with *P. Mungo* proper and the variety *Roxburghii*.

**Area.** — *Urd* is the most highly prized of the pulses of this genus, and is largely cultivated in India, sometimes even in green manuring (see p. 225). Unfortunately the crop area is not uniformly and continuously recorded, so that only isolated quotations can be cited. In Bombay (including Sind) it occupied in 1905–6, 223,281 acres, but it would appear that either the wrong scientific names have been used in the official publications of Bombay (and in Mollison’s *Textbook Ind. Agri.*) for this and the next pulse, or that the names *mag, mung* and *uddid* have the opposite significations in Bombay than the usage prevalent in the rest of India. In the Panjáb in 1904–5 *mung* and *mash* together occupied 443,307 acres, and in 1906–7, 563,364 acres.

According to Duthie and Fuller, *uddid* is grown commonly as a subordinate crop with millet or cotton, but more often by itself. Sowing takes place at the commencement of the rains, and the crop ripens, one variety in August and September, another in October and November. When grown alone it is sown broadcast at the rate of 4 to 6 seers per acre. It prefers the heavier classes of soil, and is thus unlike *mung*, which prefers lighter soil. In this respect, it will be seen, Mollison holds a slightly different opinion, since he believes that both beans prefer heavy soils. Its average outturn when grown alone is about 5 maunds grain per acre with three times this weight of straw. In Bombay, Mollison states that *uddid* is grown generally subordinate to *juár* (*Sorghum vulgare*) or other cereals. It is a very important crop in the black soils of Khandesh, and is grown fairly extensively in Násik, Satara, Belgaum, Thána, and Ahmadabad. Of the total area during 1905–6, Khandesh had 106,670; Satara 33,673; Nasik 22,200; and Belgaum 14,689 acres. The total *rabi* crop came to 2,809 acres, of which 1,482 acres were in Kanara and 731 acres in Kolaba. It is raised mostly as a rain crop, subordinate to *juár*, but to a small extent alone in the *kharif* season, and over a considerable area in the *rabi*, chiefly as a second crop after rice.

**Uses.** — The green pods are eaten as a vegetable and the ripe grain is the most esteemed of all pulses in India. It is boiled and eaten whole or after being split, in the form of *dál*. Parched and ground to flour it is made into balls with spice, or is eaten in the form of a sort of porridge or baked into bread — it is the chief constituent of the wafer biscuit known in Bombay as *pêpad*. In the Panjáb it is used in the form of two preparations known as *bari* and *sepa*. Both are prepared by soaking the seed for a couple of days in slightly warm water, then crushing to a pulp, drying and mixing with *gхи* or buttermilk. Both the grain and the straw are valuable as horse and cattle food. *Medicinally* this pulse is highly valued by the Hindus.

P. radiatus, *Linn., Sp. Pl.*, 1753, 725; Prain, in *Journ. As. Soc. Beng.*, 1898, lxvi., 422; *P. Mungo*, *Fl. Br. Ind.*, ii., 203 (in part); Duthie and Fuller, l.c. 37–8, t. ix. Green Gram, *mung*, *maq*, *pessara*, *kheruya*, *bulat*, *ghora muga*, *chhimi*, *pucha-payar*, *vuthul*, etc. This pulse is a native of India and is met with both wild and cultivated throughout the plains, ascending to 6,000 feet in the outer ranges of the North-West Himalaya. There are three varieties, characterised by having green, yellow and black seeds. The confusion in nomenclature has already been explained under *P. Mungo*.

**Area.** — *Mung* is cultivated all over the Peninsula, though no estimate can be given of the total production. In Bombay, where it is returned separately (*Season and Crop Reports*), it is the fifth pulse in value, and occupied in 1905–6, 189,942 acres, and in Sind 32,690 acres. The most important centres are Dhārwar, Ahmadnagar, Khandesh and Bijapur. In Berar it would appear there were in 1904–5, 29,306 acres under it. The method of cultivation is essentially the same as for *urd*. Duthie and Fuller state that it is almost invariably a subordinate crop in fields of millet or cotton. It is, therefore, a *kharif* crop, sown at the commencement of the rains and reaped in October. Cultivation is the same as for cotton or millet. If sown alone, the seed-rate is about 12 seers to the acre. It is reaped about a fortnight before the millet crop, and threshed out by bullocks in the usual way.

Its chief cultivation is the *kharif*, but in Dhārwar, Kolāba and Kanara it is grown in the *rabi* season as a second crop after rice. It is then sown alone, subordinate to *juār* and other cereals. It does best on good, deep soil of fairly dense consistency, and with a well-distributed rainfall of 30 to 35 inches. When grown after rice in the *rabi* season, cultivation is the same as for *vál* (*Dolichos Lablab*), though the seed-rate is rather less (15 to 20 lb. per acre) and the preparatory tillage more careful. In the Deccan this pulse is sometimes sown alone in the *kharif* season as a catch crop before sugar-cane and other irrigated crops, which are planted in the *rabi* season (Mollison). The preparations made from *mung* are the same as those described for *urd*.

**Date Palms.**

*Phenix*, *Linn.*; *Fl. Br. Ind.*, vi., 424–8; Gamble, *Man. Ind. Timbs.*, 1902, 730–2; Prain, *Beng. Plants*, 1903, ii., 1095–6; Brandis, *Ind. Trees*, 1906, 644–6; *Palmeae*. A genus of palms which comprises some seven or eight species, all of which yield more or less edible fruits and are important from an economic point of view.

P. *dactylifera*, *Linn.*. The Edible Date; tree — *khajur*, *kasser*, *mach*, *karmah*, *pinā chiri*, *tār*, *perīta*, *swon-palvon*, etc.; fruit = *khurma*, *chāhāra*, *kukyān*, *pinā*, *chirvi*, *jarikha*, *tāmara*, *perīch-chankey*, *sombłon-zi*, etc.; *sindhi*, *seindhi*, *sendri* are names for this tree that denote its origin from Sind. A tall tree, often 100 to 120 feet, producing, when young, offshoots or “suckers” at the base of the stem. According to De Candolle, it has existed from prehistoric times in the warm-dry zone which extends from Senegal to the Indus basin, principally between the parallels 15° and 20°.
IN SIND AND THE PANJAB

CULTIVATION.—In India it is cultivated and self-sown in Sind and the Southern Panjab, particularly near Multan, Muzaffargarh, the Sind Sagar Doab, and in the Trans-Indus territory. Near Dera Ghazi Khán the trees are numerous, on a strip of country 10 to 12 miles long from north to south. A few are planted in the Eastern Panjab, at Saharanpur, in the Ganges Doab, and in Bandalkhand. It is also grown in the Deccan and Gujarat. In recent years, through Government agency, plantations have been started in various places, e.g. in Sind. The chief difficulty in cultivating the tree is to secure the exact climatic conditions necessary for success. [Cf. Sly, Exper. in Cult. of Dates, in Agri. Journ. Ind., 1906, i., pt. iii., 256–7.]

Climate.—Fletcher (Agri. Ledg., 1906, No. 1) gives a full account of the conditions under which successful cultivation is carried on in other countries. The relative low humidity and rainfall in typical date-growing regions is a marked feature. Rain at the time of flowering spoils the pollen, and during the ripening season causes fermentation of the fruit. The former, in all regions of successful production, is March to May, and the latter, August to November. Where the best dates are produced, more than half the total yearly rainfall occurs between November and March, thus before flowering commences. On an average, rainfall during the flowering and fruiting season should not exceed 5 inches.

In addition to this amount of rainfall, irrigation is absolutely essential, for if there be sufficient rainfall to dispense with irrigation, it will be too great to allow the flowers to pollinate and the fruit to set fully and ripen well. The requirements as to temperature are peculiar. In a dormant condition, it can withstand temperature as low as 20° F., but an extremely high temperature is necessary to enable it to ripen its fruit. Neither flowers nor fruits are formed unless the mean temperature rises above 64°5° F., and for the best and latest varieties (e.g. the Deglet Noor, Ayata, Algeria) the mean temperature for the fruiting season (May to October) should be above 84° F., and for one month at least above 94° F.

Soils.—The physical character of the soil, sand, loam or heavy clay appears to have little influence on growth and productivity, except that perhaps on light loam and sandy soils it comes to maturity and flowers and fruits earlier than on heavy soils. It is also peculiar in its indifference to the quantity of alkali in the soil. Investigations on the soil of Algerian palm-bearing tracts have shown that though it can grow in soils with 3 to 4 per cent. their weight of alkali, it does not fruit unless the roots reach a stratum where the alkali is below 1 per cent., and does not yield abundantly unless there are layers with less than 0.6 per cent. [Cf. Swingle, Date Palm and Its Util. in S.W. States, Bureau Pl. Industr., U.S. Dept. Agri. Bull., 1904, No. 53.] The alkali in question consists of chlorides and sulphates of sodium and magnesium.

Propagation.—Propagation may take place by seeds or offshoots. The latter method is the best, for if seeds are sown, half the seedlings turn out males, and, moreover, female seedlings seldom produce fruit equal to that of the stock. The offshoots are borne at the base of the stem of trees from 6 to 16 years old. These are removed from the parent when from 3 to 6 years old. The large leaves are cut away, leaving only the rootless stump of the offshoot, with its bud protected by leaf-stalk and young leaves. For India, April to September is probably the best time for removal of the suckers. They should be planted out in rows 25 feet apart.
with similar intervals between the rows. Holes 3 feet deep and broad are made. Half of the excavated earth is mixed with its own volume of farm-yard manure, with 4 to 5 lb. of oil-cake, and filled in, the offshoot being set in the centre of the hole. Care should be taken not to cover the central bud and young leaves with earth. These should be retained a few inches above the level of the ground, and a circular trench, a foot in width, dug round for irrigation. Transplanted shoots should be watered every day the first month, twice a week the second month, and then every month for a year. For the first year, also, they should be protected from November to March by wrapping them in straw or matting.

**Watering.**—After planting out the offshoot, its chief requirements are irrigation and pollination. No general rule can be given with regard to the amount of water required. This depends on local conditions; and further, the palm needs more water during certain seasons of the year than others. Generally, at the time of flowering (February–March) little or no water should be given; from May till the fruit ripens (September), water should be given liberally.

**Seasons.**

**Maturity.**—The age at which palms commence to flower varies with the character of climate and soil, and the amount of water given. Eight years from the date of sowing may be stated as the age at which appreciable quantities of fruit begin to be produced. The male inflorescence consists of a stout stalk with a large number of slender branches to which the flowers are attached, the whole enclosed in a sheath, which is at first closed but later splits open. The inflorescence is cut from the tree generally immediately before but sometimes after the splitting of the sheath. One or two of the slender branches bear sufficient pollen for a whole female inflorescence; and as a male inflorescence bears over 100 branches, one suffices to pollinate 50 or 100 female inflorescences, according as one or two branches are used for each. The female inflorescences are also borne within sheaths, at first closed, later open. When they open, one or two branches of the male inflorescence are inserted among its branches. About three months after pollination, two of the three fruits produced by each fertilised flower fall off, leaving only one to ripen. At this time also (the beginning of June) some of the clusters of fruit should be removed from the tree to increase the supply of food to the remainder. About 10 to 12 clusters are usually allowed to remain. The period of ripening varies from June to October, according to variety and locality.

**Pollination.**

**Uses.**

**Usable.**—The tree yields a gum (hukm chil), used medicinally in the Panjab. In that province, mats, fans, baskets, and ropes are made from the leaves, known as bhútá, pattra, khúháb. Woodrow (Notes on Journ. from Poona to Nagotna, in Rec. Bot. Surv. Ind., i., 94) states that a species of *Phoenix* (identified as *P. robusta*, Hook. f.) grows on the Western Ghats, Poona, known locally as šhalu, and is the source of the so-called date-matting made in the district. The petioles (čhár) make excellent light walking-sticks, and split up they furnish material for crates and baskets. The fibrous network which forms the sheathing base of the petioles, called kobál, khaífár ka boká or khaífár mání, is used for pack-saddles for oxen, and the fibre separated from it for cordage. In the Panjab the bunch of fruit stalks, bhútá, is made into brooms.

From the fresh spathes (called *tara*) is obtained by distillation *tara*-water, a strong but agreeable perfume, which is highly valued by Arabs and Persians but does not seem to be prepared in India. The date forms a large part of the food-supply of the countries where it grows plentifully. Even in the Panjab and Sind it is largely utilised. In Multan the hard and unripe date is called *gandorá*; when it turns yellow, *doká*; when one side becomes soft, *dang*; when quite ripe,
THE DATE-SUGAR PALM

Pind. Pind dates may be ripened on the tree, van di pind, or ripened after gathering, pind luni. Dates which have shrivelled on the tree are known as kuk or kukun. In Sind the fruit, when ripe, is designated khurma, and chhuwar when plucked before ripe. In Muzaffargarh the most esteemed kind is called chhirni. This is split down the middle and dried in the sun. The second best is called pind, and is eaten as it comes from the tree. The least esteemed, bi gri, is boiled in oil and water. The terminal bunch or heart of young leaves (gichi) is preserved when a tree is cut down, and eaten as a vegetable and made into curry. Like P. sylvestris, this species also yields a saccharine juice, from which Sugar and a fermented drink may be prepared; but it is comparatively little used for this purpose, as when of good quality it is too valuable to be subjected to that treatment. The hard kernels of the fruit are ground into Food for camels, goats, sheep and horses. The green date, khanafi, is also given to sheep and cattle. The roasted kernels have been used as a substitute for coffee. The wood is light and fairly durable, and is used in Multan and Sind as beams for supporting roofs in Native architecture, and also for water-channels, bridges and other purposes.

TRADE.—Exports.—The exports of Indian dates are not as yet important; they have averaged about 130 cwt., valued at Rs. 1,215, during the four years ending 1904–5, but in 1905–6 were only 34 cwt., valued at Rs. 364, and in 1906–7, 14 cwt., valued at Rs. 254. The re-exports, during the same period, were as follows:—1900–1, 34,444 cwt., valued at Rs. 1,69,263; 1901–2, 27,632 cwt., valued at Rs. 1,41,939; 1902–3, 47,041 cwt., valued at Rs. 2,15,455; 1903–4, 25,330 cwt., valued at Rs. 1,27,277; 1904–5, 22,260 cwt., valued at Rs. 1,24,684; 1905–6, 23,542 cwt., valued at Rs. 1,31,373, and in 1906–7, 27,945 cwt., valued at Rs. 1,69,639.

Imports.—The foreign supplies, on the other hand, are large and important; in 1900–1 they came to 871,272 cwt., valued at Rs. 41,94,972; 1901–2, 901,006 cwt., valued at Rs. 42,11,091; 1902–3, 663,390 cwt., valued at Rs. 31,43,967; 1903–4, 725,003 cwt., valued at Rs. 36,27,590; 1904–5, 812,284 cwt., valued at Rs. 40,96,034; 1905–6, 867,229 cwt., valued at Rs. 44,87,709; and in 1906–7, 814,781 cwt., valued at Rs. 48,37,461. The largest quantities come usually from Turkey-in-Asia, viz. 479,200 cwt. in 1906–7; Arabia, 238,101 cwt.; and Persia, 73,863 cwt., and are received chiefly by Bombay and Sind, which took as their shares 562,355 cwt. and 205,571 cwt. respectively.

Bull., 1903, No. 54; Cunningham, Plagues and Pleasures of Life in Beng., 1907, 348, 350, etc.]

P. sylvestris, Roxb. The Wild Date or Date-sugar Palm, sendhi, kejur, salma, boichand, kharak, sandoleka-nar, itchumpannay, ita, ichal, etc.; pindakharjura, kharjura (Sansk.). A tree 30 to 40 feet high, distinguished from the former by the absence of root suckers. It is indigenous in many parts of India, being most abundant in Bengal, Bihar, on the Coromandel Coast and in Gujrarat.

Like the former, this species yields a Gum, and the leaves, petioles, flowering spathes, etc., are variously utilised for purposes similar to those indicated above. The reader will find these detailed in the article Baskets and Wicker Work (pp. 115, 188). The tree flowers at the beginning of

885
the hot weather and produces an inferior yellowish or reddish fruit, which is eaten by the poorer classes.

In many localities, however, especially in Jessore and other districts of Bengal, this species is of considerable importance as a source of food-supply, owing to the extensive use of its sap in making Sugar. The Government of India (Resolution dated March 20, 1889) mention that it had been ascertained after a careful inquiry that there were 168,292 acres under cultivation of this palm connected with the sugar supply. A full account of the process of tapping the trees and of the manufacture of sugar from the crude sap is given in the Report on the District of Jessore, 1874, by the late Sir James Westland. Tapping ordinarily commences in November, and the largest supply of juice is obtained during December and January. An average amount of 5 seers of juice per night may be got from a good tree. The juice is boiled down into a dark brown, half viscid mass, called gur. About 7 to 10 seers of juice are required to produce 1 seer of gur. The tapping season lasts 4½ months or 67 nights. Thus at 5 seers a night, 335 seers of juice are obtained, or about 40 seers or 1 maund of gur per tree, worth, say, Rs. 2 to Rs. 2–4a. After the juice is boiled down into gur, it is then sold to the sugar-refiners and by them is manufactured in various ways into different grades of sugar. The best known is termed dhulua, a soft, moist, powdery sugar, used largely in the manufacture of Native sweetmeats. A purer, granular and more expensive sugar than dhulua is called pucka. The waste molasses, collected during the preparation of sugar, is called chitiya gur; this is boiled down into a black, sticky treacle, which is largely utilised for mixing with the tobacco for the Native hookah and also for making cheap Native sweets. A small proportion of the juice, instead of being used in the above way, is consumed as a drink, either unfermented or fermented, under the name of tari, or is converted into vinegar (see Spirits, p. 1046; Vinegar, p. 1109).

In recent years an interesting endeavour has been made to promote the manufacture of palm-sugar in the Central Provinces. A company has been formed under the name of the Khandwa Sugar Manufacturing Company. Full details regarding this will be found in a pamphlet (pub. 1901) by Mr. Haridas Chatterji, Managing Director, and in a report on the result of the first year's operations. [Cf. Kanjilal, Date Sugar Industr. of Beng., in Ind. For., 1892, xviii, 451-7; Pharmacog. Ind., 1893, iii, 520; Rept. Land Rec. and Agri. P. Emblica, Linn. The Emblic Myrobalan, aonla, amlaki, dáula, gondhona, álá thana, meral, svam, nélle, wér, авалкат, bhoza ámái, toppi, urékți, shabju, etc. A moderate-sized deciduous tree, found almost throughout India and Burma, ascending the hills to 4,000 feet, chiefly in dry deciduous forests (Gamable). It yields a Gum of which little is known. Fruit, bark and leaves are employed in Dyeing and Tanning. Hooper (Agri. Ledy., 1902, No. 1, 52-3) states that the dried pulpy portion of the immature fruit affords as much as 35 per cent. tannic acid, but in a ripe state only traces are found. The leaves are regarded by the Bengal chamar as one of the best tans, and are said by

886
PIMPINELLA ANISUM
Anise

Hummel to contain 18 per cent. tannic acid. The bark is employed for tanning in Travancore. An extract prepared at Dehra Dun from bark supplied from the Central Provinces yielded 28·2 per cent. of tannin. As a dye, the fruit gives a blackish grey, if used alone, but is generally mixed with salts of iron or the barks of others trees to produce a black. Bark and leaves give the same colours as the fruit. Duncan (Monog. Dyes and Dyeing in Assam, 1896, 40-1) mentions that in the Jorhat Division of the Sibsagar district, the barks of three trees, viz. Terminalia Chebula, Eugenia Jambolana, Psidium Guajava, are used along with that of Pipturus to produce a black colour.

The fresh juice is used with that of the other uxyrobalans as a cooling, refrigerant-scherbet and as a flavouring ingredient in vinegar (see p. 1109); while the fresh ripe fruits are largely employed as astringent and laxative medicines. The fruit is also eaten by Natives and made into preserves. An interesting use of the fruit pulp in the manufacture of pottery has been published by Hooper (Journ. As. Soc. Beng., 1906, n.s., ii., 65). This was originally made known in 1896 by Mr. James Martin in a letter from Raipur, in the Central Provinces. The fruit is boiled, Martin says, in water till it becomes soft, then pounded; and after the stones are removed, the pulp is beaten and worked up into a dark-brown sticky mass. The manufacturer now takes an earthen vessel and plasters it over with a thick layer of the pulp. It is then set aside to dry, and when quite hard, the put inside is broken and the pieces removed. These curious pots are sold in the district at from 4 to 8 annas each, and are much sought after, as they are durable and ornamented by coloured seeds (rati) sunk in the fabric in elaboration of a pattern. I may add that publication of this curious discovery was delayed pending the investigation of its possible adaptation as a waterproofing material or for other purposes which it seemed likely to fulfil. According to Gamble, the Wood makes good poles and is useful for agricultural implements, building and furniture. It is durable under water, and can be used for well-work. [Of Baber, Memoirs (Leyden and Erskine, transl.), 326; Bontius, Hist. Nat. et Med. Ind. Or., in Piso, Ind. Utri. re Nat. et Med., 1829, 109-10; Basu, Agri. Lohardaga, 1890, i., 133; Banerjei, Agri. Prov., 1904, 8; Joret, Les Pl. dans L'Antiq., 1904, ii., 297.]

P. Niruri, Linn.: jatamül, bhein-an-valah, sada-hazurmuri, niruri, kizhkyunelli, nela-usirika, mi-ziphiyu, etc. A small herb found throughout the hotter parts of India from the Panjáb eastwards to Assam, and south to Travancore, Malacca and Ceylon, ascending the hills to 3,000 feet. The whole plant is considered a useful diuretic, and is much employed in Native medicine. [Of Pharmacog. Ind., iii., 265.]

P. reticulatus, Poir.: panjoki, makhí, buin-owla, kabonan, kamohi, pawana, datwan, pillànji, nalla-purugudu, etc. A large, often scented shrub, common throughout tropical India, Burma and Ceylon, especially on low, moist ground. Leaves, bark and juice are all used in Native medicine, while the root is said to be employed in Madras to produce a red dye. [Of Pharmacog. Ind., iii., 264-5.]

PIMPINELLA ANISUM, Linn.; Umbelliferae. The Anise, saurif, sdnjñ, anisín, mühür, eredos, seva, burri-shep, sombú, kuppi, dodda-jirage, jeramanis, sa-mung-sa-ba, etc. An annual herb, native of Egypt, Crete, Cyprus and many islands of the Greek Archipelago; introduced from Persia into Northern India, where it is cultivated by the Muhammadans.

An odorous principle is obtained by distilling the fruit, the product being the "oil of aniseed" of commerce. Arak-budíd, or water of anise, is a favourite perfume in India. Anise as a medicine and spice is mentioned in many of the early classical writings. The Indian trade in it is not large, the imports in 1904-5 having amounted to 1,041 cwt., valued at Rs. 11,152, and in 1906-7 to 990 cwt., valued at Rs. 11,802. This ordinarily goes chiefly to the Straits Settlements and Ceylon, but in 1905-6 the United Kingdom took 1,513 cwt. The European market is supplied chiefly by Russia, Germany, Scandinavia, etc. For a full account of the history of the oil and of its properties, the reader should consult

Oil of Aniseed.
PINUS
Khasya

THE PINE TREES OF INDIA

D.E.P., vi, pt. i. 238-42.

P. excelsa, Wall. The Indian Blue or Five-leaved Pine. The chila, kail, lim, longchê, lamshing, rassalla, byana, yari, katar, ter, biar, keśri, partal, sam, lágma, etc. A large evergreen tree of the temperate Himalaya at 6,000 to 12,500 feet, extending westward to Kafiristan and Afghanistan; eastward, except for gaps in Central and North-West Kumaon and Sikkim, to Bhutan (Gamble).

The wood is highly resinous and affords turpentine and tar. Tapping is done by vertical cuts as in the long-leaved pine. The trees are tapped for about three years, then allowed three years' rest, after which tapping can recommence on another side. The more highly resinous parts of the wood are much employed for torches, which are known as mäshāl in Hindustani and Panjábi, jagni in Pashtu. The resinous cones are valuable for lighting fires. In certain dry winter seasons, the leaves and twigs become covered with a copious, sweet exudation. The "Manna," thus found is collected and eaten by the Natives. Gamble states that the wood is good, and very largely used in construction throughout the Western Himalaya, and that it is also exported to the plains.

For planking, doors, windows and furniture it is better than deodar (Cedrus Libani, var. Deodara) as it is less brittle, has not the oil, which in the deodar absorbs dirt, while it is free from strong scent. In Kangra and Kulu it is said to be used for tea-boxes. [Cf. Thurston, Resin and Turpentine from Ind. Pines, Imp. Inst. Handbook, 1893, 7-19; Ind. For., 1893, xix., 367, 407; 1894, xx., 92-4; 1897, xxxiii., 282-9; 1900, xxvi., 497-503; 1905, xxxi., 369-72; Laurence, Valley of Kashmir, 1895, 80; Agri. Ledg., 1896, No. 14, 98; For. Working Plans and Admin. Repts. Pb. and U. Prov.

P. Gerardiana, Wall. The Neosia or Edible Pine, gunober, rhi, newr, kannuchi, shangri, ronecha, chiri, prita, galboga; seeds = chilgorza, neozza, zanghóz. A moderate-sized evergreen tree of the inner, dry and arid North-West Himalaya, generally between 6,000 and 10,000 feet; mountains of Northern Afghanistan and Kafiristan; also Harib district at 7,000 to 11,000 feet (Gamble). The chief product of this species is the almond-like nuts, contained in the cones. The cones ripen in October, are plucked before they open, and heated to make the scales expand. The seeds are then removed, and are largely eaten by the Natives and stored for winter use. In Kunánar, they are said to form a staple food with the inhabitants. They are also exported to the plains, from the hills of the Panjábi, and large quantities are imported annually into India from Afghanistan. The wood is hard, durable and very resinous, but rarely utilised since the tree is so highly valued for its seeds. [Cf. Pharmacog. Ind., 1893, iii., 379-80; Agri. Ledg., 1896, No. 14, 96-7.]

P. Khasya, hoyre. The dinglya, tinyu, taru. A large evergreen tree of the Khasya hills, hills of the Lushai country of Chittagong, Shan hills and hills of Martaban in Burma at 3,000 to 7,000 feet.

The resin of this species is perhaps the most valuable obtainable from any species of the genus. Samples were reported on by Armstrong (Imp. Inst. Tech. Repts., 1905, 187-9). The crude turpentine, which is a grey, thick, pasty mass, furnishes by distillation with steam about 13 per cent. of its weight of oil. On a former occasion Armstrong obtained from a sample of P. Khasya 17 per cent. of oil. The original turpentine and the distilled oil have a slight but agreeable odour, less pronounced than that of French turpentine. Chemical examination also proved that the oil of P. Khasya is strictly comparable to French oil of turpentine, and Armstrong states that in his opinion the oil is of the highest quality and will be found to serve every purpose for which oil of turpentine (French or American) is used. Samples submitted to a London firm of brokers (Agri. Ledg., 1896, No. 14, 102) were valued at £4 to £6 per ton for the crude turpentine, and at £24 per ton for the refined spirit, while the resin

888
obtained was valued at £5 to £6 per ton in London. At present, however, it appears that the area of forest is too small to make the industry of much importance in Assam, while in Burma the distance from the rivers and coasts of the chief forests precludes its profitable extraction at the figures quoted. [Cf. Thurston, i.e. 19–22; Scott, Gaz. Upper Burma and Shan States, 1900, i., pt. 2, 317–8; 1900, ii., pt. 1, 318–9; Max and Bertha Ferrars, Burma, 1900, 116; Teichrin, Die Harze und die Harzbehalter, 1906, i., 594–5.]

P. longifolia, Roxb. Long-leaved or Three-leaved Pine, *salla*, *chir*, *dhup*, *gnet*, *teadoung*, *kolan*, *sapin*, *nashtiar*, *ranzuru*, *gula*, *thansa*; oleo-resin = *gandabora*, *chir-ka-gond*, *koto*, etc. A large, more or less deciduous tree of the Outer Himalaya and Siwalik Range, also valleys of the principal Himalayan rivers at 1,500 to 7,500 feet; extending west to Afghanistan and east to Bhutan.

*Resin.*—This species is the chief tree tapped for resin. Tapping in a systematic manner was commenced in Jaunsar, but has now extended both to the Panjāb on the west and to the forests of Kumaon on the east. Gamble states that in 1888–9 about 9,600 trees were tapped in Jaunsar, each giving about 8½ lb. of resin. The total yield of the year was over 1,000 maunds resin, which produced at the Forest School Factory, Dehra Dun, about 900 maunds of *colophony* and 1,740 gallons of *turpentine*, which sold for nearly Rs. 9,000. There are two methods of tapping the trees, Native and European. The system employed by the hillmen of Kumaon and Garhwal is to cut a niche into the trunk about 3 feet from the ground, the bottom of which is hollowed out. The resin is collected as the niche fills, sometimes every second or third day, usually between the fourth and fifth days. The niche has to be deepened and lengthened from time to time, and the same niche may be used for two or even three years. By the European method an incision about 1 foot long, 4 inches wide and 2 deep at the base, not including the bark, is cut into the tree, and a curved incision about 5½ inches long is made just below that, into which a piece of zinc is inserted so as to form a lip from which the resin may flow into a pot suspended beneath. The cuts are renewed about twice a month. Of the manufacture of turpentine and colophony from the crude resin a full account is given by Birbal (Ind. For., 1900, xxvi., 497–503).

At the present day the Government are the only producers of resin and turpentine in India, and the supplies come through the Conservators of Forests in the Panjāb, Central Circle, School Circle, United Provinces, Dehra Dun. [Cf. Proc. Dept. Rev. and Agrl., May 1905, Nos. 12–3.] In 1901–2 the outturn of resin, colophony and turpentine was as follows:—

In the Panjāb (For. Admin. Rept. P.6., 1901–2, 15), 63,188 trees were tapped, and yielded 495,850 lb. resin, 256,824 lb. colophony, 7,081 gallons turpentine; in Naini Tal (For. Admin. Rept. U. Prov., Cent. Circ., 1901–2, 14), 38,632 trees, yielding 222,300 lb. resin, 88,888 lb. colophony, 2,204 gallons turpentine; in Dehra Dun (For. Admin. Rept. U. Prov., School Circ., 1901–2, 8), 14,420 trees, yielding 135,500 lb. resin, 103,976 lb. colophony, 2,693 gallons turpentine. In 1903 turpentine was sold by the
THE CUBEBS AND LONG PEPPER

Conservator, Central Circle, United Provinces, at Kathgodam railway station, for Rs. 2-4-0 per gallon, and colophony, at Cawnpore, for Rs. 4-8-0 to Rs. 4-12-0 (10 to 11 annas represents carriage to Cawnpore) per maund of 82 lb. The average price in the Panjâb Circle was Rs. 6-14-0 per maund at Amritsar for crude resin, Rs. 1-14-0 per gallon at Amritsar for turpentine, Rs. 3-3-3 per maund at Calcutta and Amritsar for colophony. The colophony is sold chiefly for soap manufacture, and the turpentine is in great demand for various industries, but chiefly in railway workshops. Indian resin is softer than ordinary trade samples: to overcome this defect it has been recommended to heat the resin more completely during distillation (Bhaduri Rept., Labor. Ind. Mus., 1902-3, 22-3; also Hooper, l.c., 1903-4, 25).

The roots of felled trees are also utilised in the manufacture of Tar, which in Jaunsar has for some years been systematically prepared in closed masonry kilns. The tar is boiled down into pitch and exported to the plains for sale. The needles were found on distillation to yield only 0-1 per cent. of the essential oil. They contained a large proportion of resin, and their fibre was found unsuitable for paper-making. The leaves yield no nitrogen and less mineral matter than straw. They, however, constitute a good litter for stables and cattle-sheds (Hooper, l.c., 1904-5, 26; 1905-6, 31).

Trade.—The foreign Imports of India in resin, during 1904-5, amounted to 49,003 cwt., valued at Rs. 2,98,073; in 1905-6 to 64,602 cwt., valued at Rs. 5,51,279; and in 1906-7, 96,486 cwt., valued at Rs. 8,82,060. In recent years the United Kingdom has been the chief source of supply, and in 1906-7 contributed 66,203 cwt., followed by the United States, 16,416 cwt., and then by Germany, 12,895 cwt. The Exports in 1904-5 amounted to 1,918 cwt., valued at Rs. 37,515, and in 1906-7, 60 cwt., valued at Rs. 1,815.

P. Chaba, Hunter, As. Res., 1897, ix. 391-2; châb, châvi, kankala; wood and roots = chaikath. A native of the Moluccas, cultivated in India for its fruit, the chaba of Indian Medicine. The wood and root are used in Bengal for dyeing and give a pale brown on cotton if used alone, but mixed with bakas (Cesalpinia Sappan), a brownish-red. [Cf. The Bower Manuscript (Hoernle, transl.), 1893-7, 81, 94, etc.; Pharmac. Ind., iii., 176; Dutt, Mat. Med. Hind., 1900, 244, 295.]

P. Cubeba, Linn., f.; Cubebes, kabâb-chini, timmuce, luiit-marz, himis-hiire, tada-miir, dumki-mirchi, val-muellaghu, chalavamiriyalu, bâla menasâ, komunkus, sinban-karava, etc. A native of Java and the Moluccas, cultivated to a small extent in India, and the fruit imported. It yields an unimportant gum-resin. The fruit, known as Cubebes, has been used in European Medicine from the Middle Ages, and yields a thick, colourless essential Oil, with an aromatic odour and flavour of camphor and peppermint, [Cf. Acosta, Tract. de las Drogas, 890]
PIPER BETLE

Cultivation

1578, 113; Linchoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), ii., 130; Pharmacog. Ind., iii., 180; Gildemeister and Hoffmann, Volatile Oils, 1900, 322.

P. longum, Linn. Long Pepper, pipumind, pipal, ralli, hitil daris, tippili, yippali, lunda, mulgav, peik-khyen, etc. A perennial shrub, native of the hotter parts of India from Nepal eastwards to Assam, the Khasia hills and Bengal, westwards to Bombay, and southwards to Travancore, Ceylon and Malacca. As manifesting antiquity of knowledge, it may be mentioned that the Sanskrit name pipalli was originally given to this plant, and only within comparatively recent times had been transferred to black pepper. Long pepper is mentioned by Pliny (Holland, transl., bk. xii., ch.7), and is referred to in the Periplus (1st century).

Long pepper is cultivated in Bengal and South India, and is the pepper chiefly exported from Calcutta. It is propagated by suckers and requires a rich, high, dry soil. The suckers are transplanted after the periodical rains set in, at a distance of 5 feet from each other. Each bigha is said to produce 2 maunds of pepper the first year, 4 maunds the second, 6 maunds the third, after which the roots are grubbed up, dried and sold. The plants require no irrigation, but at the commencement of the hot season the roots are carefully covered with straw to preserve them from the heat. Radishes, barley, or brinjal (Solanum melongena) are usually cultivated in the space between the plants. The fruit is gathered when green in January, and is preserved by drying in the sun. The dried unripe fruit and the root have long been used in Medicine. [Cf. Pharmacog. Ind., iii., 176; The Bower Manuscript, l.c. 78, 80, 88, etc.; Gildemeister and Hoffmann, Volatile Oils, 1900, 322; Dutt, l.c. 243-4.]

P. Betle, Linn.; Hunter, As. Res., 1807, ix., 390-1; Bot. Mag., 1832, 3132. The Betle, pán, tambuli, tamhula, vilayade, videcha-pánā, nágurel, vettilai, nágavalli, viledel, kínjoc, etc. A perennial dioecious creeper, probably native of Java; cultivated for the sake of its leaves in the hotter parts of India and Ceylon.

History.—According to Hobson-Jobson (ed. Crooke, 89) the word betle is the Malayan vettila, i.e. veru-tila, which means "simple or mere leaf" and comes to us through the Portuguese betre and betle. The Natives of India and the Indo-Chinese countries have from remote times been in the habit of chewing the leaf, generally mixed with areca-nut, lime, and catechu in the case of the poorer classes, with cardamoms, nutmegs, camphor, etc., in that of the rich. Marco Polo (ed. Yule, ii., 306, 311), in the 13th century, writes that the people of India have a habit of keeping in the mouth "a certain leaf called Tembul," and adds that the richer classes and the King have these leaves prepared with camphor and other aromatic spices, as well as quicklime. In 1442 Abd-er-Razzak, in the narrative of his journeys in the East, thus describes the method of eating it. They bruise a portion of faulfel (Areca), otherwise called sipari, and put it in the mouth. Moistening a leaf of the betel, together with a grain of chalk, they rub the one on the other, and roll them in the mouth. They thus take as many as four leaves of betel at a time, and chew them. Sometimes they add camphor to it, and sometimes they spit out the saliva, which becomes of a red colour." García de Orta (Coll., x.), writing in 1563, corroborates these facts, stating that the Indians are in the habit of keeping the nail of the right thumb pointed and sharp, in order to remove the midrib of the leaf. Many of the other early travellers refer in similar terms to the practice of chewing the betel-leaf. [Cf. Narrative of Journal of Abd-er-Razzak, 1442, in Ind. in the 15th Century (ed. Hakl. Soc.), 32; Linchoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), ii., 62-8, etc.; Pyrard, Voy. E. Ind., 1601 (ed. Hakl. Soc.), ii., 362-3; Bernier, Travels, 1656, in Constable, Or. Misc., i., 13-4; Barbosa, Coasts E. Africa and Malabar (ed. Hakl. Soc.), 73; Mandelso, Travela, in Olearius, Hist. Muscovy, etc., 1662, 42; Fryer, New Acc. E. Ind. and Pers., 1672-81, 40; Diary of W. Hedges, 1681-7 (ed. Yule), ii., ccxxxii.; Hamilton, New Acc. E. Ind., 1727, i., 304; Jorot, Les. Pl. dans L'Antiq., etc., 1904, ii., 261.]

CULTIVATION.—The cultivation of betel-leaf is attended with many difficulties; it requires a constant temperature, a fairly uniform degree of moisture, and much attention on the part of the cultivator. The plant is propagated by cuttings or sets grown under shade, and in many parts of India within specially constructed houses of grass, reeds or mats having

flat grass roofs so designed as to admit of a diffused light. The plants are grown in parallel rows that allow spaces for the owner to pass between, but nothing more. In other cases, the vines are cultivated under the shade of trees, very often the areca-nut palm or other trees specially grown for the purpose, and planted in the form of a compact garden surrounded by a protecting hedge. Pan-leaf is hardly ever grown by the consumer, but is regarded as a special cultivation that requires expert knowledge. The methods pursued vary considerably in different localities, and may be best considered under the names of the provinces in which the leaf is chiefly produced; but unfortunately statistics are not available for all provinces, and only for certain years of those that are returned.

Bengal.—As far as can be estimated, the area under the betel-vine in 1904–5 exceeded 43,000 acres. The greatest possible confusion has existed regarding the varieties and races met with in this province. The commercial value of one form of pan-leaf is so infinitely greater than another that the comparison between them (in point of price) is as great as that between the produce of the very poorest and the very finest vineyards. A uniform rate of rental for land yielding so entirely different products would obviously be unjust.

The following information regarding the methods of cultivation is abstracted mainly from Mukerji and Roy. There are three main varieties—deshi, extensively cultivated in Central and Southern Bengal; gach, cultivated in North Bengal; and sanchi, cultivated to a smaller extent all over the country. According to the former writer, the finest pan is grown at Bantul, half-way between Ulubaria and Midnapur, on a light loam slightly reddish in colour. Ordinarily a black, friable clay loam, containing a large proportion of organic matter, and situated above inundation-level, is chosen for the crop. After selecting the site, shrubs and trees growing on it are uprooted or burned down and a trench is dug round, the earth obtained being spread over the surface of the garden. Before planting the betel-vines, a roofing is manufactured for the purpose of securing shade, evenness of temperature and security from high winds. Rows of bamboo or other stakes are planted, 4½ cubits remaining above ground. Over these are placed dhaincha or jute-stalks and sometimes a thatch of ulu-grass. The garden is fenced round with the same materials. Each row of cuttings is planted between two lines of stakes, with intervals of 6 inches between the cuttings. Cuttings are taken from plants two years old or more. These are made of lengths 12 to 18 inches, each with five or six joints, two of which are buried in the earth, while the portions left above ground are made to recline on the surface. They are then covered with date-leaves and watered morning and evening till they strike root and put forth buds. Planting time is May to November. Occasionally cuttings are first planted in nurseries, and, when rooted and have sent forth new leaves and buds, are transplanted. As the plants go on increasing in length, one or two jute-stalks are stuck in the ground close to each, the upper ends reaching the roof, and the betel plants are tied to them by ulu-straw. When the plants reach the roof they are bent downwards, a portion is made to rest on the ground and is covered with a little earth, while the bud end is again bent upwards and tied to another support. This process is repeated about three times a year, and every time a few leaves are plucked away at the points where bending takes place. Pond-mud and other kinds of well dried and pulverised earth are placed between
the lines and used to earth up the plants. Each time earthing-up takes place, dried and pulverised pond-mud, cow-dung, and oil-cake are used as manure.

If planting is done in July-August, plucking commences in October-November, but if planting be done in October-November, plucking takes place in May-June. Two pluckingings are made each month. Two to four leaves are got on each occasion, and in the rains four to six leaves a plant. The plants are in full bearing for some five years, at the end of which time the garden or baroj requires to be thoroughly overhauled. Mukerji gives the outturn from one acre as about 80 lakhs of leaves per annum, and the total cost per acre for a period of three years as Rs. 1,422. Taking 3,000 leaves per rupee as the average price of pan, Mukerji estimates the outturn of leaves at Rs. 2,500.

[Cf. Basu, Agri. Lohardaga, 1890, pt. 1, 83; Banerjei, Agri. Cuttack, 1893, 96-9; Chaudhury, Note on Piper Betel in Backergunge, Nov. 1898; Mukerji, Handbook Ind. Agri., 1901, 428-38; Roy, Crops of Bengal, 1906, 170-4.]

United Provinces.—H. R. Nevill states that the plant thrives best on a stiff soil, retentive of moisture, and says the site selected for the garden is generally an elevated spot with a good slope. The land is ploughed, levelled and thoroughly cleaned, and then enclosed with stakes and brushwood and covered with a roof of sentha-grass. Shallow trenches are next scooped out, 2 feet wide by 5 or 6 inches deep and 5 feet apart, which are filled with water; and when the soil is saturated, planting commences. Full-grown plants, stripped of their leaves, are cut down close to the root and divided into three or four portions, which are laid horizontally in the trenches and covered with earth. In a few days sprouts appear at each knot. Planting goes on from February to April, and each row is watered two or three times a day. Stripping the leaves begins about the middle of June and is continued regularly for about a year, after which the plant is exhausted and is used for stockage a fresh plantation while the old garden is allowed to rest for a year or two. The leaf is sold in bundles of 200 called dholis, the price varying according to age and quality. [Cf. Duthie and Fuller, Field and Garden Crops, pt. iii., 51-3, tt. 91, 1a; Nevill, Dist. Gaz. U. Prov., 1904, xlvi., 36-7.]

Central Provinces.—In the Central Provinces one of the forms most highly prized and sent very largely to Calcutta is known as the kafuri. In the Settlement Report of Wardha the method of cultivation is fully described. The leaf is cultivated by a class of people called bureks, and the garden is known as bureja or pan-ka-tanda. The pan-gardens are generally held by a cultivating brotherhood, forming an independent section in the village and paying rent to the landowner through the head of their body. A portion of the village land is recognised as belonging to this caste. The garden is enclosed on all sides with bamboo and mat coverings. The vines are planted in ridges, varying in length with the area of the enclosure, and the ridges are divided into a certain number of units of length, called lani, which are portioned off among the brotherhood. The plants require constant care, and much water and manure are also essential. In two years they cease to bear leaves of any marketable value, and new gardens are then made. The first year of cultivation is called wotuk, the second korea, the produce of the latter being more esteemed and more sought after than that of the first year. At the end of the second year the ground is allowed to remain fallow for periods of two or three years.
In Nimár the method presents several interesting features. A garden once established is said to yield steadily for ten or twelve years. The ground is similarly prepared to that in Wardha, but trees are grown to afford shade, such as the *saora* (*Sesbania aculeata*). The plantation is also surrounded by poles of *pángrá* (*Erythrina indica*), to which bamboo mats are attached. After the *saora* trees die down, they are replaced by poles of the *sales* (*Boswellia serrata*). Meantime plantains have been set all over the garden, at intervals of 10 or 12 feet, for purposes of shade. No matting is used overhead or for partitions. Every year, after the leaves have been gathered, the creeper is coiled down at the root till only some 3 feet are left above ground. A fresh root is thus struck, and the old coil is next year cut away. The crop is irrigated at all seasons except during the rains, and at the commencement of each hot season (March) the plants are pruned, manure is applied to the roots, and fresh earth piled round them. Before the ten or twelve years are over, the garden soil thus increases in depth by about 2 feet. After that time the garden is removed, hemp is sown to clean the land, and alternate fallows and irrigated spring crops with liberal manure follow for some years to render the land again fit for *pán*. [Cf. Rept. Land Rev. Settl., Nagpur, C. Prov., 1899, 68–75.]

**Bombay.**—The area under the crop in 1904–5 was returned as 3,958 acres, of which 1,343 acres were in Dharwar, 518 acres in Poona, 390 acres in Belgaum, 380 acres in Kanara, 372 acres in Satara, etc., and in the following year (1905–6) the total area was 4,048 acres. The system of cultivation differs in no essential particulars from the method followed in other localities. In Dharwar, *pán* is the most important garden crop. The shoots are planted in the open, trained on quick-growing trees, an acre of land containing upwards of 2,000 plants, and the crop lasts only four to seven years. The vines are then dug up, the leaves of the trees on which they were trained are used for vegetable manure, and the wood for fuel. The garden is deeply dug all over, allowed to lie fallow for one year, and afterwards planted with sugar-cane. After the sugar-cane, it enjoys another year of fallow, when betel plantations are again laid out.

In Poona, betel is also an important garden crop. It is grown on light red soils, requires much manure and constant watering, and if well-cared for may last fifteen to twenty years. The garden generally covers about an acre, the vines are trained on various trees, planted in rows and polled, and the whole garden is sheltered by high hedges or grass screens or mats. Every year in March, April or May the upper half of the vine is cut, while the lower half is coiled up and buried under fresh red earth and manure.

In Kanara the plant is described as cultivated in gardens on mango-trees. The leaves are picked three years after planting the young shoots, and the yield is estimated at 100 to 200 leaves from a full-grown vine every fortnight. An acre of spice-garden containing 500 plants is said to produce some 40,000 leaves annually, worth Rs. 20 and costing Rs. 8 to grow.

**Madras and Mysore.**—The plant is widely distributed in the Presidency, being found chiefly in the moister regions. Cox (Man. N. Arcot, 1895, 1, 265–6) fully describes the method of cultivation, which differs in no essential particulars from the methods already described. It is a three-year crop, grown on land capable of incessant irrigation. The
plants begin to yield when nine or ten months old, and continue to yield for two or even three years. The leaves are tied in bundles of 400 each, and the usual price of such a bundle is an anna. An acre in two years produces 5,000 to 7,500 of these bundles, worth Rs. 300 to 500.

In Mysore the cultivation is thus described by Rice (Mysore Gaz., 1897, i., 160-2) :—A black soil is required, and the plant thrives best in low ground where it can have a supply of water from a reservoir. In the east (e.g. Chaitra or Vaisakha), the ground is trenched over 1 cubit deep and surrounded with a mud wall, within which a hedge, chiefly of Euphorbia Tirucalli, is planted. If there is not plenty of rain, it must be regularly watered for six months. The garden is then dug and formed into beds with a space of 20 feet between them and the hedge. By an elaborate system of channels for supplying and draining off water, the garden is divided into blocks. In the centre of each, a row of small holes is formed, 1 cubit distant from one another, and in December-January into each hole are put two cuttings of the betel-vine, each 2 cubits long. The middle of each cutting is pushed down and slightly covered with earth, while the four ends project and form an equal number of young plants, which for eighteen months are allowed to climb on dry sticks. For the first week after planting they must be watered twice a day, for another week once a day, and till the end of the second month once in three days. A small drill is then made across each division of the beds, and between every two holes in each, in which seeds of agase (Sesbania grandiflora), nugge (Moringa pterygosperma), etc., are planted. The young betel-vines must have some manure, and for four months require to be watered once in three days. Afterwards all the channels are filled with water once in four days. When a year and a half old, the plants are removed from the sticks. Two cubits of each next the root are buried in the earth and the remainder, conducted close to the root of one of the young trees, is allowed to support itself on the stem. At the end of two years, 2 cubits more of each plant are buried, and afterwards this is repeated once a year. At the end of the fourth year the cultivator begins to gather the leaves, and continues to obtain a constant supply for six or seven years.

In the west, the betel-vine is grown with the areca-palm. When the areca plantation is fifteen years old, in the month following the vernal equinox a hole is dug near every tree, one cubit deep and one and a half wide. After the earth has been exposed for a month, it is returned to the hole and left for another month. A little earth is then taken out, the surface smoothed and the ends of five cuttings of betel-vine buried in it. For a month they are watered once every two days, and shaded with leaves which are afterwards removed, and the earth in the holes stirred with a stick. In the first year, the waterings are repeated every day, and the whole must be hoed once a month and manure given to each plant. In the second year, the vines are tied to the palms, and the garden hoed and manured once in two months, but watered only in the hot season. At the end of the second year, the vines begin to produce saleable leaves. In the third year and every year after, the part of the vines without leaves next the root is buried. Once in six months the garden must be hoed and manured, and watered every other day during the hot weather. [Cf. Sturrock, Man. S. Canara, 1894, i., 206-7.]

Burma.—No statistics are available regarding the extent of pān.
PIPER NIGRUM
Cultivation

cultivation. The following account from the Sagaing district is given by Parlett (Rept. Settl. Operat. Sagaing, 1903, 130-1). Small plots planted with betel-vines are found in most Sagaing gardens. At Tada-u, where land is devoted solely to raising betel, a site is chosen usually under tamarind-trees, and occasionally a few plantains or other trees are grown for shade. The gardens are divided into blocks, some 30 feet square, and the plants set in rows about 2 feet apart in each direction, connected by small water-channels. Between every six or eight rows is a pathway (yin-gwe) about 3 feet wide. The vines are always irrigated from wells and in the hot season are watered alternate days; in the early rains at intervals of two, and in the cold weather, of three days. While rains are continuous, irrigation ceases. A top-dressing of leaf-mould every year is said to improve the yield. Leaves may be gathered within a year after planting, but plucking is often deferred to the second year, and the third to fifth years are best. After the sixth year the vines are often cut down. In Sagaing old or weakly vines are cut down from year to year and replaced by new slips, and the same ground is occupied by the vineyard for twenty years or more. In Tada-u the garden is worked as long as it is remunerative; then the vines are cut down and the land allowed to fallow for two years. Each block is usually plucked once a month or once in two months, always before 9 a.m., as plucking in the heat of the day exhausts the vine. The average price of young plants is Rs.15 per 1,000; of the leaves, Rs. 25 per 100 viss. The average mortgage price works out to Rs. 226 per acre, and the annual rent to Rs. 100 per acre. The ground-rent per acre averages Rs.113 for the life of the vine—five years—or about Rs. 22 a year. It is estimated that 1,000 vines yield an average annual profit of Rs. 35, i.e. Rs. 350 per acre. [Cf. Upper Burma Gaz., 1900, ii., 344.]

Trade.

TRADE IN PÁN-LEAF.—The habit of chewing this substance is very widespread, especially in the towns and cities, the supplies being often drawn from great distances. The Central Provinces send a large portion of their produce to Calcutta on the one side, and Bombay on the other. Neither in the official returns of trade by rail and river, nor by sea coastwise, is there any mention of pán-leaf, so that no information exists as to the extent or direction of the internal movements. There are no foreign transactions.

Black Pepper.

Cultivation.

P. nigrum, Linn.; Hunter, As. Res., 1807, ix, 383-90; Bot. Mag., 1832, 3139; The Black and White Pepper; gulmirch, filfilgird, habush, vellajung, murichung, spot, martz, dāru-garm, mīri, kālāmari, choca, mildāq, mīryāla tīge, menasu, lada, sa yo mai, etc. A climber, usually dioecious, wild in the forests of Travancore and Malabar, and cultivated in the hot, damp localities of Southern India.

CULTIVATION.—Pepper was one of the most important articles of early Indo-European trade, and has been extensively cultivated on the western coast of South India from very early times. Vincent (Periplus, etc., 1800, app., 42) speaks of it as grown in Malabar. It has accordingly been specially cultivated there since at least the 5th century. But a much earlier knowledge is shown by the frequent mention of pepper by the Sanskrit medical writers. It was also known to the Greeks from the time of Theophrastes onwards. Though cultivated from remote times in Sumatra, the Straits, Siam, and the Malay Peninsula generally, Malabar
has always been considered to produce the best pepper. The provinces where pepper is most extensively grown to-day are Madras and Bombay. Hanausok (Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 374) states that pepper is adulterated with ground olivestones.

**Bengal.**—Pepper is cultivated to a limited extent only in the northern parts of Jessore. Elsewhere in Bengal it grows wild during the rainy season. "The creeper is planted in the beginning of the rains, and as it grows in the shade the seeds of the stout dhunecha hemp plants are sown near it to afford shelter as they grow." [Cf. Admin. Rept. Beng., 1901—2, 17.]

**Assam.**—Basu (Agri. Ledg., 1898, No. 7) gives a full account of the cultivation of black pepper in Assam. The crop, it would appear, is not cultivated appreciably in any particular part. A little, however, is found in Sylhet and on the southern slopes of the Khasia hills. It is usually grown to meet home requirements, and what is left over is sold. Like the betel-vine, it is commonly raised on betel-nut palms (*Areca Catechu*), while the mango, jack, and other garden trees are occasionally utilised. It is propagated either from suckers, which spring from underground roots, or from shoots from the stem. When shoots are used, they are bent down into the ground to strike root before they are severed from the mother-plant. The young plants are generally uprooted at the beginning of the rains, and planted at the foot of the trees on which they are to grow—as a rule one plant only is placed along side of each tree, and at first it has to be carefully tied to its support. Like the betel-vine, it requires liberal manure; cow-dung and household refuse are used and applied at the end of the rains and at intervals through the cold weather. This is simply heaped round the base of the tree on which the vine climbs; and to keep the moisture in the manure-heap, pieces of the leaf-sheaths of the plantain-tree are laid over the top and renewed from time to time. The plantation must be hoed and cleaned once a year at the close of the monsoon rains, and in May the manure-heaps are levelled down and spread over the ground. The vine begins to bear in from three to five years after planting, and continues for at least twenty years. It flowers in May and the berries are plucked in December, when just beginning to ripen.

If intended for the cultivator's use, the berries are boiled in water for a few minutes to soften the husk, which is then removed by rubbing over a bamboo basket. If intended for the market, they are simply dried in the sun after boiling and allowed to retain the husk, which assumes a black colour. The highest outturn that can be obtained from a single vine is said to be about 3 seers of dry cured pepper, and the average yield about 1 seer for each vine in a plantation. The retail price for Assam black pepper varies from 10 annas to a rupee per seer, and the wholesale price from Rs. 17 to Rs. 20 per maund. [Cf. Basu, Cult. Black Pepper Assam, in Agri. Dept. Assam Bull., 1898, No. 4.]

**Bombay.**—The area under the crop in 1904—5 amounted to 6,736 acres, and in 1905—6 to 7,483 acres, practically the whole of which was in Kanara. The following information is mainly abstracted from Mollison (Agri. Ledg., 1900, No. 3; 1901, No. 3). The plant is propagated by layerings or from cuttings. When the betel-palms are seven or eight years old, pepper is planted at the bottom of the stems. A long, healthy shoot from an established plant is layered in the leaf-mould surrounding the palm on
which it is intended to climb. When it has taken root it is severed from the parent plant and trained on its living support. Two or three shoots are sometimes layered to one palm. The best months for propagating are June and July. The main vine should divide freely into subordinate branches so that a number of shoots can be trained to ascend. They are secured to the stem by bands stripped from the sheaths of fallen leaves of the betel-palm. Heavy applications of good manure are given annually for three years after planting. Subsequently the pepper participates in the general cultivation given to the betel, and an application of manure is made to both crops every second year. The manure is heaped over the bare roots of the betel-trees and pepper-plants in a circle round the stem. The best manure is made from green leaves and twigs plucked in the monsoon, used as litter in cattle-byres, and thence removed to a manure pit every day or second day, together with the dung and urine of the cattle. This manure is sufficiently decayed by the following March, and is applied in that month or in April. A plantation is in bearing three or four years after it is started, and if the old vines as they get worn out are at once replaced by new layers, the plantation will keep in vigorous growth for a long period. Flowers appear in July and August and the berries are ripe in March. The vines, in full bearing, give in a good season about 1,000 clusters, which should yield about 7 seers of dried pepper (1 Bombay seer = 7 lb.).

Ordinarily the bunches are plucked when the berries are green or changing colour. The berries are then sorted out, the ripe ones separated, soaked in water for seven or eight days, or heaped till the pulp ferments. They are then rubbed or trampled underfoot till the pulp is rubbed off the "stone" which furnishes the white pepper of commerce. But that article is prepared, to a small extent only, in Kanara. The chief product is black pepper, which is got from unsorted berries. These are heaped for about four days till such as are green get soft and change colour, and the pulp of all is more or less squashed. They are then spread out and dried. The skin and part of the pulp adhere as a dark, wrinkled covering to the stones, and the pepper is black in appearance. White pepper is worth Rs. 10 to 11 per maund, and black Rs. 7 to 8 per maund.

**Madras and Mysore.**—In certain respects it might almost be said that we know very little more regarding the pepper industry of South India than was understood in the first and second decades of the 16th century. Varthéma (Travels, 1510 (ed. Hakl. Soc.), 1863, 157) will be found to give a vivid picture of the plantations in and around Calicut:—"It is like a vine climbing on trees: from each of the branches are produced five to eight clusters of berries, a little longer than a man’s finger; they are like raisins but more regularly arranged, and are as green as unripe grapes; they gather them in October and November, and lay them in the sun on mats, when they turn black as they are seen among us, without doing anything else to them. And you must know that these people neither prune nor hoe this tree which produces the pepper.” So also Barbosa, in the beginning of the 16th century (Coasts E. Africa and Malabar (ed. Hakl. Soc.), 1866, 219), gives a detailed account of the plant, and of the trade in pepper from Calicut shortly after the arrival of the Portuguese in India. The spice had to pay an export duty to the King of Calicut and was shipped via Cambay to Persia, Aden, Mecca, Cairo and Alexandria,
MALABAR PEPPER

Cultivation

thence to Portugal. Mandelslo (Travels, in Olearius, Hist. Muscovy, etc., 1662, 93, 111) gives certain particulars of the pepper cultivation of the "Cuncam or Decam." He states that the traffic goes via Surat.

According to modern writers the method of cultivation presently pursued is very simple. Cuttings are put down during the rains in June—July, in rich soil, not subject to excessive moisture, and liberally manured, not with cow-dung as in Bengal and Assam, but with leaf-mould. The trees selected as supports are mostly those which have a rough or prickly bark, such as the jack-tree, the murukku (madar, p. 523), etc. The vines may grow to 20 or 30 feet, or even higher—they are never pruned. All suckers are removed and the ground around kept clear of weeds. In three years the vine begins to bear. From the third to the seventh year the plant improves. After that it remains in good condition for three or four years, and then deteriorates for about the same period, when it is cut down and new shoots planted. The fruit is gathered as soon as the berries at the base of the spike begin to change colour. [Cf. Rew Bull., 1895, 178–80.]

In April of 1905 a Government farm, under the superintendence of Mr. C. A. Barber, Government Botanist (for the scientific study of the cultivation of pepper), was started at Talliparamba near Tellicherry, which may be spoken of as the centre of the South Indian (indeed of the Indian) pepper production. A very large amount of work has already been accomplished, of which Barber has published as yet only a brief note (Agri. Journ. Ind., i., pt. ii., 163–4). "Any one," he observes, "at all conversant with a plantation of black pepper, will have noted the great variation in the bearing power of different vines." This is a consequence of some plants bearing wholly male (staminate) flowers, others only female (pistillate) flowers, while still a third possess both stamens and pistils, but the former so sparsely as to lessen fertility. "In choosing vines for propagation, it will, therefore, be necessary to first determine whether the plant is fully provided with stamens." "It may be taken as a rule that any vine, if fully provided with stamens, will give a good crop, while any vine not so provided will be capricious in its behaviour, being dependent on its neighbours for the swelling of its berries."

Barber (Varieties Cult. Pepper, in Dept. Agri. Mad. Bull., 1906, iii., No. 56, 126–32, tt. 1–3) says that there are "three main types of good vines freely provided with stamens, the Balamcotta, Kallivalli and Cheria-kodi. Each of these has variations in all directions."

Balamcotta.—This is all round the best pepper, is widely distributed, and apparently the main Tellicherry variety. The leaves are the largest of all. Its general colour is light green, and when full grown is twice as long as broad, oval to ovate, broadest at the middle and one side frequently broader than the other. Flowering branches, drooping. Spikes long, usually up to six inches, and the individual flowers distant. It is a strong-growing plant, flushing all over at the same time, and a heavy bearer.

Kallivalli.—This has the reputation of being a heavy bearer, but the flushing is irregular. The leaves are fairly constant, but vary in width according to age. In general colour they are dark green, and the veins much more deeply impressed, almost corrugated, than in balamcotta. Flowering branches stand out stiffly and joints close together. Spikes shorter than in balamcotta and frequently seen branched; sometimes, in fact, the spikes appear tassel-like. The flowers are also a good deal closer

together, and though abundantly supplied with stamens, yet the plant may be spoken of as less fixed as a type.

Cheriakodi.—This name is given to a well-marked variety, small in all its parts—a dwarf form, under 15 feet in height. The leaves are not large and the spikes are small and crowded with small berries. The leaves are arranged uniformly over one another like the tiles of a house, almost vertically downwards, and thus hiding a large number of spikes.

Under each of these main forms there are several recognisable races as well as two well-marked jungle peppers that have found their way into estates. These are characterised by dark-green leaves, very large berries, and an immense growth on tall forest-trees, and usually hairy spikes.

Diseases and Pests.—Until quite recently very little had been published on these subjects. Butler (Agri. Journ. Ind., i., pt. i., 30-6) gives an instructive account of the Pepper Wilt. He suspects this disease first appeared in the Wynaad district of Malabar about 1900. By 1904 he found alarm general. The disease had produced a vast amount of damage in three or four years. “Its possibilities in this direction,” says Butler, “are evident from the fact that over four thousand acres of pepper cultivation are in the hands of Europeans in South Wynaad, and perhaps five times as many are grown by Natives. A far greater amount is grown in the coast districts of Malabar, but it is impossible to estimate how much this may be.” He then describes the appearance of the diseased plants. The leaves first droop, the production of leaf is discontinued, the stems of the vine separate from the support or standard owing to the decay of the clinging roots, the leaves turn yellow and fall off, and lastly the whole vine withers. A similar disease appeared in Cochin-China and Java about the same time as in India, and was attributed by Prof. W. Zimmermann and Dr. van Breda de Haan to the parasitic worm Heterodera radicicola—the common root eelworm. Doubt was thrown by Barber and others on the possibility of the eelworm being the sole cause, and Butler, in the paper above indicated, has shown that the primary cause is a Nectria fungus closely allied to, if not identical with that discussed under arhar, Cajanus indicus (see p. 198). Butler concludes that a critical study of the varieties and races of the pepper-vine with a view to discover or produce a wilt-proof form, is the only satisfactory method of dealing with the disease.

TRADE.—The trade in pepper is perhaps the oldest, and during the Middle Ages was the most important branch of commerce between Europe and the East. In the early days, the Malabar Coast had a practical monopoly of the trade. Gradually, however, more and more pepper was cultivated in, and exported from, the Malay Archipelago, and localities farther east, till, as early as the beginning of the 19th century, the Indian production had shrunk into relative insignificance. The following gives a brief summary of the conditions of the trade.

900
PISTACIA, Linn.; Fl. Br. Ind., ii., 13; Gamble, Man. Ind. Timbs., 1902, 210-1; Duthie, Fl. Upper Gang. Plain, 1903, i., pt. 1, 187; Brandis, Ind. Trees, 1906, 199-200; Anacardiaceae. A genus of trees containing some six species, of which two only are natives of India. Several others occur in Afghanistan and Baluchistan and yield valuable articles of trade sent largely to India, besides some of the species being there occasionally cultivated.

P. Khinjuk, Stocks, in Hook., Kew Journ. Bot., iv., 143; Duthie, Lc. 187; P. integerima, Stewart, Gamble, l.c. 210. The North-West Himalayan form (integerima) kākra, drek, gurgi, tāhāri, etc.; galls = kākrasingi, dushtapuchattu; the Baluchistan form (Khainjauk) ushgaī or buzgai, etc. A deciduous tree of the Suliman and Salt Ranges; outer Western Himalaya, up to 6,500 feet, extending east to Kumaoon; chiefly on dry slopes and in river valleys.

The hard, rugose, hollow galls, which form in October, are used to a small extent for dyeing and tanning, and have long held a place in the Hindu Materia Medica. They contain 75 per cent. tannic acid and give a blue-black colour with ferric chloride. The leaves are lopped for fodder for buffaloes and camels. The wood is used for furniture, carvings and ornamental work. According to Gamble, it is generally sold in the hill bazaars, particularly at Simla, in the form of thick, short planks. [Cf. Pharmacog. Ind., i., 374-7; The Bower Manuscript (Hoernle, 901]

**Mastic Tree.**

P. Lentiscus, Linn. The Mastic Tree or Mastiche; resin = rûmî mastîkî, kündür-rûmî, arabh, etc. An evergreen shrub of the Mediterranean region, which yields the mastic of Chios, imported into India.

The resin (mastic) occurs in small, irregular yellowish tears, brittle and of a vitreous fracture, but soft and ductile when chewed. It has been known in medicine and the arts from the earliest periods. It is used as a masticatory by people of high rank in India to preserve the teeth and sweeten the breath, and also in the preparation of a perfume. [Cf. Milburn, *Or. Comm.*, 1813, i., 139; Mooden Sheriff, *Mat. Med. Mad.*, 1891, 114-6; Holmes, *Cat. Handb. Herb. Pharmaceut. Soc. Mus. Rept.*, 1892, 29; *Kew Bull.*, 1897, 421-2; 1898, 190-1; 1903, 19-22; *Ind. For.*, 1898, xxiv., 480-1; Tschirch, *l.c.* 486-74.]

P. mutica, *Fisch. & Meg.*; Lace and Hemsley, in *Ind. For.*, 1891, xvii., 449-50; Prain, *Rec. Bot. Surv. Ind.*, i., 130; *P. Terebinthus, Linn.*, var. mutica, Atch. & Hemsley, *Trans. Linn. Soc.*, iii., ser. 2, 47. The gwan, khânjâh; resin = mastîkî, kunjad, wanjad, shîlm, etc. In the Dictionary this species is treated as the Asian representative of *P. Terebinthus*, the plant which yields the Chian or Cyprus turpentine, but it is now regarded as a distinct species. It occurs commonly in Baluchistan. The resin resembles that of *P. Lentiscus* and is used in the East as a substitute for that substance. It bears the same vernacular names, and is considered almost identical with that of *P. vera*. The leaves are very generally affected by a horse-shoe shaped gall, which extends round the margin and gets the name of gosh-wâdra (ear-lobe) from its peculiar shape. According to Aitchison the Natives regard the galls as of no use, but value highly the leaves for dyeing and tanning purposes.

**Galls.**

**Leaves as a Dye.**

**Terebinth Tree.**

*P. Terebinthus*, Linn. The Terebinth Tree. A tree or shrub, common on the islands and shores of the Mediterranean. It yields a resin (Chian Turpentine), the terebinth of the ancients, produced chiefly in the island of Sciro, where it is collected from incisions made in the stem and branches. [Cf. Holmes, *l.c.* 29; Tschirch, *l.c.* i. 482-3; *Kew Bull.*, 1903, 19-20; *Kew Mus. Guide*, 1907, No. 1, 64.]

**Pistachio Nut.**

*P. vera*, Linn. The Pistachio Nut; tree and nut = pîsta; galls = bôz-gwanjî. A small tree, form =-gwanjî; at 3,000 feet and upwards, in Syria, Damascus, Mesopotamia, Terek, Orfa, the Badghis and Khorasan; extensively cultivated in Syria, Palestine and Persia.

It yields a resin similar to mastic. The leaves are frequently affected by galls, irregularly spheroid in shape, borne on a short stalk and usually growing from the surface of the leaf. These, with the pericarp of the fruit and the unfertilised ovaries, are used locally for dyeing silk, and are exported to Persia, Turkestan and India. The fruit, known as the Pistachio nut, is oval-shaped and varies in size with the amount of cultivation the tree has received. They are exported in large quantities from Afghanistan to India, Persia and Turkestan. In India the nut is a common article of food among the lower classes, being fried with a little butter and salt and brought to the table hot. The nut is also a large ingredient of confectionery and ice-cream. It contains about 60 per cent. of a fatty oil which is occasionally extracted for use in medicine. [Cf. Aitchison, *Notes on Prod. of W. Afghanistan and N.E. Persia*, 1890, 156-9; *Pharmacog. Ind.*, i., 379-81; Holmes, *l.c.* 30; *Agri. Legd.*, 1902, No. 1, 21; Firminger, *Man. Gard. Ind.* (ed. Cameron), 1904, 262.]

**D.E.P., vi., pt. 1, 276-81.**

**PISUM, Linn.; Fl. Br. Ind., ii., 181; Prain, *Beng. Plants*, i., 368-9; Duthie, *Fl. Upper Gang. Plain*, 1903, i., 261-2; *Cookie, Fl. Pres. Bomb.*, 1903, i., 409; *Leguminosae*. This genus comprises the grey or field pea and the common garden pea, both largely cultivated throughout India.

**Field Pea.**

*P. arvense*, Linn.; Duthie and Fuller, *Field and Garden Crops*, ii., 17-8, t. xxxii. B. *The Grey or Field Pea, mattar, mawar revari, kulon, kisvan, karani, kulwana, tarairin, ghâle, etc.* According to De Candolle, this pea is wild in Italy. It is extensively cultivated in many parts of India, during the cold weather, in the same way as *P. sativum*, under which details of the method will be given. It produces a small, round, compressed, greenish and marbled seed, generally eaten as dâl by the natives. It must be carefully distinguished from khesdri dâl (*Lotusculus sativus*, p. 703), which it somewhat resembles. The straw is a valued FODDER.
THE GARDEN PEA

P. sativum, Linn.; Duthie and Fuller, l.c. ii., 17–8, t. xxxii. A. The Garden Pea, bara-mattar, bahatarna, kuda, shahna, abandil, kalon, ahea, sen, khandu, lār-kāna, pattani, gundūsani-ghelū, pai, etc. A more robust plant than the former, compared with which it is more valuable and prolific though a less hardy crop. It is not known anywhere as a wild plant, and is regarded by some as merely a variety or sub-species of P. arvense.

The field and garden peas are generally considered together by writers on Indian crops, and the methods of cultivation explained as applying equally to both. In all parts of the country the pea is a rabi crop. According to Woodrow (Gard. in Ind., 1903, 265–6), the varieties of the white form may be sown at any time between May and January, if the rainfall is not over 40 inches. A rich, deeply cultivated soil that has been heavily manured for a previous crop and contains at least 5 per cent. lime is necessary for a good outturn. The area in Bombay for 1905–6 was 15,036 acres. As a field crop peas are sown in moist land in October or November, and receive, as a rule, no manure or irrigation.

The crop is reaped at the end of February and March. Leaves and stalks are much valued as fodder, under the name of halim. In Cuttack, Bengal, Banerjei (Agri. Cuttaick, 1893, 83) states that peas grow well on loose sandy soil after maize. The maize crop is removed about the middle of August, and the land ploughed twice or thrice between 15th August and 15th September. By the 15th September the land is manured with cow-dung at the rate of twenty-five cartloads to an acre, and then laid out in ridges and furrows at intervals of one foot. The seed is sown by hand, at the bottom of the furrows, then covered over, and the field watered every evening till the plants appear, six or eight days afterwards. Watering is continued for two months more, at intervals of about six days. About a fortnight after sowing, bamboo twigs are fixed into the ground for the plants to climb on. Weeding is necessary once a month. Flowering commences about the 15th October, and the pods begin to form in the middle of November. By the middle of February the pods are dry and ready for harvesting. In the United Provinces, Duthie and Fuller write that both species of pea are largely grown in certain districts. They are not returned as a separate crop, but together with masur (Lens esculenta, p. 708) occupied in 1904–5 an area of 2,055,879 acres. They are sown from the end of September to the middle of October, and reaped in March. In the western and central districts peas are most commonly grown as a second crop after indigo or rice. As a rule they are sown on very heavy soil, which receives little if any preparation and is rarely manured. The seed is sown broadcast at the rate of 1½ to 1 maund per acre, and ploughed in. In the Oudh and Benares Division the crop is watered once; in other localities it is not always irrigated. The cost of production per acre is estimated at Rs. 12–13a. for the coarse kind, assuming that two waterings are given and the land is of higher rent. For the year ending 1902 the average outturn of peas for the province was calculated at 1,150 lb. per acre irrigated, and 600 lb. per acre unirrigated. Cultivation in the Central Provinces closely resembles that in the United Provinces, but the crop is never irrigated. The area in 1904–5 was 247,779 acres; in Berar, 10,257 acres. In the Panjāb, peas are cultivated as a field crop almost entirely for fodder. Seed is sown on sailab lands in October and November after a couple of ploughings. It may be sown broadcast on the same sort of soil, if too moist to plough. The seed-rate is 20 to 30 seers per acre. The crop is pulled, not reaped, in April, and the yield is 3 to 8 maunds seed per acre.

Uses.—The green pods are collected in many localities while the plant is growing, and are either cooked and eaten like French beans, or the young seed is extracted and eaten in the same way as by Europeans. The roasted green pods are known in the Panjāb under the name of dādhiūs and amāndū. The ripe seed is also used whole, split as dāl, or ground and made into bread. In Burna peas are employed in the preparation of vinegar (p. 1111). The green plant and also the straw are extensively used and valued as fodder, more especially in the Panjāb and Bombay where they are regarded as equal to hay. [Cf. De Candolle, Orig. Cult. Plants, 1882, 327–8; Rentham, Rev. of TargioniTozzetti, in Journ. Hort. Soc., 1855, ix., 138; Asa Gray, Scient. Papers, 1859, i., 347; Leather, in Agri. Ledg., 1901, No. 10, 372–3; 1903, No. 7, 152, 155, 184–5; Imp. Inst. Tech. Repts., 1903, 235; Firminger, Man. Gard. Ind. (ed. POGOSTEMON

HEYNEANUS

INDIAN PATCHOULI

PODOPHYLLUM EMODEI, Wall. ; Fl. Br. Ind., i., 112–3; Berberideæ. May Apple, Duck’s Foot, American Mandrake, pāḍra, bhavān-bakra, ban-kakri, chhīnkhā, wan-wāngān, etc. A small, erect, herbaceous plant, met with in the higher rich and shady temperate forests from Sikkim to Simla, Kashmir, Hazara, Tibet; the Kuram Valley and Afghanistan.

Resin.

Is closely allied to the American species P. pellatum, the source of the resin of Podophyllum of the British Pharmacopoeia. The resinous constituent, known as podophyllin, was first prepared from the Indian root from specimens collected by me at Kulu and sent to the late Dr. Dynock at Bombay in 1888. The process adopted was that recommended in the British Pharmacopoeia, which consists in exhausting the drug by percolation with alcohol, concentrating the percolate and precipitating the resin by adding water. Podophyllin thus obtained is an amorphous powder of a bright brown-yellow colour, if procured from the American species, but much lighter in colour, if from the Indian. The active portion—podophyllotoxin—consists of an amorphous principle soluble in alcohol, and isolated from a chloroformic extract of the root. Although the chemistry of the American species has been fully investigated, little had been done in that direction with the Indian plant till a few years ago, when specimens were sent by the Reporter on Economic Products to the Imperial Institute for examination. Physiological action of the Indian drug were investigated by Dr. H. G. Mackenzie and Mr. W. Dixon of St. Thomas’ Hospital. The results of these inquiries proved that the chemical constituents of both the American and Indian drugs were identical and that the podophyllin prepared from the Indian species is as valuable a purgative as that obtained from P. pellatum. Bhaduri (Rept. Labor. Ind. Mus., 1902–3, 28) found the Indian resinoid prepared at the Calcutta Medical Stores to contain 35% podophyllotoxin. The Indian drug, moreover, was found to furnish a larger proportion of podophyllin than the American, and to be consequently of greater value as a source of the resin. It is thus highly desirable that a regular trade in the Native drug should be established. The commercial value of podophyllin is subject to considerable fluctuation, but is generally stated to vary from 7s. 6d. to 10s. a pound in wholesale quantities. The root also contains a valuable dye-stuff, quercetin, which is easy to isolate. Dunstan states that the separation of the dye as a by-product of the manufacture of podophyllin would probably repay the Indian producer. [Cf. Pharmacog. Ind., i., 69–70; iii., app., 99–101; Henry, Econ. Bot. China, 1893, 25; Lawrence, Valley of Kashmir, 1895, 75, 85; Edgar Millard, Note on Ind. and Amer. Resins of Podophyllum, in Pharm. Journ., March 26, 1898, vi., 304–5; Dunstan and Henry, Chem. Investig. of Ind. and Amer. Podophyllum, in Trans. Chem. Soc., April 1898; Mackenzie and Dixon, Phsiol. Action and Therap. Prop. of Podophyllum, in Edinb. Med. Journ., 1898; Dunstan, in Ind. For., 1898, xxiv., 321–2; Imp. Inst. Ann. Repts., 1898–9, 22, 28, 41; Rept. Proc. Cent. Indig. Drugs Comm., 1901, i., 46, 62, 72–4; 211–8, 273–5, etc.; Imp. Inst. Tech. Repts., 1903, 170; White and Humphrey, Pharmacop., 1904, 557–8, 561.]

Indian Patchouli.

POGOSTEMON HEYNEANUS, Benth.; in Wall., Pl. As. Rar., i., 31; P. Patchouli, Hook., f., Fl. Br. Ind., iv., 633; Labiateæ. Indian Patchouli, peholi, pachōlí, pachāpūt, panel, moli, pachpanadi, poko nilam, etc. A plant found both wild and cultivated in Western and Central India from Bombay and Berar southwards, and said to be the chief source of the Indian patchouli. The plant which affords the greater part of the patchouli perfume of European commerce is, however, P. suave, Tenore (considered by Hooker a variety of P. Patchouli), which does not appear to be met with in India at all, but to be a cultivated form of P. Cablini, Benth., a native of the Philippines. [Cf. Kew Bull., 1908, 81.]

Genuine patchouli (i.e. P. suave) is cultivated chiefly in the Straits Settlements and Penang. The patchouli of Assam is obtained from Microtoma cymosa, Prain. In the Central Provinces and Berar I found P. Heyneanus growing
in the betel-leaf houses and sold apparently by the owners to the perfume manufacturers. This may be, at least partly, the patchouli of Bombay. Gilde- meister and Hoffmann, at all events, speak of the drug being shipped from both Calcutta and Bombay, but of poor quality. From the differences in chemical composition they suspect that the Calcutta herb is the Assam plant (M. cymosum). The Bombay plant, as suggested, may be derived from the pan-house cultivation, but in that case the supply must be very limited indeed. On the Girnar hills, Kathiawar, I was shown a plant († Melanthes lanceolatus, Schrank.) the large sticky and sweetly scented buds of which were being collected to be sent to Bombay as a perfume († patchouli substitute).

The following is the method of patchouli cultivation pursued in the Straits. The soil most suitable is a stiff clay with a small percentage of silice. The land is trenched, the plants deposited in rows, 2 feet apart (during the wet season), and carefully shaded till the first crop is obtained. Two other crops are secured at intervals of six months, after which the plants are dug up and the land retrenched and manured. The crop is gathered by cutting down all but one stalk on each root, and placed to dry in the sun during the day and under cover at night. The dried stems are then made up into bales and sold. Adulteration with the leaves of ruku (Oecimum Basilicum, Linn., var. pilosum) or with those of perpulai (Urena lobata) is said to be common. The oil is prepared by passing steam through the leaves in a large copper cylinder and condensing the distillate. One pikul (133 lb.) of the raw material yields from 20 to 30 oz. of the oil, and if free from the heavier stalks, about double that amount. The oil is very largely used in European perfumery. [Cf. Sawyer, Odorography, 1892, 283–308; Kew Bull., 1897, 65; Gildemeister and Hoffmann, Volatile Oils, 1900, 656–8; Thorpe, Dict. Appl. Chem., 1900, iii, 123; Schimmel & Co., Semi-Ann. Rept., Oct.–Nov. 1905, 52; April–May 1906, 49–50.]

**PRUNUS Linn. Fl. Br. Ind., ii, 312–7; Gamble, Man. Ind., Timbs., 1902, 311–5; Roxacez. A genus which contains some 21 species within the Indian limits, including the almond, peach, apricot, plum and cherry.**

**P. Amygdalus, Stokes.** The Almond, badam, bildti-badam, vadam-kottai, badam-vittulu, etc. A moderate-sized tree, indigenous in Western Asia and occasionally cultivated in Kashmir and the Panjab.

There are two varieties, bitter and sweet, but these cannot be distinguished botanically. The almond yields a GUM, the badam or Hog-traganth, which is exported from Persia to Bombay and re-exported to Europe, while from the fruit are obtained two OILS, an essential and a fixed. The fixed oil is procured by expression from the seeds of both varieties. It is clear, yellow, with an agreeable flavour and is much used by perfumers, though frequently adulterated with gingelly, poppy or mustard oils. The essential oil is got from the bitter variety and is known as "oil of bitter almonds," but according to Gildemeister and Hoffmann, "only a very small amount of the bitter-almond oil of commerce is prepared from bitter almonds. For the manufacture of the oil, the seeds of the apricot (P. armeniaca) serve almost exclusively, and the oil thus prepared does not appear to differ in any respect from the oil obtained from bitter almonds." It is produced by submitting bitter-almond or apricot cake, left after expression of the fixed oil, to distillation with water, alone or mixed with salt. MEDICINALLY the almond has been used in Europe for many centuries, but is little esteemed in India. The kernels of the sweet variety are largely used in dessert and confectionery. [Cf. Bentham, Rev. of Targioni-Tossetti, in Journ. Hort. Soc., 1855, ix, 162; Pharmacog. Ind., i, 563–7; Gildemeister and Hoffmann, Volatile Oils, 1900, 436–42.]

**P. armeniaca, Linn.** The Apricot, Mishmus, or "Moon of the Faithful," chihari, zardalu, khubani, pating, kusum-dru, galdam, iser, cherkush, hari, shiran, mandata, nakhter, etc. A moderate-sized deciduous tree, cultivated in the Western Himalaya, hardly ever ripening its fruit on the eastern section. Roxburgh and De Candolle, however, consider China its original home. Stein (Ancient Khotan, 1907, 131, 337, etc.) says that the labourers employed by him, in his excavations, identified the wood found in the houses, as also in the remains of orchards, as being the urik (the apricot)—a plant with which they were fully conversant. This would fix its cultivation in ancient Khotan as at least prior...
to the closing decades of the 8th century—the date at which the last of the series of cities was abandoned and enveloped in sand.

The apricot yields a Gum similar to tragacanth, commercially as Cherry-gum. A clear Oil is extracted from the seed and used in burning, cooking, and for the hair. As already explained, from the cake is obtained the bitter-almond oil of commerce. The seeds are brought from Asia Minor into Europe as "peach kernels." The fruit ripens from May to September, according to elevation. In the North-West Himalaya dried apricot forms a considerable portion of the Food of the people, but the fruit is also eaten fresh. By Europeans it is largely employed in this state for making jam, and when dried for cooking. The dried fruit is also an important article of trade, being brought to the plains of India from Afghanistan and the neighbouring hills. The emporium of this trade is Leh, where, according to a writer in Capital (Oct. 19, 1905), about 300 mounds are imported annually from Baltistan or Little Tibet. The same writer states that in the Afghanistan khubam the trade is in the hands of Kabulis, who retail the moist stoneless fruits in the Calcutta market at 8 annas to 1 rupee per seer, and the dried fruit at about Rs. 1–8 per seer. Gamble states that the wood is handsome and used in the Panjâb for various purposes, while in Lahoul and Upper Kunawar it is the chief firewood. [Cf. Hoffmeister, Travels in Ind., 1848, 392–3, 464; Bentham, l.c. 163; Smythies, in Agri. Ledg., 1894, No. 15, 5–6, 45–6; Ind. For., 1895, xxi., 70–2; Ind. Gard., May 18, 1899, 205; Gildemeister and Hoffmann, l.c. 437; Firminger, l.c. 245; Sly, Fruit in the N.W. Front. Prov., in Agri. Journ. Ind., i., pt. iii., 268–9.]

**Dwarf Cherry.**

**P. Cerasus, linn.** The Sour or Dwarf Cherry, alu-bâlu, gîlas, olchi, jera-sayna, etc. According to De Candolle, this is a native of the region stretching from the Caspian Sea to Western Anatolia. In India it is cultivated in the Panjâb Himalaya and North-West Provinces, up to 8,000 feet. It yields a Gum similar to tragacanth. In Europe the kernel is used for flavoring alcoholic liquors and the fruit for making preserves, while the wood is valued by cabinet, musical instrument and pipe makers. [Cf. Bentham, l.c. 160; Smythies, in Agri. Ledg., l.c. 42, 46–54; Firminger, l.c. 246–7.]

**Plum.**

**P. communis, Huds., var. insititia.** The Plum, aluča: fruit = aul, khârâ, alu-bukhâra, aleacha, bhotiya badâm, olchi, e, gardalu, luni, alpoqâd-pâzham, etc. A moderate-sized tree, cultivated (or indigenous) in the Western Himalaya from Garhwal to Kashmir, at 5,000 to 7,000 feet. It yields a yellow Gum of little value, which somewhat resembles gum-arabic. An Oil prepared from the kernels, the "Plum-oil" of Europe, is used for illuminating purposes. The ripe fruit is eaten by all classes and is much esteemed. In a dried condition, a variety, the Sokhara plum, is imported in quantities from Afghanistan, and is much used as an article of diet. It also forms an ingredient of a common chutney. The true plum (var. domestica) is cultivated to a small extent in the plains of Northern India, but the fruit is inferior. Gamble states that the wood is smooth to work and is used in Kashmir for the framework of the so-called papier-mâché boxes. [Cf. Bentham, l.c. 161; Smythies, in Agri. Ledg., l.c. 42, 46; Woodrow, Gard. in Ind., 1903, 306; Firminger, l.c. 245–6.]

**Bird Cherry.**

**P. Padus, linn.** The Bird Cherry, jamana, lîk-kir-u, hîl sa, hot-kir, bombaksing, zamb-chule, pâras, kâlakât, gidâr-dák, bart, züm, etc. A moderate-sized deciduous tree of the Himalaya from the Indus and Kuram Valley to Sikkim, at 6,000 to 10,000 feet (Gamble). It yields an inferior Gum and a poisonous Oil, which may be used MEDICINALLY. The fruit is eaten by the Natives and the leaves form an excellent cattle FODDER. The wood is occasionally used for making railings, agricultural implements and spoons.

**P. persica, Stokes.** The Peach and Nectarine, aru, takpo, rek, sînînâ, chinnând, bem beint, mandata, shafatu, guareshtai, etc. A small tree, native of China, cultivated all over India, especially on the western side, and often found running wild. The tree flowers, according to elevation, from January to May, and the fruit ripens between May and October. For the method of propagation the reader should consult Smythies and Firminger. Like other species of *Prunus,* it yields small quantities of unimportant Gum. From the kernels an Oil is obtained, used by the Natives of the North-West Himalaya for cookery, illuminating purposes, and as a dressing for the hair. [Cf. Garcia de Orta, 1563, Col., xlvi.; Bentham, l.c. 163; Smythies, in Agri. Ledg., l.c. 17–8, 42, 46; Woodrow, Gard. in Ind., 1903, 303–6; Firminger, l.c. 242–4.]
THE GUAVA FRUIT

PTEROCARPUS

P. Puddum, Roxb. Wild Himalayan Cherry, paddum, kongri, piya, chamiar, analgisch, padma-kasta, etc. A moderate-sized (in Sikkim a large) deciduous tree, wild in the Himalaya from the Indus to Assam, between 2,500 and 7,000 feet; Khasia hills; hills of Upper Burma; often cultivated. It yields an abundant Gum, which is not made use of, and the kernels contain an Oil, similar to that of bitter almonds. The fruit is little eaten by Natives, but is sold in quantities to Europeans for the manufacture of hill cherry brandy. According to Kanjialal, the stones are made into rosaries and necklaces by fakirs. The wood is used in the Panjab Himalaya for walking-sticks (made of saplings, or root-suckers), and in Darjeeling is worked up into furniture. [Cf. The Bower Manuscript (Hoernle, transl.), 1893-7, 102, 104, etc.]

PSIDIUM GUYAVA, Linn. ; Fl. Br. Ind., ii., 468; Talbot, List Trees, etc., 1902, 166; Gamble, Man. Ind. Timbs., 1902, 355; Prain, Beng. Plants, 1903, i., 487; Cooke, Fl. Pres. Bomb., 1903, i., 498; Myrtaceae. The Guava, amrut, peyara, madhuriam, amuk, gaya, anjir, zard, pera, jambó, guava, segapu, cova, sebe, pela, madalak beng, etc. A small evergreen tree, introduced from America and now cultivated and found semi-wild all over India.

It is grown solely for its fruit. According to Firminger, the best qualities are produced in Allahabad and its neighbourhood. Young plants are easily raised from seed during the rains, but propagation by layers is usually resorted to, and rooted suckers may also be taken from the base of the main stem. It requires no particular cultivation and thrives in any soil. The tree blossoms during the hot season and continues to do so and to bear fruit to the end of the cold season. The finest fruit, however, is said to be obtained when the general bearing season is over. There are two varieties, one known as the Pears Guava, the other as the Apple Guava, but they are so alike that they can scarcely be distinguished till cut open. The fruit is eaten by all classes, but by Europeans is generally preferred stewed or in the form of jelly or of the well-known “Guava cheese.” According to Gamble, the wood is made into spear-handles and special instruments. In Vellore, North Arcot, it is said to be used for latticework.

In Assam, the leaves and bark are employed in Dyeing, and in Bengal and the United Provinces are occasionally employed in TANNING. [Cf. Merian, Insect. Surinam, 1705, tt. 19, 57; Pharmacog. Ind., 1891, ii., 30–2; Duncan, Monog. Dyes and Dyeing, Assam, 1896, 41; Agri. Ledg., 1901, No. 9, 346; 1902, No. 1, 43; Firminger, Man. Gard. Ind., 1904, 235–6.]

P. dalbergiolais, Roxb.; P. indicus, Fl. Br. Ind., ii., 238 (in part). Andaman Redwood or padouk, chalanga-dá of the Andamans. A large tree sparingly cultivated in Bengal and Southern India. It has frequently been confused with the next species, a Burman plant also known by the name of padouk.

In the Andaman Islands this "is the principal timber tree and its wood has of recent years obtained a good place in the markets of Europe and America as a handsome wood for furniture, parquet floors, railway carriages, door-frames and balustrades, etc. In India it has long been in use as a gun-carriage wood, and stores are kept in the arsenals of Calcutta, Madras and the Kidderpore Dockyards" (Gamble). Recently it has been successfully employed in England in paneling, and in America in the building of Pullman cars. [Cf. For. Admin. Repts. Andaman Islands; Todd, Rept. Explor. N. Andamans, 1905; Anderson, Rept. Explor. N. Andamans, 1905; Gilbert Rogers, Rept. Dept. Conservator of For., Andaman Islands.; Ind. For., 1905, xxxi., 511–7; also Todd, 1906, xxxii., 581–7.]

P. indicus, Wild.; Fl. Br. Ind., ii., 238 (in part). A deciduous tree believed to be indigenous in the Malay Peninsula and Archipelago; cultivated in Moul-
PTEROCARPUS  MARSPIUM

INDIAN KINO

mein, Amherst and Tavoy. This is the species hitherto supposed to be the source or a source of the wood known generally as padouk of Burma, and with which the previous species, *P. dalbergioides*, was, till Prain studied these trees, commonly confused. The circumstances that led up to this are fully discussed by him (Ind. For., l.c. 6). It seems certain that the name *padouk* is not applied to *P. indica*, and possibly that *P. indica* is not an indigenous species anywhere in Burma. [Of. Greeshoff, in Natt. Ind. Pl., in Kolin. Mus., Amsterdam, Extra Bull. 1896, 107.]

*P. macrocarpus*, Kurz. Burma *padouk* or simply *padouk*. A deciduous tree of the eng and upper mixed forests of Burma; Shan, Chin and Karen hills of Upper Burma, Pegu and Martaban. According to Prain, this species alone is entitled to the name Burma *padouk*. Gamble states that the wood is harder and heavier than that of *P. dalbergioides*, but, though fine hardwood, is probably not used outside Burma.

*P. Marsupium*, Roxb. Hooper, in *Agri. Ledg.*, 1901, No. 11. The Indian Kino Tree, bija, bijasal, piasal, hitum, murga, pedei, radat bera, dhorbela, bibila, hini, houn, dian, vengai, pedegu, pedagi, benga, karin, kagara, etc.; the gum = *hiradokhi*, nit-ká-dammul-akhvain, kandámiruga-mirattam, vennap pasha, etc. A large deciduous tree of Central and South India and Ceylon, extending northwards as far as the hills of Bihar, Binda and the Kumaon Terai.

This species yields the gum-kino of European Materia Medica. To E. M. Holmes is due the credit of having originated the modern interest taken in Indian *kino*. In a letter, September 23, 1895, he drew my attention to the high prices then ruling in Europe for the extract. He recommended that the Indian production should be investigated and an improved supply cautiously introduced. In consequence an inquiry was instituted all over India, and the information thus brought together was published by Hooper. The manufacture of *kino* from the juice of *P. Marsupium* is conducted in the district of North Malabar. The best season for collecting is the dry weather during February and March, when the trees are in blossom. The right to tap the trees is put up to auction. In other cases, the tapping is conducted by rangers under the supervision of the district forest officers. The following is the method of collecting adopted a few years ago by Mr. J. C. F. Marshall, the District Forest Officer. A longitudinal cut is made with an axe or knife (macha katti) through the bark of the tree down to the cambium, about 1½ feet long, and side cuts are made to lead into this. A bamboo tube is then fixed at the bottom of the main incision to catch the juice. In about twenty-four hours the flow of gum ceases and the bamboo is taken down. When several of these bamboo tubes are nearly full, they are carried to headquarters and emptied into a large cauldron and boiled. During the boiling, the impurities which rise to the surface are skimmed off. When sufficiently concentrated it is exposed to the sun in shallow vessels till dry enough to crumble to pieces. It is then weighed and packed away in boxes. Another method, more recently adopted in North Malabar, is to dry the juice in shallow trays in the shade. The trays are arranged on tiers or shelves in a shelter constructed of bamboo, and the dust excluded by muslin-covered doors. The gum is poured into the trays in layers about one-eighth of an inch thick, and takes about seven or eight days to dry, producing a dark ruby *kino* of great purity. Marshall found the yield to be about 1½ lb. of juice per tree, equivalent to ½ lb. of the dried gum, ready for medicinal purposes. The yield of dry *kino* from the liquid exudation depends on the constancy at the time of collection, but is usually 50 per cent. E. White has recently pointed out that the peculiar insolubility of Malabar *kino* in alcoholic and aqueous solutions is due to the action of an enzyme. From this Hooper infers that commercial *kino* is improved by boiling before evaporation to dryness (Rept. Labor. Ind. Mus., 1903-4, 31).

In North Malabar alone, it is stated that about 2,000 pounds of *kino* can be procured annually, at the price of 3 to 4 annas a pound, but there is scarcely any demand for the article in India except by the Medical Store Departments of Calcutta, Madras and Bombay. In addition to its medicinal use it is said that *kino* is also employed at a certain stage in the preparation of some wines. The drug collected in Malabar finds an outlet in the ports of Calicut and Tellicherry. The Native State of Travancore exports its grain through Cochin and Alappuzha, while gum collected in South Kanara is despatched from Mangalore. Much of the *kino* is known as Cochin grain, probably because Cochin is the principal port of call. Gamble says “there is a considerable demand for *kino* gum

908
for export, much of it going to France." In 1897-8 the price for genuine "Cochin" grain was 10s. per lb.; in 1899 the price fell during the year from 10s. to 2s. per lb., and in 1900 it is said to have been sold at 1s. per lb. In a report by Dunstan, of September 1905, the market price in London is stated to be 4d. per lb. Recently the drug has been examined with a view to discovering its value as a tanning material, and a report (Kino as Tanning Mat., Imp. Inst. Repts., Sept. 13, 1905) was issued on the results obtained. Dunstan considers that kino would be quite suitable for use as a tanning material, on a commercial scale, provided it could be obtained at a sufficiently low cost to enable it to compete with other tanning materials. He regards a price of about 2d. per lb. as the limit. Experiment seems to prove that the kino prepared by the method of merely drying the juice in the sun is the best for use as a tan.

The bark is occasionally employed for dyeing. Sir Thomas Wardle found it to contain a brownish-red colouring matter, which produced reddish-fawn colours with tannin silk. In the territory of Goa it is also employed for its astringent properties. The leaves make an excellent fodder, and are reported by Mollison to be specially valuable as a manure. After teak and blackwood, the kino wood is said to be the most important in South India, and to be in great demand for door and window frames, posts and beams, furniture, agricultural implements, cart and boat building, and has also been used for sleepers. It has a high reputation in the manufacture of double-headed drums, being regarded as specially sonorous. ([Cf. Pharmacog. Ind., i., 464-7; Schaan-Strassburg, Drachenblut und Kino, Reprint from Proc. Germ. Pharm. Soc., 1901; West African Kino, in Der Tropenpflanzer., June 1902, vi., 305-8; Imp. Inst. Tech. Repts., 1903, 176-8.])

**P. santalinus**, Linn. f. Red Sanders Tree, Red Sandal-wood, rabbe-chamnan, undum, hilaparni, ranjana, radanji, tāmbāda, chandana, shen-shandanan, erragandhapu-cheekha, gandham, remnyungalha-cheke, sondaku, etc. A small tree of South India, chiefly in Cuddapah, North Arcot and the southern portion of the Karnul district. On a small area, near Kodūr, in Cuddapah, it has been very successfully cultivated (see p. 976).

In former years the great use of the wood of this species was as a dye, and large shipments were made annually from Madras to Europe, where it was employed as a colouring agent in pharmacy, for dyeing leather and for staining wood. The demand, however, has now greatly declined, due probably to the increase in the use of artificial dyes. In India it is chiefly employed in marking idols and for staining the forehead in certain caste markings. The value of the wood as a dye is due to a red colouring principle, Santalin, soluble in alcohol and ether, but not in water. When dissolved in alcohol, it dyest cloth a beautiful salmon-pink.

The Wood is highly prized for house posts, and in the South Deccan is universally employed for plough-poles and other agricultural implements. It is also in great demand for carved work, wood idols, boxes and picture frames. ([Cf. Garcia de Orta, 1563, Coll., clxi., Pharmacog. Ind., i., 402-4; Hadi, Monog. Dyes and Dyeing in U. Prov., 1896, 81; Holder, Monog. Dyes and Dyeing in Madras, 1896, 4; Dutt, Mat. Med. hind., 1900, 154; For. Admin. Repts. Madras; Hanauke, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 252.]

In many parts of India and Burma it is cultivated for its fruit, which, however, according to Firminger, is not to be compared with that brought down annually by Afghan traders from Kabul. It is not particular as to soil, is said to succeed even in the driest, but does not thrive in very damp climates. To yield good fruit, it must be manured every year, preferably in December. Plants may be multiplied either by seed, by cuttings, or by layers. The best method is to raise seedlings and graft on them, when of sufficient height, from trees of a superior kind. It bears fruit principally during the cold season. Before the fruit is a quarter grown, it is frequently penetrated by a caterpillar which devours the interior and causes the remainder to rot. To prevent this, when still
small, it should have the calyx cut clean off and then be tied up loosely in a piece of linen cloth. When ripe it is about as large as a full-sized apple, with a hard rind of a brownish-red colour. The quality varies in different localities. In the Lower Provinces and Bengal it is inferior to that of the North-West and hilly regions. By the Natives, a cooling sherbet is made of the pulp, and from remote times it has been valued for its medicinal properties.

In various parts of India the flowers are used as a red dye, while the astrigent rind of the fruit and the bark are valuable tanning materials. The wood is not used for any purpose, but according to Gamble might be substituted for boxwood. [Cf. Merian, Insect. Surinam, 1705, tt. 9 and 49; Pharmacog. Ind., 1891, ii., 44; Cameron, For. Trees of Mysore and Coor. 1894, 150–1; Monograph. Dyes and Dyeing:—Duncan, Assam, 1896, 42; Hadi, U. Prov., 1896, 80; Fawcett, Bomb. Pres., 1896, 34; Russell, Cent. Prov., 1896, 14–5; Agri. Ledg., 1902, No. 1, 43–4; Woodrow, Gard. in Ind., 1903, 319–20; Firminger, Man. Gard. Ind., 1904, 234–5.]

PYRUS, Linn.: Fl. Br. Ind., ii., 372–80; Gamble, Man. Ind. Timbs., 1902, 321–4; Rosaceæ. A genus of moderate-sized trees, occurring in the Himalaya, Khasia hills and Burma. Several bear edible fruits, of which the best known are the apple and the pear. In this place may be mentioned the closely allied plant Cyttonia vulgaris, Pers.—the quince or bili—small tree cultivated in the Western Himalaya.

PYRUS communis, Linn. The Common Pear, nashpáti, nak, kishtha, bahira, tang, amrúd, charkeint, li, etc. A small tree believed to be wild in Kashmir, cultivated throughout the Himalaya, on the Nilgirs, at Bangalore and elsewhere in South India.

The pear-tree thrives well in most parts of India, and is easily propagated by layering or grafting. The latter operation should be performed in February or March. Cuttings will also strike root if put down in February during the rains. The fruit ripens about August or September; as a rule, the tree does not come into bearing before it is ten years old. A full account of the method of cultivation on the hills is given by a writer in Indian Gardening (Feb.–March 1899). The fruit of the ordinary hill-pear is generally hard and flavourless, and, though eaten by Natives, is little used by Europeans except for cooking purposes. In Kangra and the lower inner ranges of the Himalaya, pears from imported European stocks are grown to great perfection, and the produce is exported to the hill stations and the plains. In Europe the wood is prized for engraving and turning, but especially for drawing implements, such as set-squares, etc. [Cf. Bentham, Rev. of Targioni-Tozzetti, in Journ. Hort. Soc., 1855, ix., 138; Smythies, in Agri. Ledg., 1894, No. 15, 5, 34–47; Coldstream, Rept. on Fruit Cult. in Simla Dist. and Kullu, 1894, 7, 14; Woodrow, Gard. in Ind., 1904, Gard. i., 249–50.]

D.E.P., iii., 449.

P. Malus, Linn. The Apple, seb, kilshú, sher, tshánt, sín, ching, li, pahu, manra, sévu, etc. A moderate-sized tree indigenous in Eastern Europe and possibly also in the Western Himalaya, between 5,000 and 9,000 feet; largely cultivated in the Himalaya, the Panjab, Sind, North-West Provinces, Central India and the Deccan. Stein discovered apple-wood (alma) used in the house-construction of ancient Khotan (see the remark regarding the Apricot, p. 905). In India, apple-trees are propagated by layering and grafting on the common country, or long acclimatised stock. Firminger, quoting General Jenkins, states that cuttings may be planted in January and February near water and also during the rains. When they shoot strongly they should be planted out and cut down to two or three buds, and of these the strongest shoot only should be allowed to grow. This should be trained straight up to a height of about three feet. Grafting takes place in March. A gravelly soil is most suitable. The best fruit is produced in the Kangra Valley, whence it is exported in quantities to Simla and the plains of India. The traffic from Kashmir to Rawalpindi and the Panjab generally has become a large and important one. Government orchards have been established in Kumaon, where apples of choice English sorts are successfully grown. The Municipality of Simla has also made an effort to utilise as an orchard the tract of hills reserved as the catchment area in water supply. Sly (Agri. Journ. Ind., 1907, ii., pt. i., 70–3) reviews the available information regarding the apple cultivation of the hills of India. In Afghanistan, he tells us,
the apple is raised from seed and is not grafted. Baber (Memoires (Leyden & Erskine, trans.), 281) mentions the apples of Kabul. In the Shan States (Burma) the apple is grafted on to Dacrydium indica. [Cf. Bentham, l.c. 159; Symthies, in Agri. Ledg., l.c. 3-5, 45, 38-41; Fruit Cult. on the Hills, in Ind. Gard., Dec. 1, 1898, to Feb. 16, 1899; Woodrow, l.c. 306-7; Firnunger, l.c. 247-9.]

**The Indian Oaks**

**Quercus semecarpifolia**, Smith. Common Brown Oak of the Himalaya, ghees, karshu, khareu, barchar, jangal ka parungli, kreu, sawi, etc. A large overgrown tree of the inner Himalaya extending westward to the Safedkoh and Afghanistan, eastward to Bhutan and the hills of Manipur, usually at 8,000 to 12,000 feet.

According to Gamble, the timber of this species is not in great demand, but is of good quality, strong and durable. It is an excellent firewood and yields charcoal of the best description. The leaves and young shoots are plucked for drying and used as a medicine.
THE RADISH

RAPHANUS SATIVUS, Linn.; Fl. Br. Ind., i., 166; Prain, Beng. Plants, i., 1903, 223; Duthie and Fuller, Field and Garden Crops, pt. iii., 14; Duthie, Fl. Upper Gang. Plain, 1903, i., 48; CRUCIFERÆ. The Radish, māli, muro, mula ānāki, tara māra, māngra, māgnā-gadde, mullangi, bili, lobak, etc. An annual herb, cultivated throughout the plains of India and in the Himalayas up to 10,000 feet. The Rat-tailed Radish (R. caudatus, Linn.), is commonly cultivated in Western India and the Panjāb.

According to Roy (Crops of Beng., 1906, 142-3), high and well-drained sandy loam is invariably chosen for radish cultivation. All through the rainy season and after, the land is frequently ploughed and thoroughly pulverised in preparation for this root crop. The seed is sown from the middle of August to the middle of November, 1 seer per acre, and the field is immediately harrowed. Cow-dung manure at the rate of 60 maunds per acre is applied directly after sowing. The crop is weeded and irrigated at intervals, and a month after sowing is ready for harvest. In many parts of the country it grows larger than an average good-sized carrot, and is eaten more as a vegetable than as a flavouring ingredient in salad. There are, in fact, several distinct cultivated races, the radish most common in Bengal being a long tapering root of a purplish rather than a scarlet tint. Roxburgh's description is admirable. "The root," he says, "grows to the size of a man's leg, or more, and is only half immersed in the soil." Duthie and Fuller allude to its value as a famine food, a crop being rapidly obtained on the climatic conditions proving favourable. The root is eaten both raw and boiled, and is occasionally pickled.

The radish is cultivated not only for the root, but also for the young seed-pods and the leaves, all of which are eaten. The unripe pods (especially of the rat-tailed radish) are boiled and eaten with ḍhī or cooked in curries, and are also sometimes pickled. Both roots and seeds yield on distillation with water a small amount of a colourless sulphuraceous Orr, heavier than water. This is used medicinally. A special form is in fact cultivated in Sylhet on account of the sweet oil obtained from its seeds (see Duncum, p. 491). [Cf. Bentham, Rev. of Targioni-Tozzetti, Journ. Hort. Soc., 1855, ix, 146; Pharmacog. Ind., i., 129; Basu, Agri. Lohardaga, 1890, pt. i., 77; Banerjei, Agri. Cuttack, 1893, 114—5; Dunstan, in Agri. Ledg., 1899, No. 12, 137, 144, 150; Gildemeister and Hoffmann, Volatile Oils, 1900, 417—8; Woodrow, Gard. in Ind., 1903, 161—2; Firminger, Man. Gard. Ind., 1904, 189—90; Joret, Les Pl. dans L'Antiq., etc., 1904, ii., 255.]

RHEUM EOMODI, Wall.; Fl. Br. Ind., v., 56; POLYGONACEÆ. The Rhubarb, Hindi-révand chini, doli, padam-chal, chukri, archu, chutiāl, khābīram, pambash, āti, nādi-maṇjat-china-kishangu, etc.

Found wild in the sub-alpine Himalayas of Nepal and Sikkim at altitudes of 11,000 to 12,000 feet, and is usually considered to be the source of the so-called Himalayan Rhubarb. Commercial rhubarb, known as Chinese and East Indian, is said to be obtained from R. officinale and R. palmatum, which grow in South-East Tibet and North-West China. [Cf. Prjevalski, Mongolia, 1876, 912]
ii., 81–0, and note to same by Sir H. Yule, 291–8.] Both Garcia de Orta and Linchoten state that rhubarb is brought from China (Tartary) through Persia and thence to India. The officinal part of the plant is the decorticated and dried root or root-stock. Himalayan rhubarb is usually stated to be of little commercial importance, and the rhubarb sold in the bazaars of the plains is ordinarily affirmed to be from London. Considerable quantities are, however, annually conveyed to the plains from the Kangra district of the Panjab. An inquiry in 1894 revealed the fact that the exports from that valley came to about 1,000 maunds a year. Further, it was stated to be largely used in the fabrication of certain external applications (Pres. Add. Med. Congress, Calc., 7). It is remarked in the Pharmacopoeia of India that were the Himalayan rhubarb cultivated with due care, there is reason to believe a drug equal to the Chinese or Turkey rhubarb might be obtained. [Of. Paulus Eginaeta (Adams, transl. and Comment.), iii., 316; app., 478–80; Mesua (ed. Marinus), 1562, 50; Garcia de Orta, 1563, Coll., xvii.; Linchoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), ii., 101–2; Boyum, Fl. Sin., 1588, S; Du Halde, Hist. China (Engl. transl.), 1736, i., t. 17; Turner, Emb. to Tibet, 1800, 394; Milburn, Or. Comm., 1813, ii., 516–7; Pharmacog. Ind., iii., 152–7; Henry, Econ. Bot. China, 1893, 32–3; Ind. Mus. Ann. Rept., 1894–5, 31; Hesse, in Agri. Ledg., 1896, No. 29, 289, etc.; Rept. Cent. Indig. Drugs Comm., 1901, i., 144.]

RHIZOPHORA MUCRONATA, Lamk.; Fl. Br. Ind., ii., 435; Gamble, Man. Ind. Timbs., 1902, 323–2; Prain, Beng. Plants, i., 475; RHIZOPHOREÆ. The Mangrove, khama, bhara, rai, kunro, upu-poma, byu, bakam, etc. A small evergreen tree of the muddy shores and tidal creeks of India, Burma and the Andaman Islands. The Bark is exported from Mergui to Rangoon, and a considerable trade is also done from the Perak coast. It yields a Dye and Tan. Samples of bark of R. mucronata were sent to the Imperial Institute in 1890 (Imp. Inst. Tech. Repts., 1903, 180–90), and were found to vary greatly in yield of tannin, one sample giving over 27 per cent., while another gave only 4 per cent. An extract, prepared presumably from the former sample, contained 76 per cent. tannin. In the Report of Forest Administration in Burma (1904–5, 19), mention is made of the establishment of a tannin factory in accordance with a system recommended by Dunstan. So far the extract thus prepared sold at less than its cost. For dyeing cotton, an extract was declared superior to that of other mangroves, but much inferior to the best qualities of cutch. The fruit is said to be sweet and edible, and a light wine is made from the juice. From the aerial roots, salt is occasionally extracted. The wood is reported to be good but rarely made use of. [Of. Ind. For., 1897, xxii., 413; Hooper, in Agri. Ledg., 1902, No. 1, 35–6; Grass, Berichte über Land- und Forstwirtschaft in Deutch Ost Afrika, 1904, ii., 178–9, 182–5; Bull. Imp. Inst., 1906, iii., No. 4, 345–52.]

RHUS, Linn.; Fl. Br. Ind., ii., 9–12; Gamble, Man. Ind. Timbs., 1902, 207–10; Brandis, Ind. Trees, 1906, 196–9; ANACARDIÆÆ. A genus of trees or shrubs, indigenous chiefly to the warmer temperate regions of both hemispheres. All are highly astringent and used as tans. Some twelve species are native of India and Burma.

R. Coriaria, Linn. The Sumach Tree of Europe, tatrak, mutchli, sumok, etc. A small tree, wild in the Canaries, Madeira, the Mediterranean region, eastward to Afghanistan; often extensively cultivated. Inzenga (Ann. di Agric. Sic., etc., Palermo, 1832) wrote an interesting paper on the cultivation of this plant (translated into English by Sir H. Yule, in Edinb. Bot. Soc. Trans., 1867–8, ix., 341–55). The leaves contain a coloring matter, and together with the twigs are largely used in Europe for Tanning. They are also imported into India, usually from Sicily, for use in the large European tanneries. Moroccan leather is tanned with this material, and it is usually held to be one of the best tans for leathers intended for use in bookbinding. In the Kew Bulletin (1895, 239–6) an account of the manufacture of and trade in Sicilian sumach is given. The leaves ripen about
RHUS VERNICIFERA  

JAPANESE LACQUER

Season. August, when the plant is cut down, spread on the field to dry, and the leaves stripped off and conveyed to the mills. Here the leaves are separated from all foreign admixtures and are then ground to powder. This powder is again subjected to a further treatment with which is roughly treated as a tanning material. The real sumach is locally known as "strong," in contradistinction to a similar plant known as "sommacco femminello," the leaves of which are smaller and of less strength than those of the former, in the adulteration of which they are largely used. [Cf. Journ. Soc. Chem. Industr., 1902, xxxi., 1207; Priestman, Micro. Examin. of Sumach Adulterants, in Journ. Soc. Chem. Industr., 1905, xxiv., 231–3; Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 300.]

Powder Prepared. R. Cotinus, Linn. The Elm-leaved Sumach, tunga, chanid, ámi, phain, bauru, largá, manu, darengrí, erandi, etc. A shrub or small tree of the Suliman Range and Western Himalaya to Kumaon, ascending to 6,000 feet. Throughout the area of its indigenous habitat, leaves, bark and wood are all used in DYEING and TANNING, but whether they could be employed on a commercial scale for this purpose is doubtful. Gamble states that the Wood is employed in South Europe for inlaid work and makes pretty carvings, picture-frames, etc. In the Himalayas, baskets are made of the twigs. [Cf. Henry, Econ. Bot. China, 1893, 42; Britton and Brown, Illust. Fl. Northern United States and Canada, 1897, ii., 389; Hooper, in Agri. Ledg., 1902, No. 1, 21; Hanausek, l.c. 246–50.]

Dye and Tan. Wild succedanea, Linn. The Wild Varnish Tree, arkol, lakah, shash, tatri, raniwalai, serhnyok, dingkain, arkhar, chokha, hala, etc. The galls are known as kakar-singi (kakar = the barking deer and singi = horns), but the true galls of that name appear to be those of Pistacia khitjak. A small deciduous tree of the Himalaya, from Jhelum to Assam, at 2,000 to 8,000 feet.

Baskets. R. vernicifera, DC. This is the species which yields the famous Japanese Varnish. It grows all over the main island of Japan, and also in Kishin and Shikoku, but it is from Tokio northwards that it chiefly flourishes. Efforts have been made to cultivate it in India, but without much success. The trees are propagated either by seed sown in January or February, or by cuttings from the roots of vigorous young plants. The juice, from which the varnish is obtained, is collected by making incisions on the stem, the punctures being repeated every fourth day at successively higher parts. The juice which oozes out is scraped off with a flat iron tool. When the tree has been tapped to its topmost branches, it is felled and cut into lengths, which are tied into faggots and steamed in water for ten to twenty days, after which the bark is pierced and lacquer collected in the same way as from the living stem. The juice thus collected is a tenacious fluid of a grey-brown colour. It is allowed to stand and settle, a skin forms over the surface, the better qualities rise to the top and the impurities sink. By stirring in the open air, the lacquer dries, absorbs oxygen and gains a brilliant black colour. The articles lacquered are invariably of wood. The varnish is spread in coats of increasing fineness, the surface being repeatedly ground down with hard charcoal and polished with the ashes of deer's horn, and relacquered again and again. The pattern, says Dr. Dresser (Edinb. Review), is sketched on fibrous elastic paper, which is warmed and fitted to the surface to be decorated, when the pressure of the hand is enough to transfer the pattern. If the pattern is to be in gold, the outline is then followed by a paper pencil dipped in lacquer, which acts as a size. When this has so far dried as to be sticky, gold-dust is shaken on it from a spoon. From Reins's detailed account, it would appear direct painting of the patterns is also practised for the higher class works. [Cf. Rein, Indust. of Japan, 1889, 338–78; Quin, Lacq. Indust. of Japan, in Trop. Agriest., Dec. 1882, ii., 514–7; Henry, Econ. Bot. China, 41; Ernest Hart, Canton Lect., May 27, 1895, in Journ. Soc. Arts, Sept. 13, 1895, 875–6; Journ. Soc. Arts., Sept. 11, 1896, 808–9; Thorpe, Dict. Appl. Chem., ii., 914.
THE CASTOR-OIL PLANT

RICINUS COMMUNIS, Linn.; Fl. Br. Ind., v., 457; Euphorbiaceae. The Castor-oil Plant, Palma Christi, Ricin de Palma Christi, erand, erand, rand, bherenda, bindi, eri, areta, orer, rak-lop, amrar, gaba or jara, grund, nerinda, rendi, harnauli, bazanjir, härán, ind, rund, amanakkam, kottei, amadan, amdi, haralu, kezu, kyetsu, etc. These vernacular names are mostly derived from the Sanskrit eranda and rvukku, with the alternative vatarî (= anti-rheumatic). The Arabic khiru, the Persian bedînîr, the ancient Greek kiki and the kroton (Herodotus, ii., ch. 94) have had little, if any, influence on the origin of the existing Indian vernacular names. The name Palma Christi is used by Holland in his translation of Pliny (Nat. Hist., 1601, 433).

A native of the tropics, where it exists as a perennial bush or small tree. Is in warm temperate tracts an annual and ascends the Indian hills to altitudes of 6,000 feet. Its cultivation seems also restricted by excessive moisture, the plant becoming again an annual (within the tropics), thus allowing of cultivation in the drier months. Rainfall after sowing, however, seems essential to liberal germination. It prefers well-drained loams, hence loose sandy or heavy clay soils are alike unsuitable. It is an exhausting crop, especially on the soil resources of nitrogen. Is exclusively propagated by seed, and in India, when grown as a pure field crop, is generally regarded as precarious, owing to its liability to being completely devoured by caterpillars. Mackenzie (Eri Silk-worm, Cachar Exper., 1889, in D.E.P., vi., pt. iii., 165) mentions a case where 30 acres were completely defoliated by caterpillars.

History.—Cultivated throughout India and naturalised here and there near habitations, distributed throughout the tropics generally, but probably indigenous to Africa. It is not, however, uncommon to discover it in the scrubby jungles of the outer Himalaya. Duthie speaks of it as naturalised in Merwar; it has been reported as wild and never cultivated in Upper Burma and universally self-sown in Assam—that is to say, in the gardens and waste lands, where its leaves are used to feed an undoubted indigenous silkworm. Taylor (Topog. and Stat. Dacca, 1840, 59) speaks of castor as found in the uncultivated parts of the district. In the Susruta A'yurveda, references to the plant are made in such terms as to preclude the possibility of the passage in question denoting an imported drug. Two varieties, a red and a white, are described, thus showing personal acquaintance with the plant. Its oldest Sanskrit name, eranda, has passed into the most diverse languages and dialects of India (Dutt, Mat. Med. Hind., 1900, 231).

 Dioscorides tells us that it was called kroton from the resemblance of the seed to the dog-tick, and it is significant that both the plant and the tick bear the name Ricinus in Latin (Pliny, Hist. Nat., xi., 34; xv., 7). Galen, Paulus Aegineta, Measne, etc., mention the purgative property of the oil. Avicenna, Rhases and other Arab writers add that it is a good application for cutaneous diseases and in rheumatism. But it would almost seem as if the Arabs had made acquaintance with the plant from India, since they call it sinsim-el-hindi (Sesamum of India), and, as pointed out by the authors of the Pharmacographia Indica (iii., 302), the properties assigned to the plant by the Arabs are those attributed to it by the Sanskrit authors. Pliny, moreover, speaks of the plant as not so very long ago introduced into Egypt.

Few of the early European travellers in India, however, make any reference to the plant. Garcia de Orta and Linschoten are silent. Aitton (Hort. Kew, 1739, iii., 377) mentions that it was cultivated in England in the time of Turner, 1562. Rheede speaks of castor as cultivated in Malabar, especially in sandy situations. Loureiro
CULTIVATION.

India exports the Oil.

Cultivation.

VARIEITIES AND CULTIVATED RACES.—Botanical writers allude to the multiplicity of forms that exist as proof of the antiquity of cultivation. Müller (in De Candolle, Prod., xv., pt. ii., 1016–21) forms sixteen varieties or rather cultivated states that emerge from the one to the other, but which are often agricultural forms of considerable value. Roughly, these have been grouped by most writers under two great types—(a) a tall bush or small tree of perennial growth, usually planted as a hedge or in lines through the fields where it affords desirable shade to other and more valuable crops. This gives a large seed with an abundance of inferior oil. (b) The other, an annual plant sometimes grown as a pure crop, though more frequently in mixed cultivation. It gives a small seed, the better qualities of which by an expensive and more careful process of expression afford the superior qualities of the oil of commerce, some of the finer grades of which constitute the medicinal oil of European pharmacy. The former, from its being extensively used in India for illuminating purposes, is often called "Lamp Oil," but it also finds a place as a valuable lubricant.

Frequent mention is made, by writers on this subject, of a third important grade, namely a castor which by special selection has come to yield a seed that contains no poisonous principle, the oil of which is edible. Smith (Contr. Mat. Med. China, 1871, 56), for example, says that a "species or variety of Ricinus is said to have smooth fruit and to be innocuous." In Ahmadabad I collected (in a garden) a perfectly smooth-fruitcd form, the leaves of which were suffused with a white fatina that gave them a remarkable glossy appearance. I was told the oil of that plant could be used in cookery.

Edible Forms.

Bengal. —Mukerji (Handbook Ind. Agr., 1901, 276–86) says that cultivation is chiefly in the Patna and Bhagalpur Division. There are three forms grown—a small, a medium, and a large-sized plant. The first and last are sown in May to July and grown with some bhadoi crop. The seed is ripe in January and February. The winter variety is sown in September and gathered in March–April. This yields a larger proportion of oil than the bhadoi crop. On devarah lands the cost of cultivation is little and the yield large. Red soils situated at the foot of the hills are specially chosen, but it is an exhausting crop, and should not be grown more frequently than once every five or six years. It is never irrigated, all the cultivation deemed necessary being a ploughing between the rows of plants to keep the weeds down. Picking usually takes place from the seventh to ninth month after sowing. When grown with other crops the yield of cleaned seed per acre is about 250 lb., and when grown by itself, 500 to 900 lb. It is generally held that the large-seeded varieties yield the best ordinary lubricating and lighting oils, and that the small-seeded afford the finer grades, especially those used for medicinal purposes. [Cf. Banerjei, Agr. Cuttack, 1833, 88–9: Roy, Crops of Beng., 1906, 84–6.]

Assam. —Basu, writing on the possibility of castor being grown in conjunction with indigo and tea, says that in the Assam valley it is never grown for its seed, but always for the leaf, which is used for feeding the eri silkworm (p. 1005). There are two varieties of the plant (a) the era and (b) the Bengali era. The former is indigenous and the latter introduced—a taller and stouter plant.
SUPPLEMENTARY TO INDIGO

Generally the crop is allowed to be self-sown, and is found in small patches in the gardens of those who rear the silkworm. The seed is allowed to shed and run waste, but occasionally careful people collect and sell it. The plant is found everywhere in Assam, though much less abundant in the Surma valley. It is also grown by certain of the hill tribes, such as the Garos, Mikirs, Kukis, chiefly also for rearing the silkworm. Hindus do not engage in the production of eri silk, and its traffic is unimply in the hands of the Kacharis and Mechis in the north of the Kamrup, Goalpara and Darrang districts, and accordingly the plant is most prevalent in the tracts of country occupied by them. But it is nowhere a regular field crop. No oil is extracted from it in Assam. In Tezpur and the Khasia and Jaintia hills, experiments were conducted, but the crops were destroyed by insects to which the plant is peculiarly prone, hence the opinion that when grown in large quantities it is a precarious crop (Physical and Political Geog., Assam, 37).

United Provinces.—In the recent inquiry into castor as a possible supplementary crop with indigo, Mr. Moreland observed that he was unable to say if it would pay, since a rabi crop is usually taken after indigo, and this could not be the case were the land occupied with castor. So far as known, it is never sown mixed with indigo. Moreover, indigo does not require nitrogenous manures, so that the cake would have no special value to the indigo planter. Subsequently (in 1903) Mr. Madi (Assistant Director of Agriculture) wrote a note which affords full particulars regarding the methods of cultivation, harvesting, extraction of oil, cost of cultivation, and diseases. It would appear to be grown all over the provinces, on almost every kind of soil, though chiefly on rich loams. It is generally sown as a subordinate crop in the rainy season with bajra, arhar, jwar or cotton, and, at the beginning of the cold season, with gram, wheat and barley. It is not uncommon as a hedge to sugar-cane fields, being in that case sown in March or April. It is seldom raised alone to any extent, except perhaps in Allahabad, where the khadar lands, on the banks of the Jumna, are often devoted to it. Castor is also largely used as a first crop on newly laid out gardens, perhaps to secure shade for young trees, for which purpose it is also occasionally grown by market gardeners.

In the kharif time a furrow is thrown up parallel to the sides of the field, and seed cast into this at a distance of every 3 feet. By the return course the seed is covered over. This system is carried throughout the field, the furrows being 6 to 10 feet apart, and when the sowing of castor is thus completed a higher ploughing is given over the entire field and the chief crop sown. Occasionally the castor is cultivated on the ridges that separate the water-beds, in irrigated land, and in that case, as also when sown as a hedge to fields, the seed is usually dibbled by hand.

The crop ordinarily takes eight to twelve months to mature. The small-seeded varieties ripen earlier than the large. The crop sown in March or April along with sugar-cane takes the full twelve months, while that sown after the rainy season is harvested in ten. The plants begin to produce ripe fruits in seven or eight months, and picking thus commences about January and continues till April. Mention is often made, in connection with Oudh, of the existence of a form with dark-brown seeds that is specially rich in oil.

The fruits are collected and stacked in the corner of a house, and covered over with straw or cloth. After six days the capsules soften and the shells decay. They are then exposed to the sun for two days and when well dried the shells split open, or if they do not open naturally they are beaten with a mallet until the shell separates from the seed. The fruits of the larger forms are buried in a pit excavated in the dung-heap, and the
mouth closed in with straw. After a week the fruits are removed from the pit, and the shells separated from the seeds. In some parts of the country the bunches of fruits are for some time then exposed to the sun.

A vigorous plant yields as much as 8 to 10 seers of seeds in a season, but those grown as hedges do not usually yield more than \( \frac{3}{4} \) to 2 seers a year—the flowering being hindered by a deficiency of light and air. Usually the plants are cut down after yielding their crop, but when grown in gardens or near the homesteads they may afford a second or even a third crop in succeeding years, but in that case they are cut down each year to within two feet of the ground, the result being that they throw out numerous branches and give a large crop, though with an inferior quality of seed. In the third year the crop is poor both in quantity and quality. The average yield for an acre is 8 to 12 maunds the first year and 12 to 18 maunds the second when grown pure, or 4 to 6 maunds as a mixed crop. The produce sells at about Rs. 4 a maund.

The strongest and largest stems are used as timber (rafters) for thatching, and are also made into pokers for sugar-cane-boiling furnaces. The dried stems and husks are used as fuel or converted into charcoal and worked up in fireworks. The green leaves are eaten by cattle with apparent relish, and are believed to increase the flow of milk in cows and buffaloes. The cost per acre of pure cultivation is Rs. 24–2–0. If the acre produces 10 maunds, sold at the low average of Rs. 3 a maund, and allowing Rs. 5 as the price of the stems, fuel, etc., obtained, the balance over cost of production would show a net profit of Rs. 10–14–0.

Mr. Hadi mentions several caterpillars which eat the leaves and young shoots; an aphid which does much damage to the flowering shoots and young leaves; white ants which do much harm—in fact the castor-oil plant is more subject to their depredations than is any other regular crop; lastly, castor is much injured by frost. [Cf. Dutchie and Fuller, Field and Garden Crops, 1883, pt. ii., 38–9, t. 43; Maxwell-Leffroy, Mem. Dept. Agri. Ind., 1907, No. 2.]

**C. Prov.**

**Central Provinces and Berar.**—There are two varieties ordinarily grown—(a) large-seeded, raised as a rainy season crop; (b) small-seeded, grown as a cold-season crop. Some few years ago (1899–1900) an estimate was made of the area under both crops, and it was then found the total came to something like 67,845 acres. It is included in official statistics under the heading of "Other Oil Seeds," which in the kharif season of 1905 occupied 262,477 acres, and in the rabi 85,188 acres. The districts of chief production are Betul, Raipur and Bilaspur. The large-seeded plant usually occupies waste or fallow patches in cultivated land. Any kind of soil suits it so long as it is well drained. The small-seeded variety is sown as a regular field crop in the month of September, about 16 to 20 lb. of seed being required to the acre. Sandy loams are preferred, and black cotton soil does not suit it. The seed is sown with a drill plough. One weeding is considered desirable when the plants are about 6 to 12 inches high. The crop is harvested in March as the pods are found ripe enough. The outturn is about 500 to 600 lb. per acre of cleaned seed. The seeds usually sell at 20 lb. per rupee. The oil is manufactured locally to but a small extent, to meet the demands as a lubricant for cart-wheels and preservative for leather. [Cf. Sly, Note, 1901.]

**Panjáb.**—The plant is nowhere systematically raised as a crop in the Panjáb, but exists (mostly self-sown) on embankments near canals, especially in Jhelum and Gurgaon. It is mentioned as abundant on the Jharsa and Raisina Bunds. The people pay no attention to it nor make any use of its seeds. Mr. J. H. Burkitt contrasts the castor-oil plant of Baroda with that of the Northern Panjáb and Kangra, and adds that the latter is different from the ordinary form of the plant. The oil-mill at Lahore manufactures approximately 30,000 cwt. of this oil a year, the seeds being procured mainly from the United Provinces. An oil-mill has recently been opened in Delhi, and a demand for the seed thus exists that may
RABI AND KHARIF CROPS

lead to extended cultivation. The oil is largely used for lubricating cold machinery and as an illuminant in railway carriages, hence most of the Railway Companies in India manufacture their own oil. It is supposed to give a clear light, to be highly economical since it burns slowly, gives little smoke, and does not generate heat sufficient to make it dangerous. Aitchison (Afghan. Delim. Comm., 1885; also Notes on Products, etc., 1890, 175) says the plant is cultivated along the banks of irrigation channels and margins of melon, cotton and tobacco fields, the seeds being collected to afford an illuminating oil. The seeds are crushed among cotton-wool, and the wool, saturated with oil, is subsequently, as required, made up in the form of tuers (maluk).

Bombay and Sind.—In 1899-1900, 44,094 acres were sown and 25,265 matured a crop—in Bombay proper, none having been recorded for Sind. In the following year, 65,646 acres were under the crop, but no mention was made of the proportion that was non-productive. In 1901-2 the cropped area was 109,475 acres, and in 1902-3 it stood at 119,049 acres. The following year it had declined to 94,257 acres; in 1904-5 there was a still further shrinkage, namely to 72,599 acres, but no mention of a Sind production, and in 1905-6 to 64,878 acres with 454 acres in Sind, practically all in Thar and Parkar. Mollison (Textbook Ind. Agr., iii., 105-8) says both perennial and annual varieties of the plant are met with in India. The annual forms are rabi crops in Bombay Presidency, and the plants are very much smaller than the perennial, which are kharif crops. The latter grow with great rapidity, and a year’s growth produces a tree 15 to 20 feet high. The foliage, branches and stems, according to variety, may be bright pale green, or green tinged with red, bright shining red, or bronze purple. Forms with the last-mentioned description of foliage are often grown as decorative plants in gardens. Mollison also states that the seeds vary in size and markings. “One Bombay variety has large seed, black in colour, with tiny specks of white. The perennial varieties are chiefly grown along irrigation water channels, on the borders of sugarcane and in highly cultivated market garden land, and a plant soon gains the dimensions of a tree.” The seed is sown, as a rule, about July. The shade which the perennial castor affords to ginger, turmeric, sugar-cane and other such crops is often valued. Perennial castors are easily cultivated and readily escape from cultivation, and consequently are often found wild in many localities.

“The plant does best in deep free working soil. The very best crops in the Presidency are produced on the bditha (alluvial) soils which fringe the course of the Tapti in Surat.” “In the sandy goradu soils of Northern Gujarât, a sprinkling of castors is usually found in the subordinate mixture (kathol) of cereal crops sown in kharif season.” “The rabi crop (a comparatively dwarf plant) requires soil of different character. A retentive clay soil or the soil of moisture-holding rice beds is suitable. On black soil the rabi crop is generally sown mixed with tuver, til or with gram, and this mixed crop is generally the sole crop of the year. In this case the land is well followed during the rains, and the mixed seed is sown in September. In rice-beds, castors and ed or castors and gram are second crops sown in October or as soon as possible after the rice is removed.”

Castor has been grown alone on the Nadiyal Farm, and the best outturn obtained, Mollison observes, was 1,390 lb. of beans per acre; and this was in a specially favourable year. The kharif (perennial) crop is very hardy, especially in fairly deep soils. It, however, does best on rich garden land freely manured and watered. Mixed castor and ground-nut is a characteristic kharif crop. An experimental crop of this nature at the Surat
THE CASTOR-OIL PLANT

FARM yielded 767 lb. castor bean per acre, worth Rs. 43-14a., and a good ground-nut crop with castor might yield in addition 2,500 lb. nuts per acre.

**Madras.**—The Madras Board of Revenue unofficially furnishes the area under castor for the five years ending 1900. It may be useful to review the figures in question. The area under the crop might be regarded as shrinking. In 1895-6 it occupied 751,173 acres, and in 1896-7 it was produced from 782,135 acres, but from that date it would almost seem to have declined, until in 1899-1900 it was returned at 600,214 acres. The districts of greatest production are Anantapur, 128,476 acres in 1895-6 and 74,422 acres in 1899-1900; Bellary, 111,599 and 90,227; Cuddapah, 110,091 and 87,023; Kurnul, 94,517 and 65,924; Kistna, 91,325 and 80,804; Nellore, 50,880 and 42,729; and Coimbatore, 39,470 and 34,567; the figures shown indicating the acreage in the years in question. The returns for the year 1905-6 show the area to have been 380,100 acres, or 32 per cent. less than the average of the ten years previous, which came to 563,100 acres; and the chief production was in the Deccan.

Francis (Gaz. Bellary, 1904, 111) describes a method of grinding the seeds which prevails in that district. A machine is used like that commonly employed for making mortar, and consists of heavy stone wheels dragged round by bullocks in a circular stone-lined channel in which the seeds are placed. The paste so resulting, he adds, is boiled with water and oil rises to the top and is skimmed off. The stench caused is, however, most offensive, and the cake obtained is used as the fuel for roasting the next batch of seeds. *Cf. Shortt, Man. of Ind. Agri., 241-5; Castor-Bean Crop, issued by Board of Rev., 1899-1905.*

**Burma.**—The Director of Land Records observes: “There is no trade in castor-oil by land or by sea, except that imported as medicine or in a semi-crude state for lubricating purposes. The plant grows wild over a large area in Upper Burma.” “The plant is not cultivated in any part of the province.”

**EXPRESSION OF OIL.**

It has still to be confessed that the report written by Col. Hawkes, in 1853, is the only authoritative statement that has appeared. Hooper (Rept. Labor. Ind. Mus. (Indust. Sec.), 1903-4, 26-7) gives certain practical results. Two samples of Nairobi (British E. African) seed were examined—the larger form yielded 47·35 per cent., the smaller 43·35 per cent. of fixed oil by ether extraction. Dubard and Eberhardt obtained an average of 40·19 per cent. with East Indian castor seed, and by the ordinary crushing and heating with water about 37·40 per cent. of oil is extracted. Leather (Mem. Dept. Agri. Ind., 1907, i. (Chem. ser.), 32-5) gives the results of numerous examinations.

**Bengal.**—N. G. Mukerji remarks that there would appear to be four methods of extracting the oil practised by the people of Bengal. (1) The seeds are crushed in a screw-press with horizontal rollers and the resulting pulp pressed in gunnies. The cold-drawn oil thus obtained amounts to 36 per cent. (2) The seeds are roasted, pounded in a mortar and placed in four times their volume of water kept boiling. The mixture is constantly stirred, and the oil skimmed off as it rises to the surface. (3) The seed is first boiled, dried for two or three days, then pounded in a mortar and boiled in four times its volume of water kept boiling, and the oil skimmed as in (2). Lastly (4), the seed is soaked overnight in water, ground in the morning in a gunny, and then squeezed within cloth till the oil has been obtained. It is generally stated that cold-drawing with proper machinery is the best and most profitable method. The kernels are pressed in gunny bags and the oil is thereafter bleached by exposure to the sun, which causes a sediment to precipitate. The oil is then filtered through vegetable charcoal and flannel bags. In some cases a fire is placed underneath the machine in which the
CALCUTTA AND MADRAS MILLS

bags are being pressed. This is said to increase the yield by 10 per cent., but it is believed some of the noxious properties of the seed are then liable to pass into the oil.

The castor-oil mills of Calcutta use up on an average close on 700,000 cwt. of seed, drawn mainly by the railways from the province of Bengal and from the United Provinces. The quantities obtained from the other provinces are inconsiderable. The large-seeded form, which they mainly use, comes from the provinces named, while the small-seeded is derived from Madras, being mainly imported by coastwise steamers. There were in Bengal 75 oil-mills that gave, in 1904, employment to 2,836 persons. These doubtless are mainly Calcutta mills, concerned chiefly, if not entirely, in the production of castor, and furnish the quantities of that oil exported from Calcutta to foreign countries. As compared with these figures, Madras had 24 oil-mills that employed 1,476 persons during 1904, but these are not by any means so largely castor-oil mills as is the case in Calcutta. The total of the oil-mills in all India came, in 1904, to 112, so that the Calcutta and Madras series represent by far the major interests in the traffic. During that year Bombay possessed only two oil-mills with 226 employees.

United Provinces.—Two different methods of extracting the oil prevail in these provinces. In one the seed is pounded and boiled, and in the other pressed in a mill. The former is the method which might be described as pursued by small growers and for domestic purposes.

The seeds are cleaned by various processes, roasted, pounded, and then boiled in water. The oil rises to the surface and by different contrivances is skinned off or decanted, and the boiling continued, the mixture being repeatedly stirred until exhausted of its oil, the last dregs rising to the surface as the fluid cools. The water mixed with the oil is next removed by reboiling until it evaporates; the impurities at the same time sink to the bottom, while the pure oil floats on the top and is decanted. The burji or professional grain-parchers are the persons who by caste are alone permitted to roast castor-oil seeds and prepare the oil by the above method when required for commercial purposes. All others would be outcaste were they to engage in the traffic, except for purely domestic necessities.

The extraction by pressing-mills may now be briefly described. About 15 seers are cleaned and husked by beating with a stone, the result being about 12 seers of kernel. That quantity is then placed in the ordinary wooden oil-mill. About one seer of boiling water is then added and the outlet of the mill plugged up until about half a seer of oil has been formed—or, say, after the kernels have been ground for 10 to 12 minutes. Meanwhile, also, the contents of the mortar are constantly heated by means of a burning torch, since heat facilitates the flow of oil. The oil that collects from the mill is removed, heated, and again poured back through the mill to help the further separation, and this is repeated until the cake produced has been exhausted. The whole of the oil is then boiled to drive off the water and cause the precipitation of the impurities. The oil produced under this method is regarded as superior to that obtained by the boiling process. The average yield is about 33 per cent.

European Machinery and Methods.—Here and there all over the country, more especially at the jails, castor-oil is manufactured by modern European machinery. Certain centres are even famous for this oil, such as Calcutta and Madras (in the latter Presidency more especially at Godavari, Kistna, Nellore and Coimbatore). But in Europe and America improved and expensive machinery has raised the standard of the oil as well as lowered the cost of production, the result being that the competition has told seriously on the antiquated methods followed in India as a whole (Capital, Jan. 24, 1894). It has, for example, been found unnecessary to husk the seed, since the husk neither absorbs oil nor imparts colour; and by using the whole seed, 41-93 per cent. of oil may be obtained by some of the newer and more satisfactory systems. These include a hydraulic press but dispense with crushing-rollers, kettle, moulding machine and cloths—economics that have effected a great saving on the older methods.

Industrial Uses.—The oil is largely burned, some few years ago more extensively than at the present time. It is believed to give a cooler and brighter light than other vegetable and mineral oils, and to burn more steadily. Twenty-five to thirty years ago, at most, every European resident in India, and all the wealthier Natives as well, employed either castor-oil or cocoa-nut oil exclusively for house illumination (see Illumination).
THE CASTOR-OIL PLANT

Oils, p. 812). The value of castor-oil as a preservative has long been known, and on that property depends its employment on leather goods of all kinds, also as a lubricant for machinery. It is frequently employed by the Indian dyers as an auxiliary in certain tinctorial results, and similarly by calico-printers. The ordinary Native oil is sold in the United Provinces at Rs. 10 to 16 per maund, the price of course varying with the quality, but the medicinal oil and the purer grades may fetch as much as Rs. 24 to 27 a maund. Medicinally the oil holds an important position, and the white seed is specially preferred for that purpose.

Turkey-red Oil.—This is a specially prepared oil used in mordanting alizarin-dyed fabrics and for dressing tanned leather. The extent to which the Indian manufacturers are using that dye may be judged of by the demand. A difficulty was long felt in turkey-red dyeing to obtain an oil that would diffuse readily in water. By the old process the fabrics and yarns to be dyed had to be soaked in oils for a week or more. By the use of a sulphuric acid or salt of soda the objects of the oil mordant may be attained expeditiously, and turkey-red dyeing has thereby been greatly simplified. Almost any oil may be employed, but Indian castor has been found the most suitable, and may be said to enjoy a monopoly in meeting this new and increasing requirement. It may be suggested that a profitable opening exists for the manufacture and exportation of turkey-red oil in place of having to import the supplies required by the Indian dyers. [Cf. Blount and Bloxam, Chem. for Engin. and Manuf., etc., 1900, 235-6.]

Castor Oil-cake.—The oil-cake is regarded as a good fuel, but it is never given as food to cattle. It is fairly largely used by cobblers for stuffing the soles of the shoes they make or repair. The cake is generally stated to contain the whole of the poisonous property of the seed, hence its not being used as an article of cattle food. It is, however, rich in nitrogen and therefore much in demand as a manure, especially for potato and sugar-cane. In some parts of India the cake, and even cheap castor-seed, are used in the manufacture of gas, which is treated exactly like coal-gas, and is in some respects superior to it. Where coal is scarce and expensive, this utilisation of castor is deserving of more consideration than has as yet been bestowed on it.

TRADE IN CASTOR SEED AND OIL.

Foreign.—It is significant that Milburn, in 1813 to 1825, should say nothing of the Exports of castor-seed from India, though he makes mention of a small traffic in the oil. Hawkes states that the average export of castor-oil during 1850-5 came approximately to 100,000 gallons. By 1878-9 the exports of the oil were 2,119,755 gallons, valued at Rs. 31,53,969, and of the seed 74,214 cwt., valued at Rs. 5,00,056. Ten years later these items were (1888-9): oil, 2,092,913 gallons, valued at Rs. 20,31,467, and seed, 585,769 cwt., valued at Rs. 31,28,741. The exports for the five years 1902-7 were as follows:—1902-3, oil, 2,073,573 gallons, valued at Rs. 24,68,222; 1903-4, 1,916,200 gallons, valued at Rs. 20,83,239; 1904-5, 1,632,106 gallons, valued at Rs. 16,43,982; 1905-6, 1,432,105 gallons, valued at Rs. 17,12,085; and 1906-7, 1,445,636 gallons, valued at Rs. 22,22,015. Similarly seed:—1902-3, 1,751,688 cwt., valued at Rs. 92,05,666; 1903-4, 1,566,838 cwt., valued at Rs. 69,19,562; 1904-5, 1,460,908 cwt., valued at Rs. 69,15,892; 1905-6, 1,298,624 cwt., valued at Rs. 78,66,786; and 1906-7, 1,505,059 cwt., valued at Rs. 1,14,16,925.

It would thus appear that since 1888-9 the quantity of castor-oil exported has declined by fully half a million gallons, but the price has considerably improved. The traffic in castor-seed, on the other hand, has very materially increased within the period indicated, namely from half a million to one and a half million cwt. These circumstances thus
seem to show that the Indian castor-oil mills are not advancing with the world's demand, an indication apparently of defective methods, or of want of capital and enterprise in keeping up with the improvements in production effected in Europe. This subject seems well worthy of serious consideration. India enjoys a distinct position of advantage in the production of the seed, and an export of so bulky and weighty a product could only be profitable through greater returns in the oil-production. The exports in oil go almost entirely from Bengal, Madras coming next with about a tithe of the Calcutta traffic. The countries to which exported may be best illustrated by the figures of 1905-6 in gallons:—To Australia, 293,677; to Natal, 255,528; to the Straits Settlements, 201,169; to the United Kingdom, 191,034; to New Zealand, 111,748; to Mauritius, 105,867; to Cape Colony, 92,070; to China (Hongkong), 68,392; to all other countries, the balance on the total of 1,432,108 gallons.

The expansion in the traffic of castor-seed has been remarkable. The record year was 1902-3, and since then the quantity has somewhat diminished, but in 1906-7 the price realised considerably improved. France formerly was the chief consuming country, but within the period named the demands of the United Kingdom have greatly increased, as also those of Belgium, Italy and Germany, while France has fallen off materially until it occupied in 1904-5 the third place, and in 1905-6 the second place among the receiving countries. Bombay is the chief exporting province: out of the total of approximately 1½ million cwt., the western capital supplied fully one million, the balance having gone from Madras and Sind. The producing regions for this export traffic would appear to be the Nizam's Territory and Bombay Presidency, which between them supplied 99 per cent. of the total amount exported from Bombay town. The balance is derived from the Central Provinces and Berar. Hyderabad is the chief centre. The Karachi exports are doubtless Panjab and Rajputana castor-seed, since, as already shown, practically no castor is grown in Sind. Bengal exports no castor-seed.

**ROPTES AND CORDADE.**—Many fibres are used for this purpose by the agricultural communities and hill tribes of India. Rural people are never, in fact, at a loss to find a bark or twig that may be extemporised into a fairly strong green string, quite suitable for tying bundles or even

923
ROPEs AND CORDAGE

repairing cattle-yokes. And many such plants are often utilised in the systematic preparation of the ropes offered for sale at the village shops or market-stalls. More rarely they are specially cultivated, in small plots or strips through the fields, as hedges on the borders of fields or by the water-courses and creeks. It might in perfect fairness be said that many of the discoveries regarding the fibrous resources of India were the outcome of the demand for serviceable ropes to be substituted in the British and Indian navies for Russian hemp. Roxburgh, the great pioneer in economic botany, wrote a special report of his experiments and discoveries (see Cannabis, pp. 253–4; also Linum, p. 722). This was followed by many other publications (Royle, Fibrous Plants, 1855, 19–26; Baden-Powell, Pr. Prod., 1868, 476–7; Gee, Monog. Fibrous Manuf., 11–3). These and such-like works give numerous details of the indigenous fibres and the local methods pursued in their utilisation. The reader should, therefore, consult the articles under the following rope and cordage plants:—

**Rope Manufacture.**

The Indian rope manufacturers who prepare cordage and rope by European machinery employ a comparatively small number of these fibres. They obtain local supplies of coir, jute, san-hemp, cotton, and Deccan-hemp, but as a rule import agave and sisal, hemp (Russian), and Manila. India has recently begun to grow Agave on a large scale, and the local production, if it has not already checked the imports of that fibre, may shortly be expected to do so. The production of Manila hemp cannot be said to have been quite so successful. Recently attention has been drawn to the possibility of using linseed stems (flax), in the production of cheap fibre to be used up in the growing demand for cordage as “binders.” One of the jute-mills of Calcutta made the attempt some few years ago to contest the large Indian market for cheap and neat European-made string, by producing various qualities of cordage, done up in balls after the familiar fashion and in various colours. Jute rope is also, to some extent, made at the rope-eries, and cotton ropes have for long been used by the tent-makers as being more serviceable for that purpose than any other class of ropes. The other rope fibres of the above enumeration are almost exclusively employed by the people of India locally, and of these perhaps few are more important or more extensively employed, especially in North India, than munj, and in South India than coir. For fishing-lines and extra strong and
FAVOURED BY THE EMPERORS

fine cordage, the fibres in most general use are Bauhmeria, Calotropis and Crotalaria.

Trade in Ropes and Cordage.—The factories and rope-works that give employment to less than 25 persons are not recorded in official statistics. In 1901 there were 11 rope-works that gave employment in all to 2,538 persons; the year following, the figures were 12 rope-works and 2,814 employees; in 1903, 14 rope-works with 2,535 employees; and in 1904, 19 works with 2,954 employees. Of these rope-works 12 were in Bengal and 6 in Madras, one being recorded in Burma.

Imports.—The rope and cordage brought to India in 1876-7 were valued at Rs. 2,60,781; in 1886-7 at Rs. 3,22,940; in 1896-7 at Rs. 4,34,724; and during the five years 1902-7 were, in 1902-3, Rs. 6,29,703; in 1903-4, Rs. 5,90,380; in 1904-5, Rs. 6,32,651; in 1905-6, Rs. 6,75,798; and in 1906-7, Rs. 6,87,048. These do not, however, include jute rope and twine, the imports of which seem to be increasing. In 1900-1 they were valued at Rs. 17,722; in 1903-4 at Rs. 30,620; in 1904-5 at Rs. 26,434; in 1905-6 at Rs. 41,271; and 1906-7, Rs. 37,927. The bulk of these imports come from the United Kingdom, the next most important country of supply being China (Hongkong), and following that, the United States of America. The receiving provinces are Bombay and Burma, which usually take (in equal proportions) five-sixths of the supply, the next most important province being Bengal.

Exports.—India also exports rope and cordage, the supplies in 1876-7 having been valued at Rs. 2,65,603; in 1886-7 at Rs. 2,93,191; 1896-7 at Rs. 5,30,959; and during the five years 1902-7 the exports were—1902-3, Rs. 6,96,087; 1903-4, Rs. 6,18,109; 1904-5, Rs. 5,67,013; 1905-6, Rs. 6,48,099; and 1906-7, Rs. 7,03,779. Of these exports by far the largest quantity goes to the Straits Settlements, followed by the United Kingdom, Cape Colony, Arabia, Persia, Siam and Turkey-in-Asia. Of the exporting provinces, Bengal comes first, having supplied in 1906-7 one-half of the total exports, the next province of importance being Madras.

ROSA, Linn.; Fl. Br. Ind., ii., 363-8; Gamble, Man. Ind. Timbs., 1902, 318-9; Rosaceæ. A genus of erect or climbing shrubs, comprising about thirty distinct species with numerous cultivated sub-species and varieties. All are known by the vernacular generic name gulab, and indeed such other vernacular names as do exist are used indiscriminately for the various species. In spite of this fact, India has many both wild and cultivated roses. Rashid-ud-Din, in the 14th century, spoke of Gujarat, where the inhabitants were rich and happy and possessed no less than seventy different kinds of roses. Baber (Memoirs, 1519, 341) tells us that he never lost an opportunity of planting roses (1526). The Emperor Jahangir (Memoirs (Price, transl.), 1605, 14) speaks of Hindustan as possessing every sort of rose, particularly the musk and damask. It is, therefore, a curious circumstance that Fryer (New Acc. E. Ind. and Pers., 1675, 104) should have spoken of Surat as a place where roses would grow if they would but cultivate them. The most important Indian roses economically are the following, in alphabetical sequence:—

R. centifolia, Linn. The Hundred-leaved or Cabbage Rose, gulab, goldâp, troja, paninir, mavav, etc. A native of the Caucasus and Assyria, but cultivated in India from ancient times. This is said to be the chief rose cultivated in Persia for the manufacture of attar and rose-water, but in India the next species is the one most used for that purpose.

925
RUBIA CORDIFOLIA

ATTAR OF ROSES

Damask Rose.

R. damascena, Mill. The Damask, Bussora, or Persian Rose, gulah, subrub, irjappi, etc. Perhaps the commonest Indian garden rose. In India, attar of roses is said to have been first discovered by Nur-i-Jahan Begum, in 1612, on the occasion of her marriage with the Emperor Jahangir. In English commerce attar of roses began to be recognised only in the beginning of last century. The attar imported by Great Britain is dured in Bulgaria and Germany. The Indian product is consumed in the country, and is apparently not exported. The chief seat of the industry is at Ghazipur on the Ganges, where distilleries have existed for fully two centuries. The following information is abstracted from the account by Jackson (Journ. As. Soc. Beng., 1839, viii., pt. i., 411-4). The gardens where the roses are cultivated are let out annually by their owners at about Rs. 5 per bigha for the land, and Rs. 25 per bigha for the bushes, about 1,000 of which go to a bigha. The expense of cultivation amounts to about Rs. 8-8 per bigha, and 1,000 bushes should yield one lakh of roses, which are sold to the distillers at from Rs. 40 to Rs. 70 per lakh. The roses flower in March and continue throughout April. In the early morning they are plucked and carried to the distillers. The distilling apparatus consists of a copper or iron boiler with a large body and narrow neck, united by a bamboo tube with a long-necked vessel or receiver, called a bhuska. The boiler is let into an earthen furnace, while the receiver is kept in a handi of water, which is changed as it gets hot. The boiler is charged with the roses, over which a sufficient quantity of water is poured and distillation is then proceeded with. The rosewater should always be twice distilled, the water from the first distillation being used to pour over the roses for the second. The distilled rosewater is then taken from the receiver, placed in a glass carboy and exposed to the sun for several days to become ripe. The mouth of the carboy is then covered with cotton, over which is put a coating of moist clay, to prevent the scent from escaping.

To procure attar, the distilled rosewater is placed in a large metal basin which is protected by wetted muslin to exclude insects and dust. This vessel is then let into the ground, which has been previously moistened with water, and allowed to remain for the night. The cooling causes a little film of attar to form on the surface of the rosewater, and this is removed in the morning and placed in a small phial. The first few days' distillation does not procure such fine attar as is obtained afterwards (see p. 821).

Much of the rosewater of India is adulterated with water before being sold, and indeed the attar can never be obtained pure, since it always contains sandal-wood oil. Sandal-wood chips are very generally added to the flowers before they are distilled. This was mentioned by Engelbert Kaempfer in connection with Persia so long ago as 1682. Gilgemeister and Hoffmann (Volatile Oils, 425, 423-30) state that as far back as 1787 Pollier observed in Kashmir that the Indian grass (P Cymbopogon Schoenanthus, p. 461) was added to the roses for distillation. This grass does not, however, appear to be used in India for that purpose. The principal utilisation of attar is in perfumery and the manufacture of snuff and soap (rose-soap) (Alex. Watt, Art Soap-making, 1901, 149). In India it is largely employed by Natives at weddings and festivals. The best bazar attar is said to be sold for Rs. 10 per tola down to Rs. 2 for the inferior sorts. In the trade statistics, one or both of the above substances must be returned under either Essential Oils or Perfumery, details of the trade in which will be found under these headings.

Indian Madder.

RUBIA, Linn.; Fl. Br. Ind., iii., 202-4; Prain, Beng. Plants, 1903, i., 580; RUBIACEAE. A genus of erect, diffuse or climbing herbs, of which the most important economically are the Indian and European Madders.

R. cordifolia, Linn. The Indian Madder, manjít, manjû, majõtê, majõti, dandû, kukarpâli, modar, shevalli, tâmra-valî, man-chettê, etc. A herbaceous creeper, throughout the hilly districts of India, from the North-West Himalaya... 926
EUROPEAN Madder

Rubia TINCTORUM

eastward and southward to Ceylon. It is a very variable plant, but there are two easily recognised primary forms:—(1) cordifolia, proper, with leaves five, rarely three-lobate, veins impressed and surface rough or hairy; (2) obtusifolia, leaves three, rarely five-lobate, veins not impressed and surface smooth. The latter is the richer in madder dye-principle.

Manjít root obtained from this plant was formerly much employed by the Natives of India in dyeing coarse cotton fabrics into various shades of scarlet, coffee-brown or mauve. It has been largely displaced by the tar dyes, but is still employed for special purposes or in remote localities. The method of dyeing practised is much the same all over India, the colour being produced by steeping the cloth in an infusion of the stem or root-chips, subsequent to being mordanted with a solution of alum. In former times madder was considerably employed in Native medicine, but to-day its uses are restricted to a colouring agent for certain oils. The trade in madder has for years been gradually declining, due to the substitution of artificially prepared alizarin and other aniline dyes. The imports of madder and manjít into India amounted in 1885-6 to a value of Rs. 2,02,038; in 1889-90 to Rs. 29,488; in 1900-1 to Rs. 10,562; in 1904-5 to Rs. 3,784; in 1905-6 to Rs. 11,305; and in 1906-7 to Rs. 5,405. The principal supplying country is Persia, and Bombay the importing province.

The exports have almost disappeared, though small quantities still are re-exported, viz., in 1904-5, 249 cwt., valued at Rs. 3,277; in 1905-6, 211 cwt., valued at Rs. 2,538; and in 1906-7, 99 cwt., valued at Rs. 1,500. [Cf. The Bower Manuscript (Hoernele, tranal.), 1893-7, 104, 107; Milburn, Or. Comm., 1813, ii., 218; Pharmacog. Ind., ii., 231-2; Banerjé, Agri. Cuttack, 1893, 200; Ann. Rept. Ind. Mus. (Indust. Soc.), 1894-5, 26, 34; Lawrence, Valley of Kashmir, 1895, 68, 92; Monographs, Dyes and Dyeing:—Duncan, Assam, 1896, 44, 45; Hadi, U. Prov., 1896, 78; Banerjé, Bengal, 1896, 25; Russell, Cent. Prov., 1896, 7, 17-8; Rept. and Prog. Coll. Ind. Mus., Calc. and Imp. Inst., 1893-6, 71-3; Imp. Inst. Tech. Repts., 1903, 211; Hooše, Rept. on Szechwan, China, 1904, No. 5, 42-3, 48.]

R. sikkimensis, kars. The moyum. A handsome creeper of the Eastern Himalaya in Sikkim and Bhutan, at 2,000 to 5,000 feet, Mishmi Mountains of Upper Assam, Manipur and the Naga hills.

This species is the source of the brilliant red dye used by the tribes in the Naga hills and Manipur to dye both cotton and hair, the latter mostly human, employed to ornament their spears, etc. It is probable that the bulk of the madder plant of Assam is derived from this species, and that a considerable portion at least of the dye exported from Sikkim may also have the same origin. [Cf. Wätt, Cat. Calc. Inter. Ezthb., 1883, ii., 55; Perkin and Hummel, Colour. Principle of R. sikkimensis, in Trans. Chem. Soc., 1893; Duncan, Lc. 46-7.]

R. tinctorum, linn. European Madder, bacho, manyunth, rodang, etc. A climbing herb with perennial roots, cultivated in Kashmir, Sind and throughout Afghanistan; distributed westwards from Persia to Spain, cultivated or wild. De Candolle considers its original habitat to be west temperate Asia and South-East Europe.

The dried and ground roots formerly constituted one of the most valued of dye-stuffs, both in Europe and Asia, but the natural dye has been almost entirely replaced by artificial coal-tar derivatives. In the Memoire of the Emperor Baber (Leyden and Erskine, tranal., 148) we read that madder was largely cultivated in Ghazni and was carried thence all over Hindustan. To-day the plant is cultivated to a small extent, the best-known qualities of the dye (in European commerce) being Avignon, then Dutch, Alsation, Levant (or Turkish madder) and Italian. It is propagated either from seed or by root-cuttings. The roots are allowed to remain for three or even five years before being removed for use. In India, cultivation is carried on chiefly in Kashmir and in some parts of Sind. The Indian methods of dyeing employed with this species do not differ from those used with the indigenous R. cordifolia. Both in India and Europe the plant is employed as fodder for cattle, and in Sind camels are said to be specially fond of it. [Cf. Bentham, Rev. of Targioni-Tozzetti, in Journ. Hort. Soc., 1855, ix., 150-1; De Candolle, Orig. Cult. Planta, 1882, 41-2; Thorpe, Dict. Appl. Chem., 1899, ii., 480-6; Rawson, Gardner and Laycock, Dict. of Dyes, Mordants, etc., 1901, 223-7; Wiesner, Die Rohst. des Pflanzen., 1903, ii., 532-48; Goodwin (Queen’s Univers., Toronto), Madder and Indigo, reprint in Ind. Planting and Gard., Feb. 25, 1903, 203-4; Joret, Les Pl. dans L’Antiq., etc., 1904, ii., 348.]
SACCHARUM, Linn.; Fl. Br. Ind., vii., 118-21. A genus of perennial grasses containing twelve species, chiefly Asiatic. Five are indigenous to India, in addition to sugar-cane, which is extensively cultivated.

SUGAR AND SUGAR-CANE.—Though chiefly obtained from sugar-cane, sugar may be procured from many other plants, of which the following, arranged alphabetically, are those best known:—

Acer saccharum, the Sugar-maple of the Northern States of America and of Canada.

Arenga saccharifera, the Sago-palm of the Malaya, also met with in Burma and Orissa. In Java, palm-sugar is prepared from the sap in much the same manner as from the date-palm in India. Marco Polo (Travels, etc., 1290 (ed. Yule), ii., 235-6) alludes to the wine of Sumatra made from this tree (see pp. 91-2).

Beta vulgaris, Linn.; Fl. Br. Ind., v., 5. Beetroot and Mangold-wurzel, palang, palak or bitupalang; Chenopodiaceae. Is fairly largely cultivated in Indian market gardens as a vegetable, and the seeds are used as a cooling medicine. Much attention has also been paid to the possibilities of mangold as an article of cattle food. It is mentioned by Buchanan-Hamilton (Stat. Acc. Dinaj., 194) and described by Roxburgh, but there can be no doubt it is of quite modern introduction and has neither a classic nor any good vernacular names. Most of the Asiatic names given to it are special adaptations from the names of older and better known vegetables.

But for many years the subject of beet-sugar has in India become one of great moment. So long ago as 1863 Royle, in his address to the Royal Asiatic Society, commended the subject to the attention of Indian investigators and administrators as worthy of serious consideration. Numerous experiments have been conducted in India with the object of establishing beet cultivation as a field crop, but so far with indifferent results. In the Report of the Department of Land Records and Agriculture, Panjáb, 1899, it is stated that the Cawnpore Sugar Works Company had been able to produce beet up to the average on the Continent of Europe. Experiments were accordingly started in Hazara, but without much success. Mention is made of experiments at the Botanic Gardens of the Nilgiri hills. In subsequent experiments at Saharanpur the crop was considered fair, and at Cawnpore in 1899-1900 the opinion was formed that to obtain the best result beet should be sown about the middle of October. Leather gave the opinion that both in outturn of root and yield of sugar, beet can be successfully grown in North India as a rabi crop, provided suitable land and facilities for liberal irrigation be devoted to it. The Report of the Botanic Gardens of Saharanpur for 1900 gives a detailed account of further experiments. Fouldock, writing of the Nilgiri hills, says that with ordinary sugar-beet can be successfully grown. But the yield of sugar from all the Indian experiments rarely exceeded 12-10 per cent., while in some instances only 5-6 or even 3-3 per cent. were recorded. As a rule the roots grew too large, and in consequence the percentage of sugar decreased. A serious objection to beet cultivation is the necessity for deep ploughing, which the Indian cultivator is both unable and unwilling to perform.

P. V. Subbiah (Principal of the Agricultural School, Cawnpore) issued (Dept. Agri. U. Prov. Bull., 1901, No. 13) a complete review of all past experiences, and, commenting on that, Moreland observes, "It will be seen that attempts to make gur by the ordinary methods were complete failures, and it seems probable that this must be the case, as unrefined beet-sugar made in Europe retains certain organic matter which gives it an unpleasant flavour." It is, therefore, assumed that "if beet is grown it will be on the central factory system, the cultivator being provided with the apparatus and engines to be taken to the factory." [Cf. Mukerji, Handbook Ind. Agri., 1901, 388-9.]

Borassus flabellifer, the Palmyra Palm or brab tree of Bombay and Madras Presidencies. This is one of the sources of the substance known in Indian commerce as jaggery. Rheede (Hort. Mal., 1686, i., 11-13, tt. 9-10) alludes to the present species of palm as being tapped for its sweet juice (ras), but says nothing of its sugar. It affords much of the sugar of South India,
especially Tinnevelly. Buchanan-Hamilton wrote in 1807 that the jaggery of this palm was more esteemed in Mysore than that of the date-palm. It is also largely utilised as a source of sugar in Burra (see p. 170).

Caryota urens, the Indian Sago-palm or Bastard Sago, is the chief source of the palm-sugar of South Ceylon and to some extent of Bombay (see p. 287).

Cocos nucifera, the Coconuut Palm, is the species most extensively used in Madras as a source of palm-sugar. Garcia de Orta (1563) speaks of the sava or toddy which, fermented, yields arrack and vinegar, or from which, when thickened in the sun or by heat, they make jagra, the best kind of which comes from the Maldives. Rhede (i.e., 1–8, tt. 1–4) speaks of "jagra" (sugar) made from the juice with the aid of lime, the mixture being boiled until it thickens, when a red-coloured sugar is obtained (see pp. 302, 932).

Manna—some thirteen or fourteen plants in India are known to yield, under the parasitic influence of insects or otherwise, a sweet fluid called manna. This is regularly collected and, like honey, enters more largely than sugar into the pharmaceutical preparations of the Hindus (see Bamboo, p. 111, and Honey, pp. 128–9). [Cf. Garcia de Orta, 1563, Coll., xxxiii.]

Phoenix sylvestris, the Common Date-palm, is perhaps the most important source of palm-sugar in India. In fact, the plant is fairly extensively cultivated in Eastern Bengal as a source of sugar. In Mysore it is also important, more so than either the palmyra or the cocunut sugars (see p. 886).

Saccharum officinarum, the Sugar-cane—the subject of the present article.

Sorghum vulgare, the Sugar-Sorghum or impehe (see p. 1041).

Vitis vinifera, the Vine. According to Aitchison (Edinb. Bot. Soc. Trans., 190), also Le Mesurier (London to Bokhara, 133), the juice of the grape is used in Afghanistan to make syrup, and in Burma refined sugar.

Zea Mays, Indian-corn or maize, often yields sugar in its stem, like that of Sorghum and Saccharum (see p. 1138).

Many substances other than those enumerated are known to afford sweet fluids, but are for the most part utilised in the manufacture of alcoholic beverages or sweet sherbets only, while others, such as indigo-sugar, are at present put to no economic purpose whatever. The mahua flowers (see p. 118) and the pineapple-apple (see p. 69) are the best-known substances available in India from which a sweet juice may be prepared (if the grape be excluded from consideration), or which are actually utilised in the production of alcoholic beverages. Honey is largely traded in all over India. Halwa (a sweetmeat, much like "Turkish delight") is said to be prepared from camel's milk and honey, and is brought into India from Afghanistan and ports on the Persian Gulf.

Saccharum arundinaceum, Retz.; Fl. Br. Ind., vi., 119. This embraces the following:—S. ciliare, Anders., S. exaltatum (Munja) and S. procerum (Sara) of Roxb. It is the sara of the classic authors of India, and bears the following vernacular names—sara, sarkanda, sarkara, ramsar, sar, ser, munja, ikar, pati, war, palva kanda, darga, gondra, ponika, etc. It is met with throughout the plains and lower hills and distributed to China. In the Panjab it often covers large tracts of country and is frequently planted in lines or dividing hedges, especially in low-lying localities subject to periodic inundation.

History.—Sir William Jones (Sel. Ind. Pl., in As. Res., 1795, iv., 247–8) says:—"This beautiful and superb grass is highly celebrated in the Puranas, the Indian God of War having been born in a grove of it, which burst into flames; the gods gave notice of his birth to the nymph of the Pleiads, who descended and secluded the child, thence named Carticeya. The cásá" (kásá or kána) "vulgarily casía" (S. spontaneum) "has a shorter culm, leaves much narrower, longer and thicker hairs, but a smaller panicle, less compounds, without the purplish tints of the sara: it is often described with praise by the Hindu poets for the whiteness of its blossoms, which give a large plain, at some distance, the appearance of a broad river. Both plants are extremely useful to the Indians, who harden the internodal parts of the culms, cut them into implements for writing on their polished paper. From the munj, or culm, of the sara was made the manuñj, or holy thread, ordained by Menu to form the sacerdotal girdle, in preference even to the cusa-grass. For its use in the treatment of vinegar, see p. 110.

Manna is obtained from the leaf-sheaths; the blades are the sar or sara used in thatching houses and as a paper material; the contained flowering stem is the bind or vind; the panicle or flowering stem is the sikri, til or thiil, used in thatching boats, carts, etc.; sentha or kána is the lower, stronger portions of the
SACCHARUM OFFICINARUM

History

flowering stem, used in the manufacture of chairs, stools, tables, baskets and screens; and tilak, tilon or ghua are names that denote the flowers. Some of these names, such as munj and sara, have been supposed to denote the products of different species, instead of different parts of one and the same plant, hence has originated much of the confusion that prevails. Sara is used in paper-making and munj as a textile fibre. The much prized munj is strong, elastic and has a wonderful power of enduring moisture without decaying. It is extensively employed in the manufacture of cordage, ropes; the famed Delhi mats, and in the preparation of baskets, etc. Munj mats are reported to be proof against white ants, but are hard on shoe-leather, harsh to the foot and fatiguing when walked on for any length of time. These are largely produced in Allahabad, Agra, Delhi, and are traded in all over India, and within recent years have begun to find their way to Europe (see Mats, etc., p. 777). In the early spring the old grass is often fired, when shortly after a crop of young leaves is produced from the stools, which is much valued as fodder.

Kāns.

Vernacular Names.

Crystallised.

methus, produced in India, as ksha, karara, kus, kāns, kānsī, rara, jasha, padar, billu-gaddi, billu-gaddi, thešira kyn, etc., etc. (see p. 1122.) Is contrasted with S. aurantium in the above.

Throughout the warmer parts of India and Ceylon, ascending to 6,000 feet in altitude. Is most at home in damp low-lying land, where it throws up flowering stems often 12 feet in height. Is gregarious, the snowy white pubescence which surrounds the base of the spikelets rendering it a conspicuous feature of the vegetation when at all prevalent. It flowers soon after the close of the rains. Owing to its vigorous growth it is difficult to eradicate, hence often becomes a troublesome weed, especially in the tea plantations of Assam and Bengal. [Cf. Batchelor, Agr. Journ. Ind., 1906, i., pt. ii., 152-8.] The grass is large and coarse and is used mainly as a thatching material. The leaves, sheaths, etc., are twisted into rope and worked up into mats, but are inferior to munj for these purposes. As a fodder plant it is usually regarded as superior to the former species, and is specially valued for feeding buffaloes. The culms are also much more highly prized for the manufacture of Native pens. [Cf. The Bower Manuscript (Hörnle, transl., 1893-7), 96, 106, 122, etc.]

S. officinarum, Linn., Sp. Pl., 1753, 54; Fl. Br. Ind., vii., 118; Rumphius, Herb. Amb., 1750, v., 186-91, t. 74; McFadyen, in Hook., Bot. Misc., 1890, i., 93-115, t. 26; Rozb., Fl. Ind., i., 287; Köhler, Med.-Pflanzen Atlas, ii., 169; Hackel, Monog. Androp., in De Candolle, Monog. Phaner., vi., 111; Krüger, Das Zuckerrohr und Seine Kultur, 1899; Gra- mineæ. The Sugarcane, ukh, uk, us, ith, ik, ak, aku, ikhari, rikhu, serdi, sherādi, gannā, ghena, nai-shalār, kumād, kūshār, purī, cherukā, charkī, khābu, karumbā, karnīpa, tebu, keyan, kyan, etc., etc. The majority of these names denote the cane-plant, others doubtless the sugar. The selection given is, however, fairly representative of the names in current use in India. In the Malay Archipelago the cane is known as tabu and in China as kan-che, a word believed to be derived from the Sanskrit khandā, a name for sugar. As a cultivated plant cane is widely distributed in India and numerous very distinctive forms exist, some of them known from the earliest historic times, others introduced quite recently.

History.—The Sanskrit name for the plant is ukh, of which the modern corruptions are ith, ukh, and unkh. Mention is also directly made of the sugar-cane in the Atharvaveda (Bloomfield, transl., xli., 100, 277). The name sarKarā is similarly given by the very earliest Sanskrit writers for white sugar, and it originally denoted "grit" or "gravel," hence its special signification as crystallised sugar. The name khandā (an ancient name for sugar), the root of which means to crush, may be considered to denote sugar from the sugar-cane rather than from palm-juices, where no crushing in any form is pursued. By modern usage, however, it became restricted, like its English derivative "candy," to a special form of crystallised sugar—the sugar-candy (sarkar-khandi).
In the same way the word gua or gusta indicates a "mass" or "ball," hence its special application to thickened sap—the modern gur or raw sugar or molasses, as also the balls of sugar that were used as coins in village commerce.

The ancient name for Bengal is Gaur, a word supposed by some to have denoted the country of gur, and hence it has been affirmed that in Bengal originated the art of sugar manufacture. This seems highly improbable, ances gusta occurs in the classic works of India, prior to the Aryan conquests of Bengal. Lastly the name jaggery, which to-day is used with the special signification of palm-sugar or palm-molasses, is but a modern corruption of sacchara, first into the Malayal chakkara, then into the Portuguese jagara, jagra. Barboes (Coasts E. Africa and Malabar, 1518, 59) speaks of "the sugar of palms which they call sugara." João de Barros (Decadas de Asia, 1553, iii., lib. iii., cap. 7) mentions the jagara made from the coconuts exported from the Maldive. Caesar Frederike (1567) calls it giagra. Rheede, in the passage alluded to in connection with the coconuts, calls it "tagra," and Buchanan-Hamilton (Journ. Myntor, etc., 1807, i. 157-8; ii., 101; iii., 145-6, etc., etc.) uses the word jargory. A knowledge of tari wine seems over so much older than of sugar prepared from the same juice. Megasthenes (320 B.C.) alludes to the value of the tala trees to the people of India (Indika of Arrian (McCindle, transl.), 199; see also Malt Liquors, p. 757). But Eratothenes (223 B.C.) is perhaps alluding to sugar-cane when he tells us that "the roots" were sweet to the taste both when eaten raw and boiled. Lucan (a.d. 65) refers to the sweet juice expressed from reeds (terea arundo), Pavlus (Egista (Adams ed.), i., 246), in the 7th century, speaks of the sugar brought from "Araby the Blessed" as being less sweet than honey. Unmistakable reference is made to sugar-cane as cultivated on the shores of the Persian Gulf during the 9th century. "The crusaders found sweet-honeyed reeds in great quantity in the meadows about Tripoli, which reeds were called sucra." Galt, who published a history of sugar, says it is certain that in the year 1148 it was largely cultivated in Sicily and that the Venetians traded in it, but he adds, "I have met with no evidence that the Saracens carried it from India to Sicily." Sanutus, who wrote of 1306, observes that in the countries subject to the Sultan, sugar-cane was produced in large quantities, and that it was likewise carried to Cyprus, Rhodes, Sicily and other places belonging to the Christians.

The Greco-Roman world had a very distorted idea of the origin of sugar. It was a kind of honey obtained from canes or mambas. In Hebrew writings there is no indication of a knowledge of sugar, so that it was not cultivated in Arabia and Egypt prior to the Jewish captivity at Babylon. The Chinese do not appear to have known of sugar from very ancient times. Bretschneider says that he has not been able to discover any allusion to it in the most ancient books. It is first mentioned, he adds, in works that date from about the second century B.C. According to the Pent Sao, a man was sent, about 627 A.D., from China to Bihar to learn the art of refining sugar. Marco Polo (Travels, 1290 (ed. Yule), ii., 313) visited India, and gives full particulars of the coast towns of the south and west. Of Quillon, he says "their wine they make from palm-sugar." But Polo does not definitely mention sugar, or rather sugar-cane, until he reaches China. Of Pekin, he remarks, "enormous quantities of sugar are made," and this "brings many merchants who traffic about the Isles of the Indies." In a footnote, Sir Henry Yule explains that there is still a great deal of sugar grown and made about Fuchau; indeed all the fine Chinese sugar-candy is produced at Fekien. If, therefore, this reference to Chinese sugar denotes sugar-cane, it is the only one in Marco Polo's record of his great explorations that can be so interpreted.

In one chapter Polo alludes to Bengal, but it has been shown that he never himself visited Eastern India and that his notions of Bengal were so imperfect that the particulars he affords regarding sugar cannot be accepted as necessarily denoting an ancient knowledge. Ramusio (in his edition of Polo) says the Chinese were taught the art of refining sugar by some men from Cairo who happened to be at the Court of the "Great Can" (Purchas' Pilgrimes, iii., 101). Sir Hugh Willoughby (about 1554) speaks of "such number of Ingenios for sugar" seen near Pekin (Purchas, i.c. 270). Most of the 16th and 16th century travellers in China mention sugar as being so good and cheap. It is commonly stated that Vasco da Gama (who doubled the Cape of Good Hope in 1497) relates that a considerable trade in sugar was at that time carried on from Calicent—the then capital of West Indian commerce. John Leo makes a similar statement regarding Nubian
Saccharum officinarum

History

Sugar during 1500 A.D., and other travellers shortly after the time indicated discuss the sugar of India. Thus, for example, Varthéma (Travels, 1510 (ed. Hakl. Soc.), 163) explored the west coast and furnished many details of the trade and industries of Calicut. He gives a full account of its fruit trees, and says of the coconut that it is the best tree in all the world. He describes its wine and sugar and tells of the monkeys stealing the former. But he makes no mention of sugar-cane. Of a town in North Kanara, identified with Sedasevaghir (which he calls Bathacala), he observes that it possesses "a great quantity of sugar," but from the previous account of the Calicut sugar it may be presumed this also was palm-sugar. It is somewhat strange that García de Orta should make no mention of sugar-cane, and it is certainly most singular that Baber (Memoirs, 1519 (Leyden and Erskine, transl.), 326-7) should furnish many interesting details of the date, the coconut and the palmrya palms, but make no mention of the sugar prepared from them nor of the sugar-cane fields of India. He speaks of the juice of the palms being called tari, and of its being drunk both fresh and after it had fermented. But he admittedly describes only the plants and animals seen in Hindustan which were different from those of his own country—Ferghana and Bokhara. He accordingly apologises for having mentioned the date-palm, which was not confined to Hindustan. It has already been pointed out that Rheede, the earliest and even to-day one of the most accurate of Indian botanists, while describing and figuring

Bovynhans

should make no mention of its sugar, though he describes the sugar of the coconut; and even still more curious is it that he is silent as to sugar-cane. The Ain-i-Akbari (1590, Biochmann, transl., 69) fortunately gives us full particulars. "Sugar-cane, which the Persians call naishakar, is of various kinds, etc., etc." Linschoten has much to say regarding sugar (sura), but his reference to sugar-cane would appear to have confused it with bamboo (mambu, as he calls it), the old error that descended from the classic times of Greece and Rome, so that it is possible even Linschoten had not personally examined the plant. Thevenot (Travels in Levant, Indostan, etc., 1687, pt. iii., 26) mentions the cultivation of the sugar-cane in Surat.

There would seem little doubt that sugar-cane cultivation originated in Southern Asia, if not in India, but it has never been satisfactorily proved to have been met with in wild in India or anywhere else, and is accordingly known purely and simply as a cultivated plant. Loureiro would, however, seem to think it was indigenous to Cochin-China (Fl. Coch.-Chin., i., 52), but perhaps with no greater justification than the statement of its having been found wild in the Car-Nicobar island. The mention of sugar, by European travellers to the west coast of India, almost invariably denotes palm-sugar, and as that part of India was first reached and explored, it seems likely that an undue importance has been given to palm-sugar (see p. 151). It is, however, to say the least of it, very surprising that the early botanists who deal with the plants of India make no mention of sugar-cane. Thus, for example, Rheede (1698 A.D.) gives a brief account of one of the naked-seeded sorghums, but says nothing of its yielding sugar. Ruaphius (1750) tells us, however, that the white-seeded sorghums often have the stems so sweet that they are regularly chewed for their sweet juices, but adds that sugar is never made from them as from sugar-cane. In a further passage he gives full particulars regarding sugar-cane cultivation in the Dutch colonies, but ventures no opinion as to the home of the plant. Miquel, Hasskarl and Blanco make no mention of wild sugar-cane in Sumatra, Java or the Philippine Islands. Crawford tells us that he failed to find it in the Indian Archipelago. It seems fairly certain, however, that the Muhammadans were conspicuously identified with the extended cultivation of both cotton and sugar. After the Muhammadans, the Portuguese were perhaps the people most closely associated with the early distribution of sugar-cane cultivation. In 1419 it was taken to Madeira from Sicily (Puchaus' Pilgrimes, i., 5), and there would seem every reason for believing that this was its first appearance on the islands of the Atlantic. Sloane (Nat. Hist. Jam., 1707, i., 108-9), while describing sugar-cane and the manufacture of sugar, dwells especially on the necessity of adding an alkaline salt or "temper" to the boiling liquid, to facilitate the formation of the crystalline article. But although the story of the Muhammadan influence is generally accepted, it is somewhat curious that Browne (Hist. Jam., 1789, 129-33) should have regarded the plant as a native of the Canary Islands. He appears to have thought it existed there before its introduction by the Spaniards and the Portu...
guese to the mainland and islands of the west coast of Africa. From Madeira it apparently was taken to Brazil, but at a very early date, for Magellan speaks of finding it there in 1519 (Purchas, l.c. 34). From Brazil it was carried to St. Domingo and Barbados. Of the last-mentioned island, Ligon (Hist. Barbados, 1657, 84 et seq.) will be found to give a detailed account. He describes all the noteworthy fruits of the island, but of sugar-cane observes, "There is one brought thencefrom as a stranger, from beyond the line, which has a property beyond them all, and that is sugar-cane." He landed in the island 1647, and found sugar-cane cultivation but little understood, though the plant had been introduced from Brazil and an "Ingenio" for manufacturing the sugar had been set up. When he left the island in 1650 the manufacture had been greatly improved, and they had discovered the period necessary for the full maturity of the canes, namely fifteen months. They had also learned to manufacture "lump sugar," "but not so excellent as they make in Brazil." Towards the close of the 18th century the French colonists of St. Domingo carried the cane to Louisiana. These brief references to the West Indies may suffice to convey the opinion that it is there an exotic, and it may not be far from the truth to add that it was the necessity for labour in sugar-planting that gave origin to the slave traffic.

John Leo, who began his explorations of Africa and Egypt about 1492, describes the sugar of Morocco and of Egypt, which appears even then to have been made from sugar-cane. Similarly Richard Jobson describes the sugar-canes of Sierra Leone and Gambia in 1629. Forster (Pl. Eec., 1786, 77) speaks of sugar-cane as grown in Polynesia for the children: in Tahitian it is known as "To." It is recorded that the Otaheite cane was introduced into Trinidad and Martinique in 1782. The date when sugar (from sugar-cane) first reached England has not been definitely ascertained. We rest of its being carried from St. Lucua in Spain to Bristol in 1526. In 1503 two ships arrived at Camporee laden with Canary Island sugar, and a century and a half later the supply from the West Indies and Brazil might be said to have been fully established and become almost a necessity on every breakfast table in Europe. At the present day sugar-cane is grown throughout the tropics and sub-tropics, and even into the warm temperate tracts, especially in the West Indies, Mauritius, British Guiana, etc., and at Malaga on the Mediterranean coast of Spain. It requires a hot, moist atmosphere alternating with periods of dry weather. It rarely flowers and fruits, so that cultivation is almost exclusively by cuttings. These are called "plants," and usually consist of two or three upper joints of the cane, the severance being by a clean cut immediately below a joint.

Hughes (Nat. Hist. Barbados, 1750, 244-52, t. 23, f. i.) alludes to the flowering of the canes in Barbados, and gives full particulars of the cultivation and methods of manufacture pursued. But with regard to the fruting and the production of fertile seed, there is no definite record of this fact having been utilised for a century later. Rumphius says, "It never produces flowers or fruits unless it has remained several years in a stony place." Roxburgh remarks, "Where wild I do not know; I have never seen the seed." But in the West Indies, about 1858, it was recorded that seedling canes had been observed to spring up around the stems (or stools) of canes that had "arrowed" or flowered, from which circumstance it was believed and oft reiterated, that the sugar-cane actually did produce fertile seeds sparingly, though more copiously under certain climatic and soil conditions. [Cf. Joret, Les. Pl. dans L'Antiq., etc., 1904, ii., 206-9.]

**Varieties and Races of Sugar-cane.**—The diversity met with would appear to have been brought about primarily by selection of sports and variations as manifested in adaptation to environment; through the study of yield of sugar to the acre; the observation of freedom from disease, etc., as also by the direct cross-breeding of the stocks thus procured and matured. Leather defines a good cane as one which will yield 70 per cent. of juice in the mill, afford 15 per cent. or more of cane-sugar, and possess not more than 17 per cent. of glucose. In the Dictionary the effort was made to divide the canes met with in India into two great sections:—(a) Introduced Canes, and (b) Indian Canes. Without going into needless details regarding the various foreign canes known to be cultivated in India, the following particulars may be furnished:—

1. **Mauritius Cane.**—This appears to have been introduced into India from Mauritius.
Mauritius about 1838 (if not much earlier) and was so named in consequence, but is in reality the yellow-violet cane of Java. It is said to excel the red Bombay cane both in size and quality, and to yield one ratoon crop or sometimes two (when grown on rich soils), but as the roots get considerably above ground it requires subsequent surface dressing.

2. Otaheite or Yellow and Straw-coloured Cane.—This was introduced into India about 1840, and became widely distributed, especially in Eastern Bengal and Assam. It is unquestionably distinct from the Mauritius canes of many plantations. The leaves are broad, pale green and droop considerably, especially on nearing maturity. It shows a marked tendency to arrow, especially if grown under the influence of sea-breezes. It has not proved a success in India, however, as it demands the finest soils, the most thorough agricultural methods, and perfect protection; is withal very liable to disease and to the attacks of white ants. According to many observers it rapidly deteriorates in India.

3. Bourbon Cane.—This is by some persons supposed to have been originally discovered on the coast of Malabar, and from there to have been carried to Reunion, improved, and then returned again to India via the West Indies. By other writers both this and the straw-coloured Otaheite canes came originally from Madagascar, while still other writers affirm that the Bourbon cane is one and the same as that often called the Singapore.

4. Batavian Cane.—There are several distinct forms, such as the violet cane, of which Sir John Lefroy wrote in 1794, "The Batavian canes are a deep purple on the outside." Wray says the yellow-violet and purple-violet or Java canes, as also the transparent or ribbon canes, all belong to this type. The yellow-violet differs from the Bourbon and Otaheite in being smaller, less juicy, considerably harder, slower of growth and with the foliage darker and more erect. When ripe it is usually of a straw-colour with the rind thick and the pith hard, but its juice is rich and tolerably abundant. The purple-violet, on the other hand, is fully as thick as the Bourbon, and has the joints from three to six inches long. The leaves are darker green than the yellow-violet, and it yields a juice richer in sweetness than almost any other cane; but it is hard, difficult to grind, and affords but a low percentage of juice. The transparent ribbon-cane is of a bright yellow, with a number of blood-red streaks; its leaves are like those of the yellow-violet, but more erect. In Jamaica it is generally planted on light sandy soils, where no other cane will thrive.

It yields a fair quantity of juice of excellent quality. This cane was introduced into India (via Bourbon) in 1838, from which circumstance it came to be called "striped Bourbon." Mr. Kobus, who visited India in 1891 to endeavour to procure fresh stock for the Java plantations, recognised the paunda canes of India (the canes grown specially to be eaten, and not used in the manufacture of sugar) as identical with the canes grown by the Dutch for sugar manufacture. The ukh and ganha (the kinds specially grown in India for sugar manufacture) were previously unknown to Kobus, and he accordingly took back with him a large supply of these. It thus seems highly probable that most of the edible canes of India have been developed from imported stocks, such as those briefly enumerated above.

5. China Cane.—This is the Saccharum sinensis, which Roxburgh regarded as distinct from the indigenous canes of India. The distinction that he made has not, however, been upheld by modern writers, namely in the leaves being flatter and the margins more hispid. The flowering panicles, Roxburgh says, are ovate in general outline, with simple or compound verticillated branches. The Indian forms he separates as having panicles spreading, the branches alternate, decompound, and the corolla one-valved (instead of having the two valves on the same side, seen in the Chinese canes). These canes were introduced into the Botanic Gardens of Calcutta in 1796. Most writers, who experimented with the China canes shortly after their introduction, reported that they were hardy and prolific, not liable to attack by white ants nor jackals, and moreover able to withstand the hot weather better than the indigenous sorts. These opinions are vouched for repeatedly in the Journal of the Agri.-Horticultural Society of India, but it is feared that if the original stock of China canes survive to this day at all, the plants have very possibly been largely merged into the indigenous forms and their origin mostly forgotten.

6. Singapore Cane.—As already affirmed, the more important of these seem to be identical with some of the Batavian and Bourbon canes. Wray gives eight different kinds met-with in Penang, Singapore and Malacca. The prin-
principal is the Selangore cane, known as *tibbu bittong berabu* (= the powdery dark cane) or *tibbu cappor* (= the chalk cane) of Singapore and Malacca. These names are due to the presence of a large quantity of white resinous substance on the stalk. By many writers this is spoken of as the finest cane in the world. But in the Straits it is often called the China cane, because grown by the Chinese settlers in the Straits before the Europeans commenced cane-planting. The leaves are very broad and deeply serrated on the edges, very dark green in colour and firmly attached to the cane. The cane-itch is usually very prevalent on this plant. The *tibbu-liit* (or clay cane) seems to be identical with the Otaheite of most writers. The *tibbu tildir* (or egg cane) seems peculiar to Taune, one of the New Hebrides. The leaves are smooth and the stems bulge between the joints to such an extent as to have suggested its name. The leaves are shed as they ripen, and the stem becomes so brittle that it breaks readily. It is prolific and easily cultivated. The juice is copious and rich in quality. The *tibbu chiam* or *obat* is the black or medicine cane of the Malays. It is a small cane of a rich purple colour.

The red-purple cane of Singapore is generally accepted as the stock from which has been developed the red canes of Bombay. This is interesting in the light of the other suggestions and opinions which point to Bourbon and the straw-coloured Otaheite canes being identical, and to their having originated from Malabar. Thus the early European sugar-planters appear to have obtained their stocks from Malabar, Batavia, Madagascar and the Straits. Hence it may be added, in conclusion, that nothing has been discovered in philology, botany or history that seriously upsets the hypothesis that all the forms of sugar-cane emanated from a common species, which was very probably originally a native of India and perhaps also of the tracts adjacent to India.

7. Indian Canes.—It has been pointed out by Benson and others that foreign canes introduced into India rapidly manifest a decline in the percentage of sugar-yielding juice. The crop of cane continues high, but the merit in sugar-production declines. This fact has led naturally to greater faith being placed in the improvement of Indian stock than in the acclimatisation of foreign canes. Commenting on the Madras canes, Leather observes that "undoubtedly some of the cane which is at present grown in the Madras Presidency is second to none in the world." A movement has, therefore, been started to study the Indian canes critically by growing them side by side at test farms. Saiyid Muhammad Hadi, having devoted considerable attention to the study of the canes of the United Provinces, published a valuable work designated "The Sugar Industry of the United Provinces of Agra and Oudh" (1902), and assorted the canes there described and illustrated into three groups as follows:

**Group I. Ukh Canes.**—These are the most numerous and most extensively cultivated of all races. They are grown entirely for the production of sugar. The majority have a fairly hard, firmly adhering skin, which cannot be detached with a knife beyond the joints. Stems (canes) small, thin, erect, reed-like, thickest a little above the middle, mostly lemon-green in colour, with age becoming pale yellow or, in a small subgroup, blotched with red. Leaves narrow, small, dark green and soft. Aerial roots proceed as a rule from but a few of the lower joints. The internodes are short, only slightly constricted at the joints, and often possess a distinct central cavity that is even surrounded with strong fibrous cords. Buds small, depressed.

These, Hadi refers to the following sections:—(a) canes other than yellow. Of this nature he forms three series as follows:—(1) *dhaus* canes, of which he figures and describes seventeen different kinds. (2) *matna* canes, of which he shows ten kinds. And (3) *kuswar* canes, which he refers to twelve different kinds. Then under (b) the red *ukh* canes, he places the *chin* or *chan* canes, of which he describes six different forms.
Hadi regards the paunda canes as foreign, but accepts the chin as indigenous. It seems possible, however, that some of these may in reality be the survivals of the Chinese canes largely experimented with in these provinces nearly a century ago.

Group II. The Ganna Canes.—Except in a few districts these are grown almost exclusively as edible canes, especially in districts where the paunda canes cannot be successfully raised. They are usually taller and thicker than most of the races of ukh canes, and have longer and broader leaves. The skin is generally hard, but easily removable. The pith is always distinctly softer than in the former group. The central cavity and filaments are also absent and the canes are juicy, though not very rich in sugar. The aerial roots are more largely produced, and the buds are large and more conspicuous than in the ukh canes. But the sugars manufactured from them are inferior in colour. Lastly, they are very liable to fungal diseases, such as "red smut" (Trichosporum Sacchari), and are readily attacked by wild animals and white ants.

The best-known examples of this group are known as agaul, merthi, dikhon, pansdhi, knald ganna, karard, baraukha, tanka and ghorara. Most of these names denote introduction from one district to another, such as Gagaul (agaul), a village in Meerut; and merthi, Meerut—but Hadi accepts the majority at least as being indigenous to India.

Group III. Paunda Canes.—These are the acclimatised canes proper, that is to say, those admitted by the people to be of foreign origin, such as the Mauritius, Otaheite, Bourbon, Batavian, China, Singapore, etc., discussed above. They are grown almost entirely for chewing, except in one or two localities where they are used for sugar manufacture. Generally speaking, their cultivation is confined to the vicinity of large towns where a ready market may be obtained. High cultivation, involving heavy expenditure, is an essential feature for the growth of these canes—hence they are more profitable as edible canes than as sources of sugar.

They are tall plants, very thick, with hard skin (easily removable), and soft, fleshy, central solid stems. The leaves are proportionately long and broad, and aerial roots more abundant than in any other canes, but their buds are proportionately small. Many of them have been so long under cultivation in India that they have had local names assigned to them. The best-known examples of this are: (1) Madras or thun; (2) Bombay (red cane of Bombay); (3) Saharanpuri; (4) lal or kala ganna; (5) Banarsi; (6) Burmi; and (7) Poona paunda.

Standard in Description.—Mollison and Leather furnish a diagram showing in outline four forms of cane, and suggest the desirability of future writers accepting these as comparative standards. They furnish particulars of 46 canes, but of 11 they have omitted to say to which type they belong, and of 9 more they are apparently not quite certain themselves. The proposed classification would thus seem by no means a very satisfactory one. In type (A) the joints are constricted but the cane not materially swollen, whereas in (C) the joints (nodes) are constricted and the internodes distinctly swollen. These would seem to correspond very largely to both the ganna and paunda canes of Hadi's classification. The following are the (A) canes of Mollison and Leather:—kali-jadi; deo-gadi; Green Mauritius; rasdali (rasdali, the juicy); Yellow-green of Bijapur; Purple Mauritius (imported in 1893), the ramarasdali of Kanara; Streaked cane of Dhawar and Belgaun; Madrasi
paunda (of Sitapur, Barabanki, Bareilly, etc.); kajli (of Bardwan); and the puri (of Bardwan). (C) canes are: the khajuria or meva (of Surat); Malabari (of Surat); the mahim Yellow-green or Poona pundia; samara (of Dumraon); and the Saharanpuri (of Cawnpore and Bareilly).

The (B) and (D) canes of this classification seem to correspond to the truly indigenous canes of India which Hadi groups under the most general Indian name ukh. Of the former the following may be mentioned:—vansi or Bamboo or betta kabbu (of South Marathá country); hulu kabbu (hulu = grass, and kabbu = sugar-cane) (of the South Marathá); sannya (= small) - bile (= white) - kabbu (of Khánápúr and South Marathá); mungo (of Dumraon); dhaul or dhawur (of Cawnpore, Bareilly and Shahjahanpur); matna (of ditto); and rakra (of Shahjahanpur).

The (D) canes are as follows:—pansabi (of Behea); khari (of Dumraon and Bardwan); the dikhan (of Cawnpore and Shahjahanpur); and the mungo (of the same place).

Lastly, the (E) canes of Mollison and Leather seem to correspond closely with the coloured ukh canes of Hadi. The examples given by the former authors are bhuri, phojbhu and songadi (of Surat); the Purple cane (of Bijapur, Bassein and Thana); and the kare kabbu (kare = black) (of Belgaum, Khánápúr and Dharwar).

I have enumerated the chief canes mentioned by Mollison and Leather, and not those given by Hadi, because the former are applicable to a wider area, and at the same time, so far as the United Provinces are concerned, correspond with many of those given by Hadi. The Imperial Gazetteer (iii., 39) says the canes of India may be broadly grouped into (a) thick, juicy, soft kinds which ordinarily require very liberal cultivation and irrigation, and (b) thin, hard, less juicy canes which, with well-distributed rainfall, succeed with less liberal cultivation and with sparing irrigation or even without any.

Seedling Cane.—In the concluding paragraph under history, reference has been made to the flowering of the cane (p. 933). But it had long been supposed that the sugar-cane, as with some other cultivated plants propagated by cuttings, had lost the power of producing seed. Unlike the beet it was only, therefore, open to improvement by the chance occurrence of bud variations or by the chemical selection of canes individually richer in sugar.

As a matter of fact, the sugar-cane is, though sparingly fertile, not
absolutely seedless. As long ago as 1858 Parris had raised seedlings from it in Barbados, and in 1888 Bovell and Harrison, in the same island, and Soltwedel in Java, succeeded in accomplishing it. This opened the way to improvement by seminal variation, which was at once taken advantage of. Thousands of seedlings were raised from seed taken from known seed-parents, but of which the pollination was uncertain. Selection was made of those with a vigorous habit and a high saccharin content.

In 1904 Lewton-Brain succeeded in hybridising known varieties by artificial cross-pollination. It thus became possible to breed on definite lines so as to combine the desirable characters of particular races. One object would be to obtain those which would resist the disease which had led to the abandonment of the cultivation of the Bourbon cane. Seedlings produced in Barbados (about 1899-1900), and known as "B 147" and "B 208," have both been found to yield fully half a ton per acre more sugar than "Caledonian Queen," and fully three-quarters of a ton more than "Bourbon." They have, in fact, been stated to produce, under favourable conditions, fully 3½ tons per acre, the best canes formerly grown having yielded only 2-53 tons, so that these seedling stocks showed an increased yield of 37 per cent.

CULTIVATION.

Area and Yield of Sugar-cane and Sugar.—There is perhaps no other aspect of the sugar industry of India regarding which more obscurity prevails than the Provincial and Imperial averages of yield of cane to the acre and of sugar to the cane. Moreover, returns are only available for six of the provinces, though these embrace about 95 per cent. of the sugar-cane area. The provinces covered by the official Memoranda, issued by the Director-General of Commercial Intelligence, are (1) Bengal, (2) Eastern Bengal and Assam; (3) the United Provinces of Agra and Oudh, (4) the Panjáb, (5) the North-West Frontier Province and (6) Madras. The areas omitted are (7) Bombay and Sind, (8) the Central Provinces and Berar, (9) Burma, and (10) the Native States. For the past eight years the first six provinces have shown an average of 2,307,618 acres under the crop, with a yield of 1,988,211 tons of crude sugar (gur). This gives an average of 1 ton of crude sugar, or say one ton to the acre, provided it be accepted as safe to frame any such estimate. But it must be observed that the crude sugar of India is ordinarily a much inferior article to that indicated by the estimates of sugar-production in most other countries. Thus, for example, much of the imports by India from Java are considerably below the Continental standard. To correct
Indian returns of raw sugar into the crystallised article, the proportion is 2½ or 3 raw to 1 refined sugar. The Indian yield of cane to the acre does not appear to be ever published, so that the relative merit of the Indian stock to that of other countries cannot be ascertained.

The cane areas of the omitted provinces (7 to 10 inclusive above) can be ascertained, but not their yield of sugar. In 1903-4 and 1904-5 these came to about 140,000 acres, so that if that area be added and the proportionate figure be worked out for the outturn, the result would not materially disturb the calculations based on the six provinces only. The area returned in 1905-6 as under cane in the six provinces was 2,110,800 acres, and in 1906-7 was estimated at 2,348,800 acres. The ascertained yield was 1,725,500 tons in 1905-6, and 2,223,400 tons in 1906-7. The Agricultural Statistics still further show that in 1899-1900 the total area for all India under sugar-cane was 2,541,470 acres; and the subsequent figures manifest a shrinkage, right down to the returns of 1905-6, both constant and serious, though the improvement in the succeeding year is more hopeful. This may be exemplified as follows:

<table>
<thead>
<tr>

</tbody>
</table>

Thus, according to these returns, the area for the eight years preceding the enactment to countervail bounty-fed sugar in 1899, showed an annual average of 2,818,250 acres, and for the eight years subsequently, of 2,429,700 acres. But it is possible these returns are not very accurate for the provinces of minor production and for the Native States. They are possibly low estimates, but doubtless are relatively correct, and therefore would seem to justify the opinion that the sugar-cane acreage of India has for some years past steadily manifested a contraction.

Turning now to the provincial returns, the United Provinces head the list with 49 per cent. of the total area, namely 1,228,900 acres in 1905-6 and 1,386,700 in 1906-7. Then follows Bengal with 19 per cent., or approximately half a million acres. Next Eastern Bengal and Assam with 11.2 per cent., or 201,500 acres in 1905-6 and 199,900 in 1906-7. The Panjáb, 13.7 per cent.; the North-West Frontier Province with 1 per cent.; and Madras, 2.5 per cent. of the total Indian area under sugar-cane. "In the North of India and in Bengal 20 tons of cane per acre is considered a good crop, and an outturn of 1½ to 2 tons of gur per acre is obtained. In peninsular India, where sugar-cane is extensively grown under well irrigation and is very highly manured, the product is much higher, 6,000 to 7,000 lb. of gur per acre being an ordinary outturn. With very careful cultivation and high manuring, even double the yield has been obtained from soft varieties of cane" (Imp. Gaz., iii., 41). Mollison and others have often said that the experiments conducted at the Government Farms have proved that sugar-cane can be more economically produced in India than in any other country in the world. [Cf. O’Conor,
THE SUGAR-CANE PLANT

Return in Foreign Countries.—With regard to the yield in other countries, H. C. Prinsen Geerding, Director of the Sugar Experimental Station of West Java, gave the following yields of cane to the acre:—in Java, 36 tons; in Sandwich Islands, 33½; in Egypt, 22; in Queensland, 16; and in Japan, 15½. Yield of sugar in tons to the acre:—in Japan, 1½; in Queensland, 1½; in Egypt, 2½; in Java, 3½; and in Sandwich Islands, 8. These results showed the further fact, namely, tons of cane to the ton of sugar:—in Java, 7½; in Sandwich, Egypt, and Queensland, each 10; and in Japan, 14½.

Thus there would seem a wide range both in yield of cane to the acre and in the amount of sugar afforded by the canes produced. By high cultivation the yield of cane has been immensely increased in the Sandwich Islands, but it would seem as if the lower returns in Queensland were compensated for by the superior methods and appliances used in manufacture, since the cost of sugar-production is in Java £8 12s. 6d., and in Queensland only £8 15s., and this in the face of the startling statement of the yield being 36 tons in Java and only 16 tons in Queensland. Queensland is thus able to produce sugar at approximately the same price per ton as Java. But this question of cost of production manifests a wide range. Thus it is £8 4s. 4d. in the Sandwich Islands; Egypt, £9 10s. 11d.; Barbados, £9 15s.; Trinidad, £10 19s. 11d.; Demerara, £12 18s. 10d.; French Antilles, £14 6s. 9d.; and the United States, £18 18s. 6d. These were sums worked out a few years ago for the countries with a gold standard in currency, but it may be useful to add similar figures for the chief silver-standard countries:—Mauritius, £6 2s. 5d.; Philippines, £6 16s. 11d.; Japan, from £13 5s. 8d. to £16 16s. 10d.; Argentina, £17 14s. 11d.; and Brazil, £22 6s. 11d.

The Manchester Chamber of Commerce (Monthly Record for Oct. 31, 1899) discussed the yield of beet-sugar as compared with cane-sugar to the acre, with the following results:—

Martineau gives an average of 2 tons per acre as fair for all sugar-cane production, a result which, considering the improvements already effected in the stocks and methods of manufacture and in the possibilities of the future, by no means justifies gloomy forebodings for the sugar-cane planter.

MANURES AND MANURING OF SUGAR-CANE.—Leather (Agri. Journ. Ind., i., pt. i., 13-24) deals with the subject under the following among other headings: history, the demands of the plant from the soil, and the manures best suited to meet this strain. He suggests a division of the manures into—first, farm-yard, poudrette, and fish manures; second, oil-cakes; and third, bones and
DISEASES AND PESTS

DISEASES AND PESTS.—The blights of cane may be grouped into three sections:

(1) **Fungal Blights.**—Butler (Mem. Dept. Agri. Ind., i., No. 3, 1-53, tt. i.-xi.) reviews the Indian literature on this subject, and furnishes much new and useful information. He describes the following diseases:—

In a further paper, The Selection of Sugar-cane Cullings, Butler (Agri. Journ. Ind., ii., pt. ii., 193-201) shows the imperative necessity to avoid using diseased stock. Barber published (Agri. Journ. Ind., i., pt. i., 44-8; ii., pt. i., 40) an account of the Samalkota Sugar-cane Farm, in which he deals with Colletotrichum and shows that successive canes have held favour in South India during the past forty years, each in turn only to become diseased, thus causing widespread loss. But both these authors show that such calamities might be, to some extent at least, prevented were the stock rigorously selected.

(2) **Insect Pests.**—Many writers have dealt with the pests, but more casually than systematically. Saiyid Muhammad Hadi (Sugar Industry of U. Prov., 45-51) reviews the papers previously published, besides contributing largely to the subject himself. Cotes (Ind. Mus. Notes, i., 22-7) worked out the life histories of some of the sugar-cane pests, but it was left to Maxwell-Lefroy to furnish full details regarding the Moth-borers of the cane. The reader will find his first contribution in The Agricultural Ledger (1900, No. 23), but this was later on followed up by The Moth-borer in Sugar-cane, Maize and Sorghum in Western India (Agri. Journ. Ind., 1906, i., pt. ii., 97-113).

(3) **Other Enemies and Pests.**—Perhaps the most serious that has to be mentioned in this place is the root parasite Striga jubata. This little flowering plant injures the cane so seriously that a large percentage may often be seen to be killed by it. The only known cure is to uproot the parasite as much as possible, and to avoid growing cane on the same field for some years subsequent to a severe attack. Wild animals, such as the jackal, the boar and the rat, often do much injury to the crop, and frost or floods are alike disastrous. White ants are also very destructive (Maxwell-Lefroy, Agri. Journ. Ind., 1906, i., pt. ii., 174-6; also in Mem. Dept. Agri. Ind., 1907, i., No. 2, 126). For fuller detail regarding the diseases and insect pests of sugar-cane, the reader should consult the important work by Krüger (Das Zuckerrohr und seine Kultur, 1899, 301-466), which, however, has more particular reference to Java.

**Bengal.**—The area under sugar-cane, according to the Final Memorandum of the Government of India for 1904-5, amounted to 633,000 acres, and the estimated yield came to 634,700 tons of raw sugar or gur. The Season and Crop Report for 1904-5 gives the areas in the various divisions as follows:—Patna, 166,000 acres; Bhagalpur, 95,800 acres; Rajshahi, 92,200 acres; Dacca, 83,700 acres; Bardwan, 79,300 acres; Chota Nagpur, 53,100 acres; Presidency, 39,400 acres; Chittagong, 17,500 acres; and Orissa, 10,800 acres. In the year following, the apparent, but not actual, decrease in area was due to 14 districts, previously returned under Bengal, having been transferred to the new province of Eastern Bengal and Assam. This leaves the normal area of Bengal for 1905-6 under cane as 421,600 acres, and for 1906-7, 423,500 acres, with a yield of 419,300 tons.

The most recent accounts of cultivation are by Mukerji and Roy. Several varieties of cane are cultivated throughout the province. According to Roy, experiments have been made, for some years past, on the Bardwan Farm with four of

these, viz.:—(1) Shamshara, (2) Kajji, (3) Poori and (4) Poona. The results attained point to the Shamshara as the best gur-producing cane. The crop grows both on clayey and loamy soils, but a mixture of the two is preferable. Mukerji states that the best canes are found at the junction of old and new alluvia on the sides of streams and rivulets, where the soils are red clay loams, rich in mineral matter. As the crop is an exhausting one, it is never grown on the same land year after year. The crops it most commonly follows are pulse, mustard, potato or dhus paddy. The best time for harvesting sugar-cane is from December to February, and the most advantageous time for planting, the month of February.

In Lower Bengal the land is prepared by frequent ploughings from the middle of October to the middle of January. In most places it is also hoed, since deep cultivation is considered essential. When the soil has been thoroughly broken up, it is harrowed several times. The field is then divided into beds, by digging broad trenches, slanting from top to bottom at intervals of 40 feet, then subdivided by cross trenches 7 feet apart. Parallel furrows, at intervals of 1 to 2 feet, are now drawn along the beds, and oil-cake put into these. The plot is then well irrigated and cane cuttings placed lengthwise in the furrows and covered up. These are taken either from entire canes or the tops of canes. The latter system is said to be that pursued in the Bardwan Division, whilst the former is adopted in Bihar and Eastern Bengal. The cuttings are previously prepared by having been kept for a week or so in a cool pit—layers of cane with wet straw and ashes between. Subsequently the land is retained in a moist condition by artificial irrigation, generally given every fifth day, and when the young shoots have come above ground, the surface is well watered and hoed between the furrows. Afterwards it is occasionally irrigated and hoed, the plants being canned up until the original furrows are converted into ridges. During the rainy season the soil is kept well drained, loose and free from weeds. From the middle of July to the middle of October the plants are tied up in clumps. Their dead leaves are removed, and oil-cake applied as a top dressing, at the rate of 4 to 5 maunds per bigha. The crop is harvested from the middle of December to the middle of February.

In some places, especially on light soils, water-channels are not made at the time of planting, but the land is simply thrown up in ridges over the cuttings. Again, in others, after water-channels have been made, as described above, holes are dug 2½ feet in diameter and 1½ feet apart, in lines 1½ feet from one another. One cutting is put in each hole with oil-cake and water, and then covered up. This is known as the Mauritius system, because supposed to be the method adopted there, and in India is mostly used on undulating ground, but the furrow system is said to be best where irrigation is required and possible.

Eastern Bengal and Assam.—The area under sugar-cane for 1904–5 in Assam proper was 44,869 acres. The largest areas ordinarily occur in Sylhet, which had 20,000 acres; Sibsagar, 6,925 acres; Cachar, 5,250 acres; Lakhimpur, 3,783 acres; Kamarupa, 3,688 acres; Darrang, 2,176 acres, etc. But since the separation of Bengal, 14 districts formerly treated as within that province are now returned under the new province of Eastern Bengal and Assam, and later statistics accordingly manifest an apparent provincial expansion. Thus in 1905–6 the estimated area and outturn in the new province were 201,500 acres and 188,500 tons, and in 1906–7, 199,900 acres and 193,500 tons.

Cultivation

ab abstracted from the account by Dr. E. Stack. A light loamy soil, with a light admixture of sand, is most suitable. It must be high land, beyond the reach of inundation. Favourite spots are the edges of a marsh or the banks of a river. The degree of manuring depends entirely upon the rainier's means and inclination. Plots in the vicinity of centres of crowded population are freely manured with cow dung and crushed mustard seed, both before and after planting with cane; on the other hand, in the more rural tracts it often receives no manure except the ashes of the grass and weeds raked out of the soil and burnt. The best cane is that raised on virgin soil or on old fallows, but land from which a crop of mustard, pulse, or summer rice (dhuri) has been first taken is sometimes preferred. A second crop of cane, unless ratooned, is never taken, but the land is left fallow for several years. Waste or fallow land is broken up in October, then left till January or February, when ploughing starts and is continued till the middle of April. The field is then divided into strips, 8 to 12 feet wide, by drains which communicate with a ditch surrounding the field. The cane-sets are invariably the topmost joints.

From the harvest season to time of planting they are kept in a cool and moist spot, placed in a half-upright position, in ground which has been turned up by the hoe, the beds of cuttings being covered with rice-straw or plantain leaves and watered if the weather be dry. The day chosen for planting out, generally about the middle of May, must be preceded by sufficient rain. In an official publication on *Seasons of Sowing and Reaping of Crops*, issued by the Reporter on Economic Products, cane is spoken of as planted from April to June. The layers are placed 2 feet apart, in trenches 3 feet distant, and these run at right angles to the drains that divide the field. After planting, a little soil, often mixed with cow-dung, is lightly scattered over them. The field is then weeded and the soil around the young shoots lightly stirred with the spade or hoe, a process which is repeated at short intervals during bright sunny weather throughout May and part of June, and at the same time manure may be applied. A few more weedicngs are given and the earth from the ridges is heaped about the roots of the canes in the trenches till ridge and trench are reversed. This goes on till the middle of August, after which work stops for about a month. A final weeding and earthing up is then given, in September or October, when the canes are tied together in clumps by the leaves stripped off the lower parts of the stems. Cane harvest, as a rule, does not begin till the winter rice has been reaped, that is, till after the 15th of January.

The operations of cutting, crushing, boiling, etc., are carried on simultaneously from this date till the end of March, or even beginning of April. The canes are cut close to the root, the tops lopped off and reserved for layers, and the stalks, stripped of their leaves, are bound in bundles and carried to the mill. From an extensive series of crop experiments, performed from 1885 to 1902, it would appear that the yield of cane to the acre is about 10 tons and that it requires about 11-6 tons of cane to afford one ton of gur.

A small proportion of the annual crop is ratooned. If this is done the stripped-off leaves of the previous crop are left lying on the field till April, when they are burnt, and a month later, when the young shoots begin to appear, the crop is hoed and manure added. Such a crop is called murha, and is harvested earlier than the other crop, viz. in the beginning of January. [Cf. Allan, *Assam Dist. Gaz.*, 1905 (Cachar, Sylhet, Goalpara, etc.): *Crop Exper. Repts., Assam.*]

**United Provinces.**—On the average of the five years ending 1904-5, it is manifested that the area under sugar-cane in these provinces amounted to 49 per cent. of the total under sugar-cane in British India. In 1905-6, the area, according to the *Agricultural Statistics*, was 1,220,716 acres, viz. 954,350 in Agra, and 266,366 in Oudh. The yield was returned as 884,000 tons, though in 1904-5 it was 1,183,400 tons or, say, one ton to the acre. In Agra the acreage in 1905-6 in the most important districts was as follows:—Meerut, 108,954; Gorakhpur, 93,599; Bijnor, 77,763; Azamgarh, 69,088; Muzaffarnagar, 56,498; Basti, 55,123; Bareli, 51,135. In Oudh:—Fyzabad, 48,157; Kheri, 41,091; Sitapur, 33,201; Barabanki, 31,691; Gonda, 27,395; Sultanpur, 22,580. The *Final Memorandum* of the Commercial Intelligence Department for 1906-7 states the area and yield for that year as 1,386,700 acres and 1,264,000 tons.

The races of cane grown in the United Provinces have already been classified, with reference to their agricultural characters and properties, into
THE SUGAR-CANE PLANT

SACCHARUM OFFICINARUM
United Provinces

Rotation.

three broad divisions, known as ukh, ganana and paundá. The methods of cultivation for the first two are the same, but differ somewhat in the case of paundá canes.

According to Saiyid Muhammad Hadí, from whom the particulars here given have been mainly derived, the crop is grown under three different systems of treatment. "In one, the land is kept fallow for a whole year following the removal of a spring crop. In the second, a winter fallow is followed by an autumn crop. In the third, the ground is prepared and cane sown immediately after a spring crop has been cleared from the land." The second system is that which is commonly pursued, especially in canal-irrigated areas. Under the first, ploughing commences as soon as rain has set in and is continued till sowing time. Under the second, it begins soon after the rain or the autumn crop has been removed, the land being watered if necessary to admit of ploughing. The number of ploughings varies from fifteen to twenty in the west and from twenty to forty in the east, but when cane is grown immediately after the land has been cleared of a spring crop, it is not ploughed more than five times. After every ploughing, the land is levelled. Manure is usually applied before planting, and incorporated with the soil by ploughing in.

Irrigation.

Cattle-dung or farm-yard manure is generally used, and at the rate of 200 to 300 maunds an acre. In the east, canes which are intended to be cut up into "sets" are left standing in the field. A day or two before planting the canes are cut, stripped of their dry leaves, and left in water overnight. They are then chopped into pieces, each piece being about 15 inches long and containing three to five buds. In the west, in the Rohilkhand and Meerut Divisions, the top cuttings are planted, which consist of a portion of the top green leaves and a few of the upper joints. These cuttings are buried in a corner of the field and covered lightly with earth, a layer of dry leaves being placed above and underneath. Every fourth or fifth day, water is sprinkled over them to keep them moist. On the day of ploughing, they are dug out and removed to the field. If the moisture in the field is not sufficient, the land is usually irrigated before planting. Planting the sets is done in the following way. A first ploughing is made parallel to the side of the field, but only just scratches the soil, and is followed by a second which deepens the furrow. A man then places the sets along the furrow at a distance of about one foot from each other. A third plough brings up the rear and covers the sets with earth.

The time for putting the sets in the earth varies from the middle of February to the middle of April. The crop is watered three to seven times between planting and harvesting, and in a dry year more is necessary. Four or five days after planting, the first hoeing is done, and after every watering two hoeings are given. When the plants are very young, each hoeing is followed by levelling the ground, and after the commencement of the rains, or when the plants are about 2 feet high, the hoed field is again levelled. The number of hoeings varies from 7 to 14.

Ratoon Crop.

In the west and parts of the Doáb, the cultivators grow a ratoon crop, known as perí. To propagate the perí crop, the roots are left undisturbed from the time of first cutting, and the stripped leaves of the first year's crop are burnt in the field before the commencement of the rains. After the rains have set in and the young shoots begin to sprout, the field is ploughed up, the furrows being 6 to 9 inches apart. By the middle of November the crop is believed to have attained maturity and to be fit for crushing. Ordinarily, however, the cultivator does not commence cane-crushing till December.

The cultivation of the variety known as paundá, grown almost entirely for chewing purposes, differs somewhat from the above. Before planting, the field is dug up one foot deep and the sets are planted earlier than the time stated above, since the sooner this variety of cane comes into market, the higher price it fetches. The method of planting is somewhat different. The sets in this case are dropped into furrows between ridges into which the field has been previously laid out, and are covered over with earth, the furrows being 24 to 30 inches apart and the distance between the cuttings about 2 inches. Poudrette instead of farm-yard manure is in this case generally applied, at the rate of 600 to 800 maunds per acre, or about three times as much as in the former case. The first hoeing is done as soon as the land gets sufficiently dry after the second watering. The field is then watered again, and subsequently the ridges are split and the field levelled and divided into irrigation-beds. Hoeings and waterings continue till the advent of the rains, and in July or August the plants are earthed up. The number of waterings varies from twelve to seventeen during the period of growth, and the number of hoeings from five to seven.

SACCHARUM
OFFICINARUM

Hadi gives estimates of the cost of cultivation in the various divisions according to the second, the commonest method, and he states the lowest, that for Mercer Division, at Rs. 60; the highest, that for Rohilkhand, at Rs. 81 per acre. Speaking of the pounded canes, he gives the total cost as Rs. 157-8 per acre. [Cf. Dutfield and Fuller, Field and Garden Crops, 1882, i., 55-63, t. xiv.; Dist. Stat. Repts., U. Prov.; Moreland, Note on Sugar Cult., app. 4, xii-xiii.; Rept. on Sugar Cult. by Bihar Indigo Planters, 1901; Hadi, Sugar Indust. in U. Prov., 1902; Nevill, Dist. Gaz. U. Prov., 1903-5; Moreland, Sugar Indust., in U. Prov., in Agri. Journ. Ind., 1907, ii., pt. i., 15-21; Exper. Farm Rept., Cannapore.]

Panjáb and North-West Frontier Province.—In the Agricultural Statistics for the year 1905-6, the area under sugar-cane is given in the Panjáb as 172,700 acres, and the yield 83,983 tons, while the previous year was 325,500 acres and 238,300 tons of gur, or about three-fourths of a ton to the acre. It has to be borne in mind, however, that in many tracts, especially with considerable Muhammadan populations, cane is grown largely, if not mainly, for eating purposes, and not used in the production of gur. The more important district areas may be given for 1904-5, namely, Gurdaspur, which had 51,590 acres; Sialkot, 34,919 acres; Lyallpur, 30,672 acres; Jallandhar, 27,797 acres; Rohtak, 24,434 acres; Hoshiarpur, 24,021 acres; Gujranwala, 20,492 acres; Karnál, 19,553 acres; Delhi, 17,575 acres; Amritsar, 16,543 acres; Ambala, 15,870 acres, etc. The area in the North-West Frontier in the same year was 26,003 acres, the great bulk of which is grown in Peshawar, 18,414 acres in the year in question; Bannu, 6,387 acres; and Hazara, 1,094 acres. The area and production in 1906-7 were 257,600 acres and 212,800 tons in the Panjáb; 28,600 acres and 32,800 tons in the North-West.

The following information applies particularly to Sialkot, one of the most important sugar districts of the Panjáb, and is abstracted from the account given by Dunlop-Smith (Gaz. Sialkot, 1894-5, 114-6). The land which is to bear the crop must be frequently ploughed. In Sialkot the preparatory ploughings vary from ten to twenty, and the ground is always manured. Cane is never grown from seed. Each year, when a field is reaped, about 5 per cent. of the stalks are carefully selected and cut into lengths of about 9 inches and buried in a pit. They are ready for planting in about three months. When taken out of the pit they are placed lengthwise in the ground and pressed down with the foot. The ground bearing sugar-cane has to be kept moist by steady irrigation when there is no rain. But unirrigated cane is generally superior to that grown on well-drained soils. Planting usually takes place in March. Before the crop ripens, it must be watered about five times. Cutting begins in December and goes on intermittently for about three months. The quality of cane depends very much on the soil which bears it. The best cane is grown on the rich darp soils in Rayā. The highly manured fields round the village sites bear a poor class of cane, though the outturn is very large.

When the cane is cut, the green tops (dāy or pānd) are broken off and the sheaths (choi) of the stalks are stripped with a sickle. The stalks are at once carried to the place where the press has been set up. The presses are of two kinds, wooden and iron. The former is a clumsy machine, sunk in a pit. The cane-stalks are made up in bundles of fifteen to twenty-five and passed through and through the press several times. The juice is received into an earthen jar sunk in the ground. The iron press is much simpler than the wooden, and stands above ground. As soon as possible after extraction, the juice is poured into a large flat iron dish (karāh) placed on an earthen oven, and boiled and stirred for two to two and a half hours till it begins to coagulate. When the mass is ready it is poured into a hole (gand) in the ground, carefully prepared by plastering with clay. The liquid is then stirred for some twenty minutes till it hardens and cools enough to be rolled into balls. [Cf. Dist. Gaz. Pb. (especially Gujranwala, Rawalpindi, Shahpur, Montgomery and Multan); Rept. on Land Res. Admin. P., 1901, ix., app. B, 111.]

Central Provinces and Berar.—Recent returns of the area and yield are not available for these provinces. The totals for 1904-5 were 31,398

945

60
acres in the Central Provinces (19,601 irrigated, 1,788 unirrigated), and 2,076 acres in Berar. The districts with largest areas are usually as follows:—Central Provinces: Chhattisgarh (Sambalpur and Bilaspur), 8,730 acres; Nerbudda (Betul) 5,324 acres; Nagpur (Bhandara and Balaghat) 4,910 acres; Jabalpur 2,425 acres; and Berar: Buldana, 922 acres; Wun, 350 acres; Basim, 342 acres, etc. Particulars are not available regarding the yield of gur from these provinces collectively, but the Revenue Settlement Report on the district of Betul (published in 1901) affords many useful particulars that may be here mentioned. The average yield of cane would appear to be 18 tons and the yield of gur about 2 tons (9 tons of cane yielding 1 of gur). The gur produced is, moreover, of excellent quality and fetches locally about 30 per cent. more than the average article imported from other parts of India. These results are no doubt higher than those obtained in the Central Provinces generally, and even in Betul the yield of gur ranges from 1,500 to 5,000 lb. Sir J. B. Fuller proposed that the standards accepted for the yield of gur should range from 1,500 lb. to 4,000 lb.

Cane is grown under two quite different systems, according as irrigation is or is not used. The only soil on which it is possible to grow cane without artificial watering is that known as black cotton soil, and there is a certain amount of unirrigated cane in all districts in which this soil occurs. Unirrigated cane is planted in November, December and January, on land which has, as a rule, enjoyed a year's fallow and has been ploughed again and again for the previous nine months. The field is manured with cow-dung at the rate of 50 to 200 maunds to the acre, it being often applied as a top dressing when the young shoots have appeared above-ground. Pulverised oil-cake is also used in Bilaspur, being placed round the roots of the plants at the commencement of the rains. An important feature in this method of cultivating cane is the covering of the ground with leaves as soon as the young shoots have come up. This checks evaporation and renders the lack of irrigation less harmful than it would otherwise be. The field is hoed and weeded between the rows of cane three or four times during the rains, and the crop is ready for cutting in November. This system is known as palwar or nachgara.

But by far the largest and most productive portion of the cane area is irrigated. With water and manure, cane can be grown on almost any description of soil, but the kinds most preferred are clayey loams. The reddish loam of Chhindwara is one of the best suited to sugar-cane in these provinces. Montgomerie (Land Rev. Sett., 1901-5, app. i.) takes a less favourable view, and says that the imports of cheaper sugars are curtailing production. He gives the cost of production as Rs. 164-10-10 and the average annual profit as Rs. 38. The following account of cultivation in Betul (abstracted from the Rept. on the Land Rev. Sett., 1901, 32-40) will illustrate the method by irrigation. The field in which the crop is grown is divided into several plots, three or four in number, and the sugar-cane is grown in each in turn. It is generally irrigated from a well, but occasionally from a hole beside a river-bed. Before the rains, manure is laid down in the plot selected, and during the rains and the first months of the cold weather it is thoroughly ploughed. At the end of December or beginning of January the field is divided into numerous plots with main irrigation channels between and smaller ones across them. The furrows are made by a plough with a triangular board fastened above and at the back of the share. The "seed," which consists of pieces of cane each with three or four eyes, is then sown. The sower lays them in the water-channels, which have been previously well watered, and partly buries them by pressure with his foot. As soon as the plot is sown a watering is given, and if well-rotted manure is obtainable, it is now spread on the land. The crop is then fenced to keep out cattle and jackals. For the first fifteen days it receives no more water, but afterwards must be regularly watered. During the cold weather no part of the crop should be without water longer than eight days, and in the warm weather longer than four days. Throughout the monsoons there is nothing to do but keep down weeds, ward off animals and bind the canes together so that they may not be broken by wind. At the end of September watering must begin again, and great importance is attached to the watering given at this time. In
the middle of December the harvest begins. The first canes to be cut are those intended for use as "seed." The cutting and manufacturing of gur commences in March. In the same Report it is stated that the best gur is made from sugar-cane raised on soil that has never before borne the crop or been manured. As the land becomes more and more saturated with the dung which is annually put on it, the quality of the gur gradually deteriorates, till it reaches the normal. When the juice is to be turned into gur, the cane is dug up with a sharp pick. The leaves are peeled off and the stripped cane is then taken to the mill. Formerly the only mill known was a cumbersome wooden structure, but an iron mill is now in universal use. As the juice is extracted, it is poured into the evaporating pan. When evaporation is complete, in about six hours the juice is poured into a wooden trough sunk in the ground. After it has cooled and hardened it is hung up in cloths to drain, and in a couple of days is ready for the market. [Cf. Fuller, Note on Outturn of Land under Crops in C. Prov., 1894, 24-40; Land Res. Sett. Repts.]

Rajputana and Central India.—The only States of Rajputana and Central India for which statistics are obtainable for a recent year (1905-6), and in which sugar is grown to any extent, are Gwalior, 5,221 acres; Jaipur, 645 acres; Bharatpur, 469 acres; Tonk, 340 acres; Kota, 320 acres; and Alwar, 220 acres.

The systems of cultivation pursued differ in no material respect from those already detailed in connection with the Central Provinces and the Panjáb. In the Dictionary full particulars will be found of individual reports, but nothing of any great interest has since been published. The yield of gur would seem to be about 30 to 40 maunds to the acre (28½ cwt.), and in some localities with good black soil and abundance of water (such as in Chitorgarh) as much as 50 maunds (36 cwt.) have been recorded. Raicon crop is not uncommonly seen in these Native States.

Bombay and Sind.—Sugar-cane is cultivated in almost all parts of the Presidency, and according to Mollison on a greater diversity of soil than is the case with any other irrigated crop. The area is ordinarily about 60,000 acres. In 1905-6 the actual area amounted to 56,333 acres in Bombay; 2,549 acres in Sind. In 1906-7 the area was 49,990 acres, and in 1907-8, 48,470 acres with a yield of 121,874 tons. In Bombay the chief centres of cultivation in 1905-6 were Poona, 12,204 acres; Sátara, 10,011 acres; Belgaum, 9,950 acres; Násik, 5,628 acres; Surat, 3,372 acres; Kanára, 3,004 acres, etc. In Sind, Karachi, 907 acres, and Hyderabád, 900 acres. In the Report of the Department of Land Records and Agriculture (1904-5, 6), the following observations occur:—"The sugar-cane crop in this Presidency is of small importance as regards area, but of considerable importance in regard to value. The United Provinces of Agra and Oudh have a million and a quarter acres under sugar-cane, and the Panjáb and BengáI together have an equal acreage. We have only some 60,000 acres, but while their cane is largely grown without irrigation, and, even when irrigated, produces an outturn of not more than 2,500 lb. of gur per acre, the Bombay cane is always irrigated and produces an average outturn of 7,000 lb. of gur; with sufficient manure and skilful cultivation, near Poona, the outturn is known to reach even 15,000 lb. The cane crop pays a considerable part of the irrigation revenue on canals and is one of the most remunerative investments open to capital in Western India, the average net profit being reported to be about Rs. 150 per acre. Experiments have been in progress regarding the best methods of cultivation of this crop for ten years, and important conclusions have been published by Mr. Mollison and a pamphlet issued this year by Mr. Knight. These conclusions are (1) that excessive irrigation is ordinarily applied by cultivators from canals; (2) that water to the amount of 2½ to 3
inches of rainfall should be applied every eight to ten days (these conclusions now regulate the Irrigation Department); (3) that the amount of nitrogen supplied per acre in manure should be about 350 lb.; (4) that this can economically be supplied by oil-cakes (this discovery has greatly influenced sugar-cane cultivation around Poona); (5) that the Poona system of cultivation in beds is better suited to the local cane than the system adopted from Mauritius."

The cultivation of sugar-cane has thus been very fully discussed by the Agricultural authorities of the Presidency, and the following is mainly a summary of their observations, drawn for the most part from Mollison (Textbook Ind. Agri., iii., 108-81):—The varieties cultivated may be broadly grouped into two, with numerous gradations between the extremes: (1) thick, juicy, soft kinds which require copious irrigation; (2) thin, hard, less juicy kinds which require lighter irrigation. Sugar-cane adapts itself to almost any kind of soil if drainage is previously secured, as a waterlogged condition is fatal. The season of planting varies in different localities. In Ahmadabad, Kaira and Baroda it is planted in May or early in June. In the Surat district, also in the Southern Maratha country, most of the cane is planted in November and December, but the season may extend to February. In the Poona district, February and March are considered the best months for planting.

According to Mollison, the cultivation in the neighbourhood of Poona is typical of what it should be elsewhere, and he accordingly describes it in full. The best soil is a clay loam and the best preparatory crop a green-manure of san (Crotalaria juncea). The san should be sown thickly in June or July (about 70 lb. seed per acre), and ploughed in when 3½ to 4 feet high. If no manure crop has been used, the land is allowed to lie waste during the monsoon. In November the field is deeply ploughed, and one or two subsequent ploughings are given in December. After ploughing, the surface is levelled with a log harrow, all clods broken, and manure applied. Poudrette or farm-yard manure, about 60 loads or 30 tons per acre, is most commonly employed. Usually, however, a smaller application is given before planting, and the crop is again top-dressed in June or July with such manures as castor-cake, karanj-cake (Pongamia glabra), fish manure, etc. Experiment has shown that the most important constituent of sugar-cane manures is nitrogen in immediately available conditions. Mr. Knight states that in the case of the Pundia canes, as much as 350 lb. of nitrogen per acre is required to give the best outturn. The manure should be evenly and carefully spread, and the land then ploughed into ridges 24 to 28 inches apart. The plough is next run across the ridges to form parallel water-channels 10 feet apart. Finally, the field is laid out in beds 10 feet square. Each compartment when complete contains four short ridges and five furrows. The crop is propagated from sets, though sometimes in other parts of the province, as in Gujarat, by planting whole canes. Each set has usually three eyes (buds) or more, and may be 15 inches to 18 inches long. One acre of good cane provides sets for 11 to 12 acres. Ratoon cane—i.e. cane grown from the root-stocks of the previous crop—usually provides the best sets, and many authorities consider the "tops" better for sets than any portion of the mature cane, but according to Mollison, it has yet to be proved whether the resulting crop is better or worse than from sets planted in the ordinary way. [Of U.S. Dept. Agri. Exp. Stat. Rec., 1897, viii., 677; 1899, x., 546; 1901, xii., 438, etc.] The argument for using the tops is that they contain no cane sugar and that the practice of reserving whole canes for sets is wasteful. In the Poona district 16,000 to 18,000 sets are said to be required per acre. Before planting, water is conducted into each bed in turn. When it has partially soaked into the soil the sets are laid along the bottom of the furrows and tramped down 3 or 4 inches into the soft mud. The distance between sets is about 4 inches. Planting should take place in February and be finished before the middle of March. A month after planting, the land should be carefully weeded with a khurpa or hand-spud. Usually four weedicings are necessary. In June or July new beds are formed. The soil is dug, levelled, weeded, and a second dressing of manure given. The canes originally planted in the furrows are earthed up with a hand-hoe, thus forming a furrow between the rows of cane. These furrows serve as new watercourses. After July or August, in the Poona district, cane requires no further attention except protection and irrigation. The land is first flooded as the sets are planted, and
thereafter two or three times at short intervals. Subsequently eight to ten
days may elapse between the waterings, the shorter interval in the hot weather,
the longer in the cold. The rainfall in the Poona district averages about 30
inches, and Mollison states that on an average sugar-cane gets during twelve
months; in addition to the rainfall, irrigation water equal to 75 to 80 inches of
rain, the crop being irrigated on an average 28 times a year. During the first
three months the crop makes slow growth, and it is common to grow with it
subordinate crops which ripen quickly, such as maize, gudar (Cynamois
pozruUoides), onions, cucumbers, melons and tobacco.

It is difficult to judge by eye when the cane is ripe. Frequently a cane-grower
tests the ripeness of his crop by a trial crushing and boiling; if a given quantity
of juice gives a satisfactory weight of gud, harvest is proceeded with. Usually
the crop gets a yellow colour as it ripens, but this colour may be caused by
irregular or deficient irrigation or by a want of manure. If the side leaves are all
dead, and the eye-buds almost to the top of the cane fully developed and firm,
the cane is probably quite ripe. If it is intended to grow a ratoon crop, the cane
should be cut with a sharp sickle at a height of 1 to 2 inches above-ground.
Mollison states, on the evidence of experiments made at Mánjrí, that it is risky
in the Poona district to take more than one ratoon crop. Generally, however, in
that district, two successive ratoon crops are taken. But Poona is the only
district where ratooning is practised to any considerable extent. If no ratoon
crop is desired, the cane should be uprooted and removed from the root-stock
by a sharp jerk. It should be reaped or uprooted in the early morning, while
the leaves are wet with dew. The dry leaves are stripped from the canes by means
of a sickle. The upper green leaves, which are useful as fodder, are usually not removed in the field. Subsequently, the cane is tied in bundles and
carried on the head or in carts to be crushed at the mill, which is often placed
conveniently near the field. Forty tons per acre of cane is stated to be a fair
average crop in Bombay. According to Mollison, the estimated cost per acre
of cultivating sugar-cane by hired labour in Poona amounts to Rs. 480-12a.
Mr. Knight gives as a general estimate Rs. 420-12a, per acre. In growing a ratoon
crop, the cost is considerably less than for a new cane. No sets are re-
quired, less manure and less irrigation are necessary, and the saving amounts on
an average from about Rs. 120 to Rs. 150 an acre. [Of. Mollison, Sugar-cane in
Bomb. Pres., in Agri. Ledg., 1885, No. 8; Knight, Sugar-cane, Dept. Land Rec.
and Agri. Bombay Bull., 1905, No. 25; Repts. on Crop Exper. Bombay; Exp.
Farm Repts. Poona, 1896, 31-57, etc.]

Madras and Mysore.—The area under sugar-cane in Madras, according to
the Agricultural Statistics for 1905-6, was 74,359 acres, while an estimated
area and yield for that year were 60,700 acres and 114,500 tons. It
seems desirable to exhibit both the actuals and the estimates, since the yield
(expressed from these quotations) would be 1'8 tons an acre. The
largest district areas in the year named were Bellary, 9,761 acres; Coin-
batore, 9,689 acres; Godávari, 8,413 acres; Trichinopoly, 7,450 acres;
South Arcot, 6,168 acres; Vizagapatam, 5,763 acres; North Arcot, 5,585
acres; Salem, 5,045 acres; Cuddapah, 4,992 acres; Anantapur, 2,624
acres, etc. And it may be added these express relatively the ordinary
areas of sugar-cane in the Presidency. Lastly, in 1906-7, 52,500 acres
with a yield of 100,400 tons. The area in Mysore in 1904-5 was 38,802
acres.

The rich alluvial soils near the mouths of rivers are best adapted to sugar-cane,
but the ground must be such that it can be irrigated for ten months of the year.
During the first month of cultivation the field should be irrigated every week
and afterwards every fortnight, but much depends on the nature of the soil. It
is not usual to cultivate the cane two years running on the same land. In parta
of Karnul, Timmelly and South Kánará, however, the stumps of the cane are
left in the ground to sprout and yield a crop the following year, and in the Nadyál
taluk of the Karnul district, a stump is left in the ground for three years, and in
the Cumbum taluk for as long as ten, the yield diminishing each year. These
instances of slovenly agriculture are, however, exceptional. The cultivator
usually permits land which has borne some other crop to lie fallow for a year,
and then prepares it for the cane by several ploughings, or by breaking it up

949
THE SUGAR-CANE PLANT

Propagation.

with crowbars and by heavily manuring with whatever manure he can obtain. The crop is always propagated by cuttings. The top of the cane is commonly used, but some cultivators leave a few canes growing in the fields from the previous year, and cut them up into lengths of one or two joints. These tops or cuttings are set horizontally in the wet soil, so that each other rows about 4 feet apart. Six days afterwards the field is again watered, and about the twentieth day, four or six shoots sprout from each cutting. In Ganjam and Vizagapatam some raiyats plant the cuttings in nurseries and afterwards transplant the shoots into the fields. After the shoots appear, the ground is weeded and hoed, and when they are about a month old, chaff, weeds, or some such manure is thrown around them. The soil is kept moist by occasional irrigation, and when about three months old the shoots ought to be 3 feet high. After this stage it often becomes necessary to give the canes support. This is done by fixing bamboos or saplings into the ground in the middle of each group of canes, the leaves being tied round so as to bind them together. Ten months from planting, the crop is ready for cutting. The cost of cultivation in the Presidency generally has been estimated at Rs. 150 per acre and the outturn at 224 tons of stripped cane, yielding 43 cwt. of jaggery worth Rs. 250. Nicholson states the outturn of cane to be 25 to 30 tons, worth Rs. 150 to Rs. 200, and of jaggery 2 tons to 2½ tons, worth Rs. 210 to Rs. 240.

The growing of sugar-cane in the Godavari district, which was in former years a profitable undertaking, has in recent times suffered considerably from a disease which has attacked the canes, and a special Government station has been opened at Samalkota for the particular study of the disease and of cane cultivation generally. The objects of this experiment are laid down by Mr. Barber, Government botanist, Madras, in a note published in 1904 (Exx. Sugar-cane Stat. Samalkota, Mad. Bull., ii., No. 48). The experiments carried on have made several points clear. Barber maintains that the quantity of water given to sugar-cane must be very carefully regulated, and that hitherto the cultivator has been in the habit of giving too much water. After each watering the land must be thoroughly and quickly drained. The highest and driest places must be chosen for the plantation and deep drains dug to throw the water off as quickly as possible, and also to secure the introduction of new varieties exempt from disease from other parts of India and the world. Still another point that seems likely to assume the form of a radical departure is the cultivation of the sets in a nursery, preparatory to their being placed in the field. This is not a new principle to India, but has never been applied to any great extent. It has been recently decided that the farm shall be made permanent, and thirty-six acres of land have been acquired for the purpose. Further details regarding the work done will be found in an article by Barber in the Indian Agricultural Journal (1906, i., pt. i., 44–8; ii., pt. i., 33–41). [Cf. Proc. Agri.-Hort. Soc. Mad., 1890, 44–50, etc.; Sturrock, Man. S. Canara Dist., 1894, i., 207–8; 1895, ii., 129–40; Cor. Mem. N. Arcot, 1893, i., 262–5; Sugar-cane in Godavaric and Ganjam Districts; Nicholson, Man. Coimbatore Dist., 1906, 233–7; Dept. Land Recl. and Agri. Mad. Bull., 1899, ii., No. 36; 1901, ii., No. 43; Benson, Sugar-cane of Mad., Bull., 1902, No. 46, 235; Subba Rao, Sugar-cane in Deccan Dist., Bull., 1904, No. 50, 289–300; Rept. of Agri. Burma.—The area under sugar-cane for 1905–6 was 2,281 acres in Upper Burma, and 10,429 acres in Lower Burma. In Lower Burma the largest areas are Thaton, 4,291 acres; Toungoo, 1,368 acres; Sandoway, 705 acres; Amherst, 688 acres; Kyaukpyu, 603 acres; Tharawadi, 557 acres; Myaungmya, 447 acres, etc. In Upper Burma, Yamethin, 1,587 acres; Kyaukse, 381 acres. These returns may be accepted as relatively correct for normal years.

The cultivation of sugar-cane in Burma was fully described (in 1885) by Mr. J. E. Bridges. We learn that the cane-producing lands may be roughly divided into two tracts: (1) that of shifting cane cultivation, where the cane is
CULTIVATION IN BURMA

SACCHARUM OFFICINARUM

Manufacture

consumed in the raw state; (2) that of permanent cultivation, where the cane is manufactured into gur.

The first tract includes roughly all the lands on the seaboard within the region of tidal creeks. The land, as a rule, is poor and will not yield a cane crop two years in succession, so that it is met with only in isolated patches. The form of cane grown is called kyauktwain or kyaukheany, a large cane of light colour with short thick joints, so brittle that when passed through the mill it generally breaks at the joints. The timber on the land selected is cut down at the beginning of the dry weather, and burnt in March. Vegetables are then planted among the ashes and afterwards sold at a small profit. In September the land is cleared of weeds and cane pieces are placed in holes at a distance of 2 or 3 feet, the holes being in rows 3 or 4 feet apart. The cane-sets are fastened down by a bamboo lashing to prevent them being washed away. In January and February loose soil is thrown up round the young plants, and in May and June supports to which they are tied are placed near each cane- stool. In some parts trenches are made to admit water during the dry season and drain the land during the rains, and in other parts the plants are watered by bamboo water-lifts. About August and September the cane are cut and sold in pieces. If hired labour is employed, the cost of cultivation is Rs. 60 per acre.

The most important portion of the tract of permanent cultivation is situated in the valleys of the Bilin and Théhyu rivers. The soil here is almost entirely grey loam, mixed here and there with light clay. The land is covered during the rainy season by river floods for a few days at a time, and a thick layer of alluvium deposited on it. The soil on which cane is grown for manufacturing purposes in the other districts of the province is generally a deep rich loam. Where new land is cleared, or land already cultivated has been left fallow, the cultivator turns up the soil with a hoe at the beginning of the rains (May or June), and then leaves it to rest till September, when he digs holes 10 inches deep and one foot wide at intervals of 1½ feet from each other. Three pieces of cane (agyawang), about 5 inches long, are then placed in a standing position in each of these holes, and partly covered up with loosened earth. Some cultivators plough the land three times at the beginning of the rains instead of turning it up with a hoe, but the more general practice is simply to run deep furrows through the land in September, and then place the cane-pieces longitudinally along the bottom. The space between the furrows varies from 2 to 3 feet. Before planting, the land is cleared of grass and weeds. Ten days after the cane-pieces have been planted, the earth is loosened between the holes and the sets further covered with mould. In the beginning of January the earth is once more loosened and the plants again covered up. About May the land is once more cleared of weeds and the cane left till August or September, when they are stripped of old and withered leaves. They are then cut close to the ground. The branches at the top are given to cattle as food and the tops preserved for planting. The remainder of the cane is divided into two pieces, tied up in bundles, and carried to the mill.

Generally three or four young shoots, or ratoons, spring from the old stool. If these are sufficiently thick, no new plants are put down after the cane has been cut, but as a rule cane-tops are planted in the intervals between the ratoons, after the land has been cleared of grass and weeds. These tops are about 5 inches long and are planted from November to January. After the second year's crop the land is either left fallow for a year, or again is replanted with cane-tops and left fallow the following year. Mr. Bridges gives the cost of cultivation in a plantation worked entirely by hired labour as Rs. 90 per acre. The greater number of cultivators, however, work the land themselves with their families, and the average cost of cultivation is calculated at Rs. 15 to Rs. 20 per acre. With regard to the outturn of jaggery per acre, Capt. H. Desvaux states that in the Kyakto district (Settl. Rept., 1898, 58) the average from Class I. soil is 2,934·05 lb.; from Class II. soil, 1,648·76 lb., and in the Toungoo district (Settl. Rept., 1900, 57) the first-class average is 6,733 lb. per acre. [Cf. Bridges, Sugar-cane in Brit. Burma, 1885; Settl. Operat. Repts. Burma; Max and Bertha Ferrars, Burma, 1900, 85; Niabet, Burmania under Brit. Rule and Before, 1901, i, 366, 445.]

MANUFACTURE.

INDIAN INDUSTRY.—Popularly it is often said that there are two main kinds of sugar—"Muscovado" (or raw) and "Crystals." The

951
Grades of Sugar.

Former is refined or worked up into loaf sugar. In India a more comprehensive classification is necessary. The following are some of the chief grades, and the more generally used vernacular names for these:—(1) The Cane Juice is ras; (2) The Refuse (Meggass) is pata; (3) The Jaggery or Raw Sugar is gur or guł (this is practically the Muscovado of the West India planters), but when more carefully prepared and dried to a greater extent, it is sometimes clarified with lime and forms a sort of low-grade sugar. This is, in fact, the sugar of the well-to-do cultivators and middle classes of the population of India as a whole. (4) When intended to be refined, the juice is not boiled down to the extent of gur, but is sold in a more liquid condition known as rāb. (5) Molasses and Treacle are two grades of the uncrystallisable sugar drained from gur, and to a less extent from rāb. They are known as bhira, choa, lapta, matth, etc., for molasses, and putri lat for treacle. (6) Country Sugar is a higher grade article than the sugar of (3) above. The juice has been boiled to a greater extent than for gur, and on cooling it is stirred with a stick till it thickens. It is not, however, refined, though fairly well drained of its molasses, and is known as lat-shakar, khānār, bhura, choyanda, etc. (7) Sugar Refined. This is often called White Sugar. The rāb is generally boiled, clarified and the scum (shira) removed, then drained of its molasses. It is at this stage called putri or, carried farther, it is washed completely free of molasses and then crystallised, when it is khand. For this purpose putri is placed in a long conically shaped basket lined with fine cloth and suspended, water in a finely diffused state being the while made to pass through. The water is derived from a layer of moist aquatic weeds placed on the top for that purpose. The weeds part gradually with the water, which is seized by the sugar. The layer of crystallised sugar formed immediately below the weeds is again and again removed until the whole has been crystallised. In place of lime various other substances may be used in the clarification, such as the ashes of certain plants or impure carbonate of soda. Milk may be employed, as also the mucilaginous substances of certain plants, such as Hibiscus, Kyaltia, etc., or, more rarely, oils are added to the boiling rāb. These mucilages coagulate, and in doing so bind up the impurities which are then skimmed off.

The various qualities of khand are recognised according to their position in the straining-basket. The top layer, the middle portion and the bottom, all constitute separate grades recognised in the trade. So also the khand of different localities have reputations of higher or lower merit. But the greatest possible diversity of opinion prevails as to the exact value of the names given to these different qualities. The clarifying and crystallising of sugar by the Native methods, thus briefly outlined, is supposed to involve such special knowledge that it is rarely attempted except by experts, and hence every village community possesses, or formerly possessed, its small refining factories. From the skimmings (shira), as also the pata, vinegar is prepared in some parts of the country (see p. 1109).

Sugar-candy or Twice-refined Sugar.—In Indian trade three widely different substances are returned as sugar-candy—misri, kuza misri, and chini. In the preparation of all three, khand is dissolved in water, boiled, and milk used in its clarification. Slightly different systems of production prevail, but these need not be detailed. The result is the same, namely, the white crystalline sugars known as misri and chini. These
are bleached and dried by exposure to the sun until they form fairly white and clean sugars. 

\textit{Kusa khand} is alone the equivalent of the English sugar-candy. When this is to be prepared, the boiled and clarified \textit{khand} is thrown into an earthen vessel in which have been suspended threads. The sugar on cooling crystallises on these and on the sides of the vessel in the form of large crystals. Certain localities are famed for their \textit{kusa khand}, such as many parts of Rajputana, Bikanir for example.

Crude though the methods may be which are pursued in the production of the various Indian sugar products, they very possibly give the suggestion of the original conceptions upon which the skilled art of sugar manufacture and refinement rests. In India, the canes of a certain neighbourhood are carried to a central locality where a crushing-mill, usually of two vertical iron rollers driven by bullocks, is owned in common by a group of cultivators. The cane is crushed and the juice boiled down there and then to \textit{rodb}, the \textit{megass} being used as part of the fuel. The \textit{rodb} is then carried to the village or homestead where its further treatment is pursued, or it is sold to the dealers and in that form retailed, or is conveyed to the refinery, where it is worked up into sugar, etc.

The \textit{Agricultural Journal of India} (ii., pt. i., which I have just received) contains three papers on sugar. Moreland deals very fully with the present position of the indigenous method of sugar manufacture and the difficulties with which the manufacturer has to contend (l.e. 16-21). Lehmann gives many practical suggestions for the improvement of the methods and contrivances that prevail in Mysore. "The Indian sugar-cane," he says, "at least that grown in Mysore, is of excellent quality, and labour is relatively very cheap, less than one-seventh of what it is in Louisiana, where large quantities of sugar are produced notwithstanding that the quality of cane is very much inferior to ours. In the present method of manufacture heavy losses occur. The average of a number of experiments indicates that more than one-fourth of the total quantity of the juice is left in the refuse, that with a larger mill one-third of this loss can be saved (still larger mills would probably save two-thirds), that as much as 20 per cent. of the total sugar in the juice is sometimes lost by fermentation, and that, as a rule, over 13 per cent. of the total juice is lost by underliming. On the whole, the losses amount to at least one pound out of every five, that is, for every four pounds of sugar now obtained at least five could be got by stopping these heavy leaks, and probably the quantity of cane now giving three pounds of white sugar would as a rule give four pounds of such sugar when these losses are prevented."

"This would probably be quite sufficient to transform a crippled industry into a flourishing one. But there are further savings which can be introduced by manufacturing directly from the cane a sugar of much higher grade than is now being done when making jaggery. Part of this sugar, without being refined, could directly replace a portion, and possibly a very large portion, of the sugar now imported, and the rest could be sent to the refinery for conversion into the highest grade of sugar, being thus transformed with a better outturn and at much less expense than an equal weight of jaggery."

\textbf{EUROPEAN INDUSTRY.}—The stages, methods and appliances used in the European factories may be exhibited briefly as follows:

1. \textit{Extraction of Cane-juice.}—The different methods pursued have been grouped under (a) Disintegration in crushing-mills; (b) Maceration; and (c) Diffusion.

By the last process, instead of being crushed in a mill (as already described), the canes are cut longitudinally in a slanting direction into slices one-sixteenth of an inch in thickness, by special cutting-machines. Very much less power is said to be required for this operation than for crushing by roller mills. The slices are then conveyed to an apparatus known as the diffusion battery. This consists of a series of cylinders, connected with each other, in which the sliced cane is subjected to water at a high temperature. This coagulates the albumen and extracts the sugar from the cells. It has been stated that 84 to 86 per cent. of the 90 to 91 per cent. sugar present is thus obtained, or about 20 per cent. more
than by the roller system. The juice, moreover, is of greater purity owing to the coagulation of the albumen. The defecation of the juice is thus rendered far more simple and easy, and is eventually drawn from the battery free from glucose and of a pale straw colour.

**II. Defecation and Clarification.**—These operations consist of various stages, such as straining, heating, tempering, bleaching and filtering. The most important of these is defecation or tempering with lime (see *Lime*, p. 712) or other chemical substance, which, combining with the acids liberated, as also with any carbonates that may be present, precipitates these in the form of insoluble compounds (see *Alkaline Earths*, p. 58).

**III. Concentration and Granulation.**—The purified cane-juice has now to be freed of much of its water so as to allow of crystallisation. This may be accomplished by heat, either in open pans (the Native method) or in basins heated by steam or boiled in vacuum pans. In the last-mentioned process the grain formed from syrup boiled *in vacuo* is larger and more solid than from syrups simply concentrated to crystallising point in open batteries. Formerly the crystallisation was effected by cold, the Chevallier process.

**IV. Curing.**—The last stage embraces the complete drying and the whitening or bleaching of the sugar. This may be accomplished by simple drainage, as in the Native process above briefly indicated. In European trade, sugar simply drained of its molasses from casks placed over tanks was known as "Muscovado," "grocery sugar," "brown sugar," etc. The trade in this form is nearly obsolete. The claying of sugar corresponds with the washing with water derived from a layer of aquatic weeds. In the European method, a layer of clay used formerly to be placed over the sugar, upon which water was poured. The water percolated through the clay, removed the non-crystallisable sugar, the colouring matter and other impurities. The sugar was thus washed and, through the removal of the insoluble sugar, was in time also dried. But these and other primitive methods have been superseded in all the larger factories by centrifugal driers or hydro-extractors. There are many forms of this, but all consist essentially of a cylindrical basket revolving on a vertical shaft, its sides being of wire gauze or perforated metal. The basket is surrounded by a casing at a distance of about 4 inches, the annular space thus left being for the reception of the molasses expelled by centrifugal force through the sides of the basket, when the latter revolves at a high speed.

**Improvement of Indian Industry.**—It would be quite possible to perfect the small hand factories of India to enable them to turn out at a cheaper rate than at present a much superior sugar. In many respects sugar manufacture and refinement are eminently suited for the hand labour and small capital of the village communities of India, but machinery and chemistry the world over are depriving all such communities of their handicrafts, and the salvation of the Indian sugar-manufacturing industry, it is feared, must be rather looked for in aids toward the establishment and encouragement of power factories, where the most advanced methods and contrivances will be used, rather than in subsidies to effete and wasteful crafts. Mr. H. F. Walker of Brisbane, Queensland, in a most instructive communication (*Bihar Sugar Comm. Rept.*, 1901, app. No. 5), discusses fully the system by which the industry has been substantially aided in that Colony. Moreland (app. No. 4) gives many

954
practical suggestions both as to methods of cultivation and systems of manufacture that might be adopted in Bihar. Minchin has strongly urged the Bihar planters to adopt the diffusion in place of the crushing system of treatment of canes. [Cf. Burkill, *Agri. Ledg.*, 1903, No. 8; Burkhill and Weinberg, *Agri. Ledg.*, 1903, No. 12; Chapman, *Sugar, Enoeel. Brit. suppl.*]

Perhaps one of the most hopeful directions of immediate improvement was dealt with by O’Conor, Hamilton and Handcock in their *Bihar Sugar Commission Report* (1901), where they discussed the advantages of the central-factory system. They studied critically the whole question of the cultivation of cane and the combined manufacture of sugar and indigo. While setting forth many agricultural and other reforms they advocated most strongly the adoption of the system of central mills and refineries as the most economical method of manufacture. But it may be urged that the possibility of the combination of two such widely remote technical industries as the production of sugar and of indigo, is the weak point of the scheme. Whichever proved the more profitable would secure the greater attention, until one or other might be ruinously neglected. Moreover, the power required for the one may very likely prove unnecessarily large and expensive for the other. But that reforms are not impossible with India generally can be seen from an inspection of the splendid results attained by Mr. F. J. V. Minchin at Aska in Ganjam. In 1852 he settled in that district, and in his own lifetime built up a great enterprise which has been described as having become the dominant feature of the trade and prosperity of a wide area. His example is one that might well be followed in every sugar-cane growing district in India both by Natives and Europeans, but in each centre a Minchin is required.

**By-products.**—The by-products of the sugar factory are most important. The *megass*, or bruised canes, left after the extraction of the juice or *ras*, is in India usually employed as part of the fuel required for boiling down the juice. Minchin holds that by the diffusion process the whole of the sugar is removed from the cane, while by the Native process a large amount still remains. To prove this point, he purchased locally 40 tons of *megass*. Passing this through his apparatus, he was able to obtain from each ton 50 gallons of molasses, which yielded 30 gallons of spirits of proof strength. Assuming an equal loss all over India, he made a calculation which he graphically represented by saying that the saving effected would go far to meet the interest of the public debt in India.

So again, it has often been said that the *megass* might be employed in paper-making; but in the greater part of India, at any rate, the difficulty of procuring firewood and the cost of collecting and transporting *megass* to the paper-mill would very possibly argue in favour of its present utilisation. In the United Provinces it was estimated that the fuel required for boiling and making the *gūr* from an acre of cane would be 108 maunds dry cane-refuse, 50 maunds dry cane-leaves, worth say Rs. 5, and about 5 maunds firewood worth Rs. 2. If firewood alone were used, 108 maunds, costing with cartage to the field say Rs. 31, would be necessary. There is thus a saving of Rs. 24 by using all the *megass* supplemented with firewood as compared with firewood only.
THE SUGAR-CANE PLANT

[SACCHARUM OFFICINARUM

Trade

Rum and Spirits.—The combination of a rum or spirit distillery with the sugar factory has been often maintained as highly profitable, and by others used as an argument against the extension of sugar factories. Country brands of rum are said to be often coloured and flavoured in order to be sold as brandies and whiskies. The spirit produced pays a duty averaging from Rs. 4 to 6. The most important factory of this kind is the Rosa at Shahjanpur in the United Provinces (see Spirits, p. 1046).

Chunam.—In passing it may be here mentioned that sugar is universally used in some form along with lime in producing the much-famed chunam plaster (see p. 293).

TRADE IN SUGAR.

Centuries may be accepted as having intervened between the discovery of sugar and the time when it began to be a necessity of European life. We read of early transactions with India, which may be indicated by the following:—In Birdwood and Foster (E.I.C. First Letter Book, 338) mention is made in the commission of certain ships sailing for the East Indies in 1609, that they were to procure "sugars of the best some twenty chests for a trial." In a similar commission (1611, 407) we read again, "sugars of the best some few chests for a trial." In one of the Factor's Records from Surat, addressed to Sir Thomas Roe in 1616 (Foster's E.I.C. Letters, iv., 327), occurs the observation—"We deny not but that Bengalla brings wheat, rice, and sugar to Indya" (Hindustan proper), "makes fine cloths, etc., which showeth the fertility of the country and the quality of the inhabitants," etc., etc. In a letter of date December 28, 1617 (l.c. vi., 280), Edward Monox threw doubt on the desirability of complying with the Company's indents for Surat sugar. He urges that the sugar is a light, spongy article, "which I am persuaded with the damp of the hold coming into our moist climate will moulder and break to pieces and thereby prove unsaleable; besides it hath such an oily taste that it will not please our English palates." Indian sugar, however, gradually assumed importance in Europe, and on cane cultivation being established as a European industry in the British Colonies, it obtained a fresh impetus. But the birth of the Colonial was the death of the Indian trade with Europe. The Honourable Company of East India Merchants becoming aware of the loss India had sustained in its failure to create, or even to participate in the greatly increased traffic, made strenuous efforts to awaken interest in the subject. Although many obstacles were thrown in the way, the Company succeeded in reviving and greatly enlarging India's foreign interests in sugar. Heavy losses were for years patiently borne in the hope of ultimate success. East Indian sugar became regularly quoted, and it improved in quality as time went on. Moreover, the internal trade of India itself gave distinct indications of expansion. The demands of the people for superior qualities had grown so strong that the imported refined article gradually came to bear, in the various languages and dialects of the country, names that denoted the foreign countries of supply, such as chini (China) and misri (Egypt). There is, in fact, abundant evidence that for centuries the art of refining was not generally known to the people of India. According to Chinese records the knowledge would appear to have been derived from

956
Egypt, and according to Indian, most probably long subsequently, from China. A century or two ago the people of India, therefore, consumed a far larger proportion relatively of crude sugar (gur) than they do even to-day. But the East India Company were wise in directing their attention to the internal trade: the demands of Bombay were obviously the most natural outlet for the surplus stock of Bengal, and the best check that could be given to the Dutch trade in supplying Bombay with sugar. But to facilitate this, the transit dues on sugar were removed and an import duty placed on the foreign supplies. Even when thus protected the Indian sugar did not, however, assume control of its own markets. Large supplies continued to be drawn from Egypt and China, as well as from Batavia and the Straits, and it was accordingly recognised that an effort must be made to improve the cheaper Indian refined sugar, more especially since still newer and more formidable producing centres had arisen in Mauritius and the West Indies which began to contest the Indian markets. And still more recently a disturbing element appeared in the supplies of cheap beet sugar, poured into India from Europe. Thus had India not only lost her European market but had become a field for European commercial enterprise in the provision of cheap refined sugar. But there has been secured at least one advantage of this new supply, namely the vigorous education of the people of India in the advantages of refined over crude sugar, and thus the opening out of a large market of which the Indian refineries have recently not been averse to avail themselves, and may do so still further in the future. It can thus be said that the people of India are able to pay a far larger sum not for sugar alone but for many other luxuries, than they ever did at any period of their past history. Further that the home market, by far the most important to the producers in India, is still largely secured to them. This is abundantly shown by the Finance Minister of India (Gaz. of India Extraordinary, March 21, 1906) by a table which exhibits the prices of refined beet-sugar at Calcutta and Bombay, and of Indian raw sugar at Cawnpore, for a number of years ending 1905. The averages of these for the past eight years would be—Calcutta, Rs. 10-14-7; Bombay, Rs. 11-7-0; and Cawnpore (gur), Rs. 5-11-0.

Counterbalancing Duty.—It has been urged, moreover, that about the time beet-sugar first appeared in Bombay, a series of bad years, which culminated in the famine of 1901-2, curtailed Indian production and opened the door for foreign sugar. So firmly, at all events, have the foreign imports been established, that the trade is by many believed to be secure and to have given evidence of an expansion rather than a curtailment. A duty was accordingly imposed in March, 1899, on bounty-fed sugar from foreign countries. It was framed with the intention exclusively of countervailing bounties paid, directly or indirectly, by foreign Governments. This produced an appreciable revenue, which amounted in 1901-2 to 37 lakhs of rupees (and in the six years of its existence to 94½ lakhs); still, it did not stop the influx of cheap European sugar. The closing of the American markets diverted a still larger supply to India, and the Enactment of 1902 was intended to countervail this artificial surplus. The action of the Indian and American Governments thus forced the ratification of the Convention of Brussels. The immediate effect of the Indian duties was to diminish the sugar imports from Europe, and to divert the trade previously carried on with India by Germany and Austria, to countries which did not come within
the scope of the new legislation, and thus liberated fresh supplies of cane-sugar that poured into India. The imports of beet sugar in 1902-3 became about half those of 1901-2, while the imports of cane-sugar, which come mostly from Mauritius, Java and China, increased by more than 40 per cent. Finally, "in December, 1903, orders were issued remitting the countervailing duties chargeable on sugar produced, after August of that year, in countries which have limited their direct or indirect bounties on sugar, and their protective duties, to the minimum permitted by the Brussels Convention of 1902." (Imp. Gaz., iv., 265). Sugar is thus now once more admitted into India free of all legislative restrictions, except the ordinary import duty of 5 per cent. on all foreign goods, and the countervailing duties against sugars produced in or exported from certain countries (Denmark, Chile, the Argentine Republic, Russia, etc.) which have not adhered to the Brussels Convention.

It may be said that the consumption of raw sugar is mainly in Northern India, and of foreign refined sugars almost entirely in Bombay, Calcutta and other large towns, more especially port towns. But it will be seen below, in the review of internal trade, that the railborne traffic manifests an expansion of the supply of refined sugar carried to the north, and thus to the regions of chief Indian production.

**Mills and Refineries.**—According to the *Financial and Commercial Statistics*, there were 28 sugar factories in India in 1904 and 4,612 employees. Of these 19 were in Bengal with 1,772 employees; 6 in Madras with 1,979 employees; 2 in the United Provinces with 747 employees; and one in the Panjâb with 114 employees. The Government of India does not record any factories where less than 25 persons are employed, so that there are crude refineries, scattered all over India, not taken into consideration, that nevertheless turn out a certain proportion of the refined sugar used by the people of India. In Eastern Bengal (Jessore more especially) there are many small refineries chiefly concerned in the production of date-palm sugar. Similarly the indigenous refineries of Bihar and Shahabad are by no means unimportant, though apparently the trade has greatly declined through the competition of beet-sugar.

**External Traffic.**—This resolves itself into two sections, Exports and Imports. It may be the most instructive course to deal with these more or less historically.

1. **Exports to Foreign Countries.**—An import duty on Indian sugar, which was practically prohibitive, was imposed by Great Britain. It came to 8s. a cwt. *more than was taken on Colonial sugar*. This disability existed until 1836, the effect of which may be seen by the following figures:—In 1800 the British imports from India (expressed as raw sugar) came to 120,471 cwt. out of a total of 3,390,974 cwt.; in 1821 the corresponding figures were, Indian portion 277,228 cwt., out of a total of 4,063,541 cwt. Some twenty years later (1841, or five years after the removal of the disability on Indian sugar) the Indian exports to Great Britain became 1,037,501 cwt. In 1851 the corresponding exports from India to Great Britain were 1,506,051 cwt. (out of a grand total of 1,607,508 cwt. exported to all countries), but the next decade marked a great shrinkage, as the exports to Great Britain then stood at only 696,012 cwt. out of a total to all countries of 845,961 cwt. And these figures (though expressed on the basis of raw sugar, viz. 2½ to 1) mark the existence of a new disturbing element. The East India Company found in its early transactions that it only paid
to export the purer article, and indeed sugar (even of the finer qualities) was treated as a ballast cargo, to be used in place of salt petre as occasion required. In none of the returns, therefore, were these exports raw sugar, though expressed as such. They were entirely Indian refined sugar, drawn from the indigenous refineries. It would not pay (so it was believed) to export raw or inferior sugars from India, the freights being then too high. With the growth of refineries in England and Scotland, however, combined with greater facilities of shipping and consequent cheapening of freights, it no longer paid to ship the refined sugars, and the consignments became more and more raw sugar to be used up by the British refineries.

The effect of this change may be briefly indicated. In 1877–8 the exports of refined sugar stood at 477,128 cwt. A sudden drop occurred in the next year, when these exports were only 51,043 cwt., and ten years later (1888–9) were only 34,523 cwt. But, correspondingly, the exports of raw sugar were in 1877–8, 360,997 cwt. The average for 1882–92 came to 1,145,685 cwt.; for 1892–1902, 733,654 cwt.; the actual for 1904–5, 192,890 cwt.; for 1905–6, 230,498 cwt.; and for 1906–7, 164,299 cwt.

Thus there can be no doubt that a severe blow has been dealt to the Indian sugar industry, which, but for its own immense resources and recuperative power, might have been calamitous. Had England continued to purchase Indian raw sugar there is little doubt an immense expansion of the area of production, and an enhancement of the yield, would have been the natural consequences. All this is now changed, and sugar represents 53.3 per cent. of the total value of the articles of food and drink imported, and is the second largest single article of importation, the first being cotton piece goods. Thus the two chief items of India’s early export trade have become her greatest modern imports.

2. Imports from Foreign Countries.—It is perhaps not necessary to trace the history of the imports of sugar farther back than to the year 1871–2. India then received 562,559 cwt. of crystallised sugar. In 1881–2 the imports were 982,262 cwt. and in 1891–2, 2,734,491 cwt. Still a decade later (1901–2) they had become 5,565,272 cwt., and roughly in equal proportions of beet and cane sugar. Taking the traffic in both refined and unrefined sugars, the following year (1902–3) a shrinkage of the beet-sugar took place, the total imports being 4,987,195 cwt. (of which 3,529,678 cwt. were cane); in 1903–4 beet still further declined, the total having been 6,038,115 cwt. (5,485,378 cwt. cane); in 1904–5 the beet began to recover, and the total imports were 6,549,797 cwt. (4,833,309 cwt. cane); in 1905–6 they were 7,696,191 cwt. (4,263,798 cane and 3,432,393 cwt. beet); and lastly, in 1906–7, they were 9,730,713 cwt. (5,926,879 cwt. cane and 3,803,834 cwt. beet) (Rev. Trade Ind., 1906–7, 8–9).

Mr. Frederick Noel-Paton, Director-General of Commercial Intelligence, observes that beet-sugar continues to rule the Indian sugar-market; he further exemplifies the extraordinary vicissitudes of the trade by a statement of the imports of beet and cane sugar, month by month, during the year 1905–6. It is there shown that beet-sugar reaches India mainly in the months of November to March, the last-mentioned month being the most important, while cane comes more uniformly throughout the year, the chief months being August to October. Analysing the returns, it is found that 3,432,393 cwt. were beet, the average value of which was
THE SUGAR-CANE PLANT

Supply

Influences on Prices.

Decline in Prices.

Cost Price.

Java.

Countries of Supply.—Of the cane-sugar perhaps the most significant feature is the rise and growth of the Javan contribution, very largely conveyed to Calcutta. In 1901–2 the total imports from Java were 446,686 cwt.; in 1903–4, 1,335,548 cwt.; in 1905–6, 1,685,391 cwt.; and in 1906–7, 3,304,366 cwt. A fair proportion of these were cheap unrefined sugars, No. 16 and under, intended to directly contest Indian production of gur. The trade from Mauritius has for many years past manifested a consistent and almost uniform expansion. In 1901–2 it came to 1,759,203 cwt., in 1905–6 stood at 2,013,012 cwt., and in 1906–7 at 2,310,023 cwt. The only other country that need be mentioned is China. The contributions from that country manifest extreme fluctuations, but on the whole seem declining. The highest record during the past five years was in 1902–3, while the figures for last year (1906–7) were the lowest, viz. 51,279 cwt. Of beet-sugar, Austria-Hungary is by far the most important source. As already mentioned, the years 1902–3, 1903–4, and 1904–5 manifested a marvellous curtailment, but the amount taken in 1901–2 was 2,257,928 cwt.; in 1905–6, 2,340,717 cwt.; and in 1906–7, 1,617,160 cwt. Commenting on these new aspects of the trade, Noel-Paton observes, "Of the refined sugar, Java, which in 1905–6 ceded the premier place to a beet-country, Austria-Hungary, resumes it (1906–7) with a quantity largely exceeding that ever before imported from a single country. She supplied, in fact, nearly 31 per cent. of the entire arrivals. The other cane country, Mauritius, follows with 24·61 per cent. of the
PRODUCTION AND CONSUMPTION

total. Austria-Hungary, diminishing her contribution by nearly 723,500 cwt., drops to the fourth place with 17.53 per cent. of the total; and Germany, with the largest arrivals she has yet recorded, takes third place with 21.7 per cent."

Thus it may be said that the Mauritius supplies of cane-sugar have hitherto been to Bombay what the Javan have been to Calcutta. But all the same, beet-sugar may be viewed as having begun seriously to contest both these markets.

INTERNAL TRADE.—Production and Consumption.—It has been estimated that India produces a little over one ton per acre of gur (crude sugar), or 2\(\frac{1}{2}\) million tons for its total acreage, which, reduced to the standard of refined sugar, would be, say, one million tons. If the imports of about 400,000 tons be added, we obtain a total supply of \(\frac{1}{2}\) million tons of refined sugar. Divided by the head of population, this might be accepted as showing the consumption. But any such calculation would be most misleading, because (1) we have no sort of certainty as to the yield—a ton of gur per acre seems absurdly low; (2) to the bulk of the people a pound of gur very possibly serves the equivalent purpose of a pound of refined sugar to other communities; and (3) with a large percentage of the people of India gur or sugar are unknown luxuries. It has been stated that the per capita consumption of India is 35 lb., a figure based on the assumption that the supply comes to three million tons, which from the above showing is probably double the actual amount. This is compared with European countries, such as Germany, where it is 28 lb., and France 24 lb. There is perhaps little to be gained by such calculations and comparisons. But it may be useful to examine the returns of gur carried by rail and river as indicative of local production and consumption.

Traffic by Rail and River.—The internal trade is returned in cwt. and divided into two sections—(a) refined sugar and (b) unrefined sugar. The grand total of the movements of the former kind came in 1906–7 to 5,984,425 cwt. Fully three-fourths of that amount is usually distributed from the seaport towns, and thus includes (with local manufactures) the foreign imports. The shares taken were:—Bombay, 2,039,492 cwt.; Karachi, 1,863,451 cwt.; Calcutta, 1,248,595 cwt.; and Madras, 111,368 cwt. And these figures are relatively correct for at least the past five years. The Calcutta supply ordinarily goes to Eastern Bengal and Assam, 572,591 cwt.; to Bengal, 363,641 cwt.; and to the United Provinces, 235,573 cwt. The Bombay supply goes to the Bombay Presidency, 843,067 cwt.; to the Central Provinces, 367,255 cwt.; to the United Provinces, 358,530 cwt.; and to Rajputana and Central India, 241,368 cwt. The Karachi supply goes principally to the Panjab, 1,427,823 cwt., and to Sind, 345,593 cwt. But Calcutta has, however, manifested a remarkable expansion which is most significant. In 1900–1 exports from Calcutta by rail and river were 477,636 cwt.; in 1901–2, 505,789 cwt.; in 1902–3, 567,200 cwt.; in 1903–4, 839,210 cwt.; in 1904–5, 1,002,185 cwt.; in 1905–6, 1,059,416 cwt.; and in 1906–7, 1,248,595 cwt. This perhaps is the direct expression of the expanding foreign imports. Thus in 1900–1 Bengal (Calcutta mainly) imported 1,342,034 cwt. of refined or crystallised sugar, and that figure was gradually augmented until in 1904–5 it stood at 2,107,461 cwt., in 1905–6 at 2,197,303 cwt., and in 1906–7 at 3,305,860 cwt. The increasing importance of Calcutta in the foreign sugar trade is a feature of great consequence.
THE SALEP PLANTS

Of the consuming provinces it is curious to observe that in 1906–7 the Panjáb heads the list with 1,664,133 cwt.; then comes Bombay, 869,528 cwt.; the United Provinces, 712,559 cwt.; Eastern Bengal and Assam, 603,223 cwt.; Central Provinces, 487,717 cwt.; and lastly, Bengal, 465,493 cwt. These figures would seem somewhat at variance with the opinions often advanced (and mentioned above) that the imported sugars are mainly consumed in the regions of low Indian production. By way of illustration it may be mentioned that the imports into the United Provinces by rail were in 1900–1, 316,722 cwt.; in 1901–2, 492,921 cwt.; in 1902–3, 385,125 cwt.; in 1903–4, 614,355 cwt.; in 1904–5, 533,580 cwt.; in 1905–6, 752,091 cwt.; and in 1906–7, 712,559 cwt. These provinces are the headquarters of Indian cultivation, and even there foreign sugars seem to be finding a profitable market.

The traffic in Unrefined sugar carried by rail and river came in 1906–7 to 9,420,832 cwt.: The chief exporting centres (as might have been inferred from the Agricultural Statistics) are the United Provinces with, in 1906–7, 4,054,814 cwt.; consigned to the Panjáb, 1,479,307 cwt.; Rajputana and Central India, 1,395,901 cwt.; Bombay, 363,912 cwt.; Bengal, 287,866 cwt.; the Central Provinces, 204,988 cwt.; the balance in smaller quantities. Next may be mentioned Calcutta with 1,958,828 cwt.; to Bengal, 1,005,932 cwt., and to the United Provinces, 468,063 cwt. Then Bengal, with an export of 1,190,857 cwt.: sent to the United Provinces, 380,831 cwt.; Calcutta, 250,290 cwt.; the Central Provinces, 198,377 cwt.; Eastern Bengal and Assam, 159,380 cwt.; Rajputana and Central India, 121,374 cwt. The other exporting centre is Madras, 887,837 cwt.: to Madras ports, 361,693 cwt.; Bombay, 215,871 cwt.; and the Nizam's Territory, 137,659 cwt.

We thus learn that Rajputana and Central India were the most important consuming provinces of the gür carried by rail and river, viz., in 1906–7, 1,857,989 cwt.; then followed the Panjáb, 1,608,556 cwt.; then Bengal, 1,331,406 cwt.; next the United Provinces, 920,815 cwt.; Bombay, 822,158 cwt.; Central Provinces and Berar, 801,722 cwt.; and Eastern Bengal and Assam, 724,821 cwt.

Perhaps the most significant fact brought out by these returns is the dependence of Rajputana and Central India, as also of the Panjáb, for their supplies of gür on the provinces of India, and for crystallised sugar on foreign countries. Another very striking peculiarity is the small share taken by the Madras Presidency in the returns of internal trade, a circumstance perhaps due to the greater success of the Aska and other Madras Presidency mills in meeting local demands.

Coastwise: also Trans-frontier.—These do not in any material respect modify the chief features of the internal trade, and need not therefore be here specially reviewed.

SALEP.—The name given to the dried tubers of various species of orchids, such as Eulophia (D.E.P., iii., 290–1) and Orchis (D.E.P., v., 492–3). It is commonly known in India as salab-—(or salep) misri (= Salep of Egypt).

According to the authors of Hobson-Jobson, salep is correctly identified by Ibn Baithar with the satyrium of Dioscorides and Galen. Perhaps the earliest reference to salep, in connection with India, is to be found in the Voyages of Ibn Batuta, of date 1340 (French ed., 1855, iii., 382), where amongst the provisions given to the travellers by the Sultan of Delhi, salip is mentioned. Again, Alexander Hamilton (New Acc. E. Ind., 1727, i., 124–5) speaking of Tatta on the
SALT

COMMON OR TABLE SALT

SODIUM CHLORIDE

river Indus, says: "They have a fruit, that grows in their fields and gardens, called salob, about the size of a peach, but without a stone. They dry it hard before they use it, and being beaten to a powder they dress it as tea and coffee are, and take it with powdered sugar-candy. They are of opinion that it is a great restorative to decayed animal spirits." The article obtained in the Indian bazâra has been ascertained to be chiefly the product of several species of属atom, viz. E. campestris, E. indica and E. vicinus (mankind or Lahore sailép of the shops), though probably also from the species of a few other genera, and is produced on the hills of Afghanistan, Baluchistan, Persia and Bokhara; but the Nigir hills and Ceylon are said to furnish part of the Indian supply. The salep of European commerce is procured chiefly from the Levant, and to some extent from Germany, etc., derived mainly from the tubers of Orchis mascula. The tubers are dug up after the plant has flowered, and the plump, firm ones are washed and set aside, and subsequently strung on threads, scaled, and dried in the sun or by artificial heat. The commercial article is met with in three forms—palmate, large ovoid, and small ovoid.

Various substitutes are sold in India. The kind known as Royal Salep (bâdshah salab) has been identified as being derived from a species of Allium (A. Macleayan, Baker, Bot. Mag., t. 6707; Aitchison, Annals of Botany, 1869-90, iii., 140-55); while the tuberous roots of Asparagus asperatus (West Himalaya and Panjâb) and of A. racemosus (Deccan) are the white musâli (D.E.P., 1., 333-6); Curculigo orchioides, the black musâli (D.E.P., ii., 630-1), and certain species of Habenaria are also so used (Watt, Comm. Letters, Upper Ind., 1894, 13). Besides these substitutes an imitation salep, made of potatoes and gum (known as banawati salab), is largely manufactured for the Indian market. A considerable Trans-frontier trade exists in salep from Afghanistan, Persia, Baluchistan and Bokhara into India. A little trade is also done in collecting and drying in India itself, mostly Kashmir and Lahoul, the tubers of Orchis latifolia, but the bulk of the ordinary article met with in the country is imported by sea into Bombay from Persia and the Levant. [Cf. Milburn, Or. Comm., 1813, i., 108-9; Pharmacog. Ind., iii., 384-7.]

History.—Salt in India is perhaps contemporaneous with the birth of Indian agriculture. Its most ancient Sanskrit name, Lávana, has few, if any, other meanings than salt or saltiness. Susrata, the father of Indian medicine, speaks of four kinds of salt, and these correspond with the four chief grades known to-day, viz. Saindhava, the rock-salt of Sind and Kohat; Sâmudra, produced from the sea; Romaka or Sákam bari, Sambar Lake salt; and Pánusua or Ushasuta, salt produced from saline earth. In modern commerce, according to Mr. A. S. Judge, there are in Calcutta some thirteen forms or grades of salt, as for example:—

(1) English pânga salt, imported from Liverpool, Middleborough, Hartlepool and Bristol—the bulk coming from the mines of Cheshire. This is consumed in the greater part of Bengal and Assam. (2) Hamburgh—a rock salt obtained from the mines. (3) Aden karkâch salt, manufactured from sea-water by solar evaporation. (4) Aden crushed salt. (5) Rawâyâh karkâch salt—this comes from the African coast of the Red Sea. (6) Rawâyah crushed salt. (7) Salîf karkâch salt—this also comes from a port (Salif) on the African coast. (8) Salîf crushed salt. (9) Salt from the Persian Gulf—this used to be brought by the Arab sailing-ships, but as these are rapidly disappearing the trade is on the decline. (10) Bombay karkâch salt. (11) Spanish karkâch salt—this is im-

963
SALT SODIUM CHLORIDE
COMMON OR TABLE SALT

Ported from Tarravieja in Spain and is obtained by solar evaporation. (12) Port Said karkach salt. (13) Madras karkach salt—this is imported by Calcutta from Cocomada, Vizagapatam and Tuticorin. It is obtained by solar evaporation, has a brown appearance, is gritty, and accordingly not much in demand.

Although India possesses a mountain range of rock-salt, immense beds of salt-bearing soils and a vast extent of salt lakes, as well as many hundred miles of sea-coast where sea-salt might be manufactured, the conviction prevails that it will not pay to carry salt over more than some 300 to 400 miles, by internal routes, from any centre of supply. Moreover, the export traffic of India originates shipping that practically conveys salt as a ballast cargo, the profit being in the return cargoes. It is on these and such-like considerations that Bengal has always been largely dependent on external sources. Owing to the immense amount of fresh water poured into the Bay of Bengal, it does not pay to manufacture sea-salt near Calcutta.

Sources of Supply.—Holland gives the following classification:

"(1) Sea-water, from which 61·8 per cent. of the total production was obtained during the period (1898 to 1903);

"(2) Subsoil water and lakes in areas of internal drainage, in both of which the origin and mode of concentration of the salt are the results of essentially similar natural processes. From these sources about 27 per cent. of the total was obtained; and

"(3) Rock-salt beds, from which 11·2 per cent. of the total was obtained by mining and quarrying."

Mining. Salt Mining in India.—There are three chief centres—the Salt Range of the Panjab, the Kohat hills, North-West Frontier Province, and Mandi State in Kangra district, Mandi. These have produced, for the five years ending 1903, the annual average of 109,000 tons, of which 81 per cent. is obtained from the Salt Range, 14·5 per cent. from Kohat, and 4·5 per cent. from Mandi.

The following particulars may be here given from Holland (I.e., 1905, 83–5):—

Salt Range. The chief deposits of rock-salt are in the so-called Salt Range of the Panjab, where the seams of salt and included marl partings have, where worked in the Mayo mines at Khewra, an aggregate thickness of 550 feet, of which five seams of pure salt make up 275 feet, the rest, known as kolar, being too earthy and impure to be marketable. These beds occur in a formation lying directly underneat beds of Lower Cambrian age, but it is suspected that they may be of Lower Tertiary age, like the other salt deposits of this part of India, and that they have arrived in their present apparently anomalous position by an overthrust of the older fossiliferous beds.

Mining for rock-salt is carried on in the Mayo mines, Jhelum district, the Warcha mines in the Shahpur district, and across the Indus at Kalabagh. The rock-salt in this area varies from white to brick-red in colour, and thus differs in colour from that of the Kohat area.

The most important of the mines in the Salt Range are the Mayo mines near Khewra (32° 39'; 73° 3'). In this area salt-quarrying was practised for an unknown period before the time of Akbar, and was continued in a primitive fashion until it came under the control of the British Government with the occupation of the Panjab in 1849. In 1872 the system of mining was reorganised, and the work now in operation was planned out by Dr. H. Warth, late Deputy-Superintendent, Geological Survey of India.

The rock-salt being raised in the Mayo mines has, on account of its purity, a wide distribution. A recent analysis of one of the seams gave the following results:

In the Warcha mine, Shahpur district, the seam of rock-salt being worked is 20 feet thick, with a one-foot parting of marl, dipping 30° to the N.N.W.

About two miles E.N.E. of Kalabagh on the Indus, rock-salt is worked in open quarries on the east slope of Sanganer hill.

The rock-salt raised in the Cia-Indus mines and Kalabagh quarries is principally consumed in the Punjab and North-West Frontier Province. During the past six years the average annual sales in these provinces amounted to 70,964 tons, or 82.3 per cent. of the total. In the same period the rock-salt sent to the United Provinces averaged 10,049 tons a year, or 11.3 per cent., whilst as much as 5.7 per cent. of the total sales, or an annual average of 4,933 tons, reached as far as Bihar, and small consignments of about 10 tons a year were despatched to Lower Bengal. The average annual amount of 580 tons which entered Sind formed 9.7 per cent. of the sales for the years 1897-8 to 1902-3.

The Kohat salt is grey in colour with transparent patches. It is worked in open quarries, and the masses exposed may be regarded as practically inexhaustible at the present rate of output. In the anticlinal at Bahadur Khel, where the salt is seen to be at the base of the Tertiary system, the beds can be traced for a distance of about eight miles, with an exposed thickness of over 1,000 feet.

In Mandi State rock-salt is worked in open quarries near the faulted junction of the Tertiary and the older unfossiliferous rocks at Guma and Drang. The Mandi salt is of a dirty plum-colour, containing earthy impurities which bring down the available sodic chloride to 60 or 70 per cent.

**Salt-evaporation in India.**—This may be referred to two sections—

(a) direct evaporation of sea-water; (b) subsoil and lake brine. The former is chiefly conducted at Bombay and Madras, these two presidencies usually contributing between them about two-thirds of India's total salt supplies. Holland (l.c. 89-91) observes:

Of the salt produced in Bombay, about 78 per cent. was obtained from sea-water, the rest being manufactured from subsoil brine at Kharaghora and Udu on the border of the lesser Rann of Kach, and possibly derived from infiltrated sea-water. The Madras salt is practically all made from sea-water, a very small quantity of spontaneous salt being collected at Pandraka in the Masulipatam Sub-division.

The chief manufacture of salt in Burma takes place also along the sea-coast, but subsoil brine is evaporated at various places in Upper Burma, notably in Lower Chindwain, Sagaing, Sisbobo, Myingyan, and Yenethin districts, and in smaller quantities in Minbu and Meiktila, as well as at Mawhko in Haipaw State. During the past six years the average annual production of this salt in Burma has been 3,132 tons.

In Sind 88 per cent. of the salt raised during the years 1808-1903 was obtained from sea-water, and 12 per cent. from the Saran and Dilyar deposits on the edge of the great desert.

The second form of occurrence (subsoil and internal lake brine) is characteristic of areas in which evaporation of rain-water is excessive compared to run-off, and the salt recovered in these areas is that merely arrested on its journey to the sea, where, in the same way, it is concentrated by evaporation of the water. The most prominent of such areas is the desert-belt of Rajputana, including the salt-lakes of Sambhar, Didwana, Falodi Lomkara-sur and Kachor-Rewass, with a brine-impregnated subsoil along the whole valley of the Luni, as well as the country to the west in Sindh around the Rann of Kach and the delta of the Indus. To the north of the Rajputana country subsoil brine is raised and evaporated for salt in a cluster of villages in the Sultanganpur mahal, south-west of Delhi. Other places occur in parts of the United Provinces and in Berar, where large quantities of salt were formerly obtained from subsoil brine in the alluvium of the Purna river. In Gwalior State salt is regularly manufactured from subsoil brine, the average annual production during the years 1898 to 1903 having been 434 tons. In Bihar a small quantity of salt is separated in the manufacture of saltpetre. The returns for the past four years in Bengal show an average of 106 tons per annum produced.

**Sambhar Lake.**—F. Ashton (Agri. Ledg., 1900, No. 13), Deputy Commissioner of Northern India Salt Revenue, wrote a brief account of the salt industry of India, also a highly instructive and copiously illustrated statement of the Sambhar Lake salt and the other salt works of
COMMON OR TABLE SALT

**SALT**

**SODIUM CHLORIDE**

Supply

Rajputana (Journ. Ind. Art Indust., 1901; ix., No. 73). He tells us that the salt industry of Rajputana produces about 200,000 tons a year and meets the requirements of 59 millions of people. The Sambhar Lake, it is believed, has been worked for salt for the past 1,400 years. It is about 20 miles in length, the breadth varying from 2 to 7 miles, and it covers an area of 90 square miles. The surrounding country is sandy and sterile, with the great Indian desert to the westward. The density of the lake brine varies with the annual accumulation of water. In years of normal rainfall it is about 3° Beaumé (the density of sea-water), but when very full is considerably less, and during years of drought it may be as high as 10° Beaumé.

The lake was taken over by the Indian Government in 1871, and since that date has yielded 4 million tons of salt. It lies within the boundaries of the Native States of Jaipur and Jodhpur. Holland remarks that “the Sambhar Lake is a silt-filled depression in the Aravalli schists and gneisses, in which a body of mud and sand with kankar and gypseum (some 75 feet thick in what appears to be about the centre of the depression) includes from 2 to 12 per cent. of sodic chloride, with smaller quantities of sodic sulphate, sodic carbonate and potassic sulphate. Every year the water brought in by the rivers, which are in flood during the monsoon, forms a lake some 60 square miles in area and 2 to 3 feet deep. The water, which is fresh when it first comes in, takes up salt from the accumulated stocks in the silt and forms a strong brine, which is partly led into prepared enclosures (kyars) for the separation of the salt by solar evaporation, partly isolated by temporary reservoirs constructed and cut off bodies of the lake-water in anticipation of the recession towards the centre during evaporation, and partly forms a thin crust of white glistening salt on the bed of the lake, where it is allowed to remain until the arrival of the next monsoon and the usual annual flooding of the lake.”

“During the past few years the quality of Sambhar salt is said to have depreciated, and it has been suspected that the large quantities which have been removed have at last made an impression on the great stores of salt which must have accumulated in the lake silt, appreciably raising the proportion of the associated compounds sodium sulphate, sodium carbonate and potassium sulphate.”

In the Records of the Geological Survey (1905, xxxii., 81; xxxiii., 100–2) will be found a highly instructive refutation of the opinion that the supply from Sambhar was decreasing. “The rise in the proportion of other salts is small and possibly at present unimportant; the rise in the level of the silt is perhaps more serious; but, whatever may be the cause, it would be humiliating to watch the failure of this lake, when one knows for certain that it contains, in its uppermost 10 feet of silt, enough salt to supply the requirements of this section of the Salt Department for another 300 years.”

Ashton explained that the manufacture of salt at the lake is dependent upon the monsoon rainfall. “This,” he says, “greatly varies from year to year, and the outturn of salt fluctuates in accordance with the quantity of the brine in the lake. The greatest quantity produced in any one year has been about 260,000 tons, and during a year of excessively heavy rainfall only about 3,300 tons were obtained.”

**Pachbadra.**

After Sambhar, the Pachbadra salt source is next in importance. This is situate in Jodhpur (Marwar, as it is well named—the land of death).
The town of Pachbadra has a population of 5,000, and stands on the right bank of the Luni (the salt) river and at a distance of 40 miles from the city of Jodhpur. The salt is found in the upper end of a sand-valley; the salt-bearing tract being about six miles long and under two miles wide. All over that area brine-springs exist, and from these the salt is manufactured. In 1878 the Government of India purchased by annual subsidy complete control of these brine-wells, the production of which is about 30,000 tons. Pits of an average length of 230 feet and a breadth of 60 feet are dug to the level of the brine-springs and become filled with brine to a depth of 3 feet. Thorny branches of *Lycium europaeum* are thrown into the pits and the salt precipitates on these, thus causing more flow of brine. The density of the brine varies from 20° to 25° Beaumé.

The salt source of Didwana is also situated in Jodhpur at a distance of 40 miles N.W. of Sambhar Lake. The supply of brine is abundant and believed to be inexhaustible, and in the dry climate of the desert manufacture could be carried on for nine months of the year. The rainfall has no effect on the salt-producing capabilities of this source. Since the Government acquired sole rights (1878) about 300,000 tons of salt have been made. The cost of production comes to 10d. a ton and it is sold at 1s. 8d. a ton, but the want of sufficient means of transit restricts the traffic. The Didwana salt is practically all consumed in Rajputana and the adjoining districts of the Panjáb. During the years 1897 to 1903 the annual average production came to 10,502 tons.

These salt-wells thus occur in what may be viewed as a former bed of the Luni river; and lower down in the present basin, just before the river debouches into the Rann of Kach, a large delta is formed through which during floods numerous channels carry the waters to the sea. In the dry months of the year, when the bed of the main stream is perfectly dry, brine percolates into the tributary channels and salt is formed naturally in thousands of tons annually, only to be swept away when the river comes down in torrents with the monsoons.

**THE SALT DEPARTMENT.**—In 1894 the Government of India had a Memorandum prepared, as a prospectus of the systems and methods of the administration of the Indian salt revenue in all its branches and in all provinces. There may be said to be four centres of administration—

1. **Bengal.**—"Bengal and the greater part of Burma obtain their salt by importation. Under the Muhammadan rule a tax was levied on salt by means of imposts on the privilege of manufacture, and by duties on the transport of salt from the places of manufacture to the interior of the country. Later on a system was gradually matured which provided for the control, the manufacture, and sale at the agency to the Company's servants. This was introduced by Clive and perfected by Warren Hastings in 1765 to 1780, and it survived in a modified form till 1862. A Government salt monopoly similar to that which existed in Bengal was introduced in the Madras Presidency at the beginning of the 19th century. In Bombay salt did not become a considerable source of revenue till 1837.

The trade in Cheshire salt rose to importance about the year 1835, and thenceforward imported salt gradually ousted the Native product in Bengal proper, until by 1873-4 local manufacture had ceased and the accumulated stocks had become exhausted. The dampness of the climate
and the large amount of fresh water discharged into the Bay of Bengal by the Ganges and the Brahmputra tell against efficient salt-manufacture on the Bengal coast, but the manufacture of salt was not finally abandoned in Orissa until 1898. Nearly half the salt imported into Bengal comes from Liverpool, and the rest principally from Germany, Aden, Maskat, Jeddah, Bombay and Madras. “Since the construction of the railway along the east coast, Madras salt transported by land has begun to compete successfully with the imported commodity.” [Imp. Gaz., iv., 248; Geake, Repts. Admin. Salt Dept. Beng., 1906; Keith, Repts. Admin. Salt in Burma, etc.]

2. North India.—This embraces the United Provinces, the Central Provinces, Rajputana, Central India, the Panjāb, and the North-West Frontier Province. Its sources of supply are Sambhar, Didwana, Pachbadra and Sultanpur evaporation works, and in addition the salt-mines of the Salt Range of Kohat and Mandi.

Under the Sikh Government salt was one among forty-eight articles liable to customs, excise, town or transit duties. But the Sikh Government did not establish any system of management nor a fixed scale of duties. Since taken over by the Government of India the manufacturing and preventive operations have been directly controlled by the Northern India Salt Departement. “Along with salt duties, the British administration inherited an immense number of transit duties, levied at intervals along the trade routes under a system requiring elaborate customs arrangements and involving an intolerable hindrance to trade and communication. In 1843 the transit duties, with the exception of those on cotton and sugar, were abolished, and the loss of revenue was partly made up by enhancing the Provincial salt duties. The cotton duties were abolished in 1855, while the salt duties were gradually raised until in the period from 1869 to 1877 the salt tax in Lower Bengal was Rs. 3-4 a maund, in the Upper Provinces Rs. 3, in the country beyond the Indus a few annas, and in Madras and Bombay, Rs. 1-13 a maund. The salt sources of Rajputana belonged to the Native States in which they were situated, and duty was levied on their produce when it crossed the frontier. These arrangements could be maintained only by stringent preventive measures. To prevent untaxed Rajputana salt, and the lightly taxed salt from the south and west, from coming into Northern India, it was necessary to maintain a customs-line extending for nearly 2,500 miles, from Torbela, near Attock on the Indus, to the Sambalpur district of Bengal. The line was guarded by an army of nearly 13,000 officers and men, and consisted, along a large part of its course, of a huge cactus hedge supplemented by stone walls and ditches. It must be remembered, however, that this line took the place of a more annoying system of innumerable customs ports scattered throughout the interior of the country.”

“In 1870 the Government of India acquired a lease of the Sambhar Lake, with a view to increase and cheapen the supply in the United Provinces; and in 1874 over 760 miles of the eastern portion of the line were abandoned, the trade in this direction having concentrated itself on the railway route. The necessity of changing the whole system was at the same time indicated by Lord Northbrook, and a few years later Lord Lytton’s Government was able to acquire the remaining salt sources of Rajputana and to equalise the duties throughout the greater part of India. Treaties were made by the Native States concerned, and in 1878 the Bengal
CONSUMPTION AND TAXATION

SODIUM CHLORIDE Trade

duty was lowered to Rs. 2-14 a maund, and the duty in Northern India to Rs. 2-8. At the same time the duty in Madras and Bombay was raised from Rs. 1-13 to Rs. 2-8 a maund. The whole customs-line was abandoned in 1879, with the exception of a portion along the Indus, maintained to prevent the still lightly-taxed Kohat salt from being smuggled across the river” (Imp. Gaz., iv., 250-1). [Cf. Repts. Admin. N. Ind. Salt Dept.; Drew, Jummu and Kashmir, 297–301; Lawrence, Valley of Kashmir, 1895, 393–5.]

3. Bombay.—Salt is produced in Bombay for local consumption and for export both by land-routes and sea to Central India, Rajputana, the Central Provinces, the United Provinces, the Nizam’s Territory, Malabar, Madras, Bengal and the Straits. Under existing arrangements exports, both by land and sea, pay full excise duty to Bombay. By an Act of 1837 the manufacture of salt was placed under restrictions, and both locally manufactured and imported salt were subject to a duty of 8 annas a maund. This was gradually raised until in 1888 it had become Rs. 2-8, and in 1903 was reduced to Rs. 2, and in 1905 to Rs. 1½ per maund. The excise system is followed, viz. licenses are issued to private manufacturers at approved places which are guarded, and whence no removals are allowed except on payment of the duty. In Gujarat all the works in British territory are the property of Government. The two chief centres are Kharaghora on the borders of the Rann and Dharasna on the coast of Surat. The Kharaghora salt is in large crystals made from brine-wells. [Cf. Admin. Repts. Bombay and Sind.]

4. Madras.—Madras salt is practically all made from sea-water. Little is known of the salt system of Madras prior to the establishment of the Government monopoly in 1805. Under this system private manufacture was permitted, but all the salt made had to be sold to Government. The salt was resold by Government at a price calculated to include purchase-money, storage, transport and other charges reduced to an average for the whole Presidency. Later on the excise system was introduced, but this has never been enforced universally, and hence there are two systems, one in which the produce has to be sold to Government, the other in which salt privately made can be dispensed as the owner pleases, but only after paying the duty. [Cf. Admin. Repts. Dept. Salt Rev., 1895–6 to 1904–5; Dist. Gaz. Bellary, 177–9; Anantapur, 127–8; South Arcot, 234–6; etc.]

PRODUCTION AND TRADE.—Consumption and Taxation.—“During the six years, 1898 to 1903, the average annual production of salt in India amounted to 979,572 statute tons.” And following on the shrinkage of 1903, there was a great increase on production in 1904, viz. to 1,171,050 tons, in 1905 to 1,291,137 tons, and in 1906 to 1,225,280 statute tons (= 1,244,939 metric tons). This expansion was mainly in Bombay and Madras sea-salts. The output of the former in 1903 was 267,619 tons, in 1904 it expanded to 430,409 tons, but in 1905 became 425,090 tons, and in 1906, 390,535 tons; while in the latter (Madras) the production in 1903 was 244,923 tons, in 1904 it became 356,834 tons, in 1905, 388,646 tons, and in 1906, 412,717 tons. During the five years ending 1906–7 the Imports of salt have been:—1903–4, 446,559 tons; 1904–5, 486,980 tons; 1905–6, 464,531 tons; and 1906–7, 467,949 tons, valued at Rs. 66,77,390 (£445,159). The total supply may thus be obtained by adding together the production and imports; thus in 1903–4
**SALT**

**SODIUM CHLORIDE**

**Duty**

it was 1,426,131 tons, and in 1904-5, 1,657,185 tons; hence home production in the former represented 68 per cent. and in the latter 70 per cent of the consumption.

It is thus evident that the reductions of the duty on salt, made successively in March 1903 and March 1905, stimulated consumption; all the provinces except Bengal (which draws its supplies from Liverpool and Germany) have shown an increased consumption. From 1888 to 1903 the duty throughout the greater part of India was Rs. 2-8 a maund of 82½ lb., but in the latter year this was reduced to Rs. 2. Again, in March 1905, the general rate for India, except Burma, was reduced to Rs. 1½ per maund. A further reduction was made by the budget of March 1907, and "the tax is now levied at the uniform rate of one rupee per maund over practically the whole of India and Burma" (Mor. and Mat. Prog. Ind., 1905-6, 75).

**Customs and Control.**—It has been fully exemplified that in the production of salt in India there are two chief operations: (1) mining and (2) evaporation. Under the supervision of the various departments, preventive establishments are maintained, to guard against illicit traffic in salt removed from natural deposits; from manufactories, whether owned by Government or private persons; and from saltpetre refineries, etc. The traffic coastwise is also subject to supervision, and special measures have been undertaken to check smuggling from French and Portuguese, as also from Native State, territories. Briefly, however, the modern policy has been to work salt so economically and scientifically that the tax may assume the form of ordinary profit on production and be collected before delivery to the traders, so as to place its subsequent movement free of all restraint. This, when contrasted with the vexatious and expensive system inherited by the British administration, will be seen to be a vast improvement. Salt is readily available throughout the Empire, its price has been equalised, facilities of traffic increased, and a system of credit established. "At the present day, for example, a trader of the United Provinces wishing to obtain Sambhar salt has merely to deposit his money at the nearest treasury, sub-treasury, or appointed railway-station or post-office, in order to receive his consignment without delay or trouble, at any railway station he chooses to name. In Madras the trade in salt is facilitated by a credit system, under which a merchant on depositing securities (with a slight margin for fluctuation of price) receives a six months' credit for payment of duty on which he can draw from time to time. A similar system, but with a shorter credit period, obtains in Bombay" (Imp. Gaz., l.c. 252).

The following statement exhibits the imports from foreign countries and the production of salt within India in relation to consumption and revenue:

These tables show the share of the salt of India that is drawn from foreign countries—approximately a little over one-third the annual supply—the quantity passed into consumption, and the duty realised therefrom. In 1875-6 the consumption was 24\frac{1}{4} million maunds, in 1904-5 it had expanded to 39\frac{1}{4} million maunds, and in 1905-6 to 40\frac{3}{4} million maunds. The consumption steadily progressed and was little, if at all, affected by the fluctuations in the rate of duty charged. But during the years 1904-6, while the duty declined materially the consumption made a record expansion. And it may be added that more recent forecasts would seem to show that the increase may soon compensate for the reduction in rate of revenue. The demand for salt would doubtless decrease in the affected areas, and yet a study of the figures of salt consumption by themselves for the whole of India during the past thirty-five to forty years give no sort of indication of the years of famine included within that period. The progression has kept pace with the increase in population, and has been little if at all affected either by famine or taxation. If surrendered to private enterprise the price all over India would rise and become unequal, thus leading to numerous difficulties and hardships. Thus it may be said salt is administered on a commercial basis and the profit secured returns in lessened taxation.

The returns of the salt trade manifest a continuous expansion with periods of sudden development rather than of shrinkage. Thus, for example, in 1878-9 the consumption was 25\frac{1}{4} million maunds and in the next year it became close on 28 million. So again, in 1883-4, the consumption was a little over 30\frac{1}{4} million maunds, and in 1884-5 it became 33 million maunds. In only two years are material shrinkages manifested, viz. 1885-6 and 1888-9, yet in these the effect was only temporary and did not in any way disturb the steady advancement. It is well known that seasons of deficient supply occur from climatic conditions retarding production, and the years 1885-6 and 1888-9 are likely to have been of that nature. At the present time salt sells on an average at one halfpenny a pound throughout the greater part of India, and still produces a net revenue of 5 to 6 million pounds sterling. The incidence of the tax prior to 1903 was 4\frac{9}{10} annas per head of population, and by recent enactments it became only 4 annas (4 pence a head), the sole contribution of a large percentage of the people to the administration.

Uses.—It is needless to enumerate the numerous purposes served by salt. It is used as an article of food, as a manure, in fish-curing (see p. 546), vinegar purification (see p. 1111), etc., etc.
Climatic Conditions.

Formation.

The necessary combination of characters is to be found in a marked degree in various districts in the Indo-Gangetic tract, especially in the Bihar section, chiefly Gaya, Tirhut, Saran and Champaran. In this part of India we have a population of over 500 per square mile, mainly agricultural in occupation, and thus accompanied by a high proportion of domestic animals, supplying an abundance of organic nitrogen. With a mean temperature of 78° F., confined to an annual range of 88°, and for a large part of the year, when the air has a humidity of over 80 per cent., with a diurnal range not exceeding 8° above or below 84° F., the conditions are unusually favourable for the growth of the so-called ‘nitrifying’ bacteria."

"With a population largely using wood and cow-dung for fuel, the soil around villages naturally would be well stocked with potash; and finally, with a period of continuous surface desiccation following a small rainfall, the subsoil water, brought to the surface by capillary action in the soil, leaves an efflorescence of salts, in which, not surprisingly, potash nitrate is conspicuous. Under these conditions Bihar has for many years yielded some 20,000 tons of saltpetre a year" (Holland, l.c. 86–7). To a less extent, commercial saltpetre is also obtained in the United Provinces (e.g. Cawnpore, Ghazipur, Allahábád, Benáres), the Panjáb, Kashmir, Central India (Bhind and Jwargarh), Bombay, Madras (Coimbatore, Salem, Kistna, Vellore, Trichinopoly, Madura), and lastly Burma (Tenasserim).

Manufacture.—Hooper has furnished a concise account of this subject. In preparing crude saltpetre from nitrous earth there are two distinct processes—(1) the leaching or exhaustion of the saline matter by allowing water to percolate through the nitrous earth; (2) the evaporation of the liquor so obtained either by the sun’s rays or by artificial heat. These processes are carried on in Bengal by a special caste of men, the lunías or nunías, but in parts of the United Provinces and the Panjáb, ordinary villagers of no special caste engage in the industry. Near Hissár, the crude-nitre makers are generally low-caste kumbhars, or other Hindus or Mussulmans. The nitrous earth is collected from November to the commencement of the monsoon. The surface of the soil is scraped off to a depth of half to one inch and the earth made into heaps or taken to the factory.
**MANUFACTURE**

In a factory examined at Murwanpur, four miles from Cawnpore, the following was the process of manufacture:—"The earth is stacked by the side of two oblong pits or filters (kuria or kohl), 7 feet long, 3 feet broad, and 1 foot deep. They are placed end to end with an earthen ghara or jar (nand), 1½ feet in diameter, buried in the ground between them. The floor of the filter is made of puddled clay, and is so arranged that the slope on either side is towards the central longitudinal line of the filter. This central line has a slope towards the outlet connecting with the jar. On the floor is laid a framework of small brushwood the sides of which rest on the clay, and the cross-pieces which are laid on top of the side-pieces. The filter is carefully packed with the nitrous earth, and water is poured on the surface, which commences to trickle out in one hour or so as nitrous brine. After the first charge of water, more is poured on the surface until the brine trickling out appears to be too weak to work. The exhausted soil from the filters is then taken out and thrown on a heap, which gets large by the time the season ends. The liquid from the nand is boiled out and transferred to an iron evaporating pan or boiler (karahi), which is supported on a brick fireplace. The boiler is 5 feet in diameter and is made up of iron sheets riveted together, and costs about Rs. 20: the liquor is boiled for about seven hours or until it is sufficiently concentrated. To determine this a drop of the solution is taken and placed on the thumb-nail. If crystals appear at once, the boiling is considered to be complete.

"The hot boiled liquor is transferred to open vessels of rough pottery to cool and crystallise. The crystals will usually have sufficiently formed to be collected next morning. They are taken out and drained in baskets which act as filters, and then thrown into a pit in the ground, where the crude saltpetre, or kachchh shora as it is called, is stored" (Hooper, l.c. 26-7).

Saltpetre thus obtained (by artificial heat) is termed jaria shora. The method of making crude saltpetre by the heat of the sun is practised in the drier parts of the Panjáb and in other provinces where the climate permits, but the saltpetre (abi shora) is not considered of such good quality. A large quantity of abi shora is made annually at Hansi in the Hissar district.

"The quality of crude saltpetre is considerably influenced by the quality of the nitrous earth from which it is made and the processes adopted for its manufacture." Analyses of various samples of crude saltpetre are given by Hooper (l.c. 31-2). The amount of potassium nitrate ranges from nearly 80 per cent. in a sample from Hamerpur, to as low as 26·8 per cent. in a sample from Okara, and an average of 53 might be given.

**Impurities.—**The chief impurity is common salt. Ordinary samples of crude nitre are stated to contain from 40 to 64 per cent. nitrate of potash, and to be worth, at manufactories within easy distance of railways in the north of India, one anna per unit per maund for the percentage of potassium nitrate present. According to Hooper, a sample containing 40 per cent. nitrate of potash would thus be worth Rs. 2–8 per maund, and samples containing 64 per cent. of nitre, Rs. 4 per maund. Samples with less than 40 per cent. nitre would be valued at less, and those containing over 64 per cent. nitre at more than one anna per unit.

**Refining.—**Before the nitre is ready for market, it has to be freed from impurities. This is done in refineries, of which there were 399 at work in Northern India (Panjáb, North-West Frontier Provinces, United Provinces, Bihar) in 1904–5; 281 of these were in Bihar (Rec. Geol. Surv. Ind., 1906, xxxiii., 19). Hooper gives a full account of the arrangements in a refinery at Jaimow, Cawnpore, in the United Provinces, to which the reader is referred for details. With regard to the methods followed, he says, "The process varies in different refineries and in different parts of the country. But as chloride of sodium is the principal impurity and as its solubility is practically constant, all the processes followed are based on the varying solubility of nitrate of potassium in hot and cold solutions."

The method pursued, according to Hooper, is essentially as follows:—In starting the refining process, nitre earth, obtained from the factory soil, is filtered and the crude nitre solution obtained boiled down, clarified by sedimentation
and set out to crystallise. "In from six to ten days the crystals are extracted and the residual tor or mother-liquor is then available for future use." In this mother-liquor, crude saltpetre is dissolved and the solution concentrated by boiling in large evaporating-pans. During the boiling a dirty white granular salt (denoted as earth) falls to the bottom of the pan and is removed as it forms. This earth is sometimes washed and the washing returned to the pan. In Bihar it is mixed with the refinery earth. "It is composed for the greater part of common salt mixed with other salts, earth and nitrogenous matter." Meanwhile the evaporation of the liquid in the pan is continued at the temperature of boiling water. The scum which forms on the surface (zag, zoga, mail or phain) may be removed at this stage or after transfer to the settling-tank. "After boiling for three hours, or until the liquid changes from a dark to a light yellow colour, the concentration is considered complete." The clarified liquor is transferred into one or more crystallising vats. "At the bottom of the settling-tanks is found a substance called mattare, which is a by-product containing nitrates, and is accordingly carried off and mixed with the nitrous earth in the factory yard. The crystallising-vats under the sheds are fitted with nitre liquor to about six inches from the top. In the United Provinces, on the surface of each is floated a trellis-work made of interlaced bamboo sticks (called tattis in Cawnpore). This device facilitates the formation of good crystals. After seven days the bamboo frames are removed and the adhering nitre crystals are shaken or picked off, and the crystals at the bottom and sides of the trough collected in a heap and drained."

"The damp saltpetre is contaminated with the mother-liquor adhering to it and minute crystals of salt, and these must be removed by washing before the salt is ready for market." "Bags containing the refined substance are placed over an empty tub or vat, which is slightly tilted to allow the liquor to drain. Cold water is sprinkled from time to time upon the saltpetre through the open mouth of each bag. This water trickles slowly through the saltpetre crystals, carrying with it inferior salts in solution. Some saltpetre is also dissolved, but the loss is not great. After the washing, the refined saltpetre is spread out and dried, and after remaining a few hours, is conveyed to the store godown" (Hooper, l.c. 36). The price of refined nitre in 1904 is stated to have been Rs. 5–8 to Rs. 6 per maund in Bihar and Hisar, Rs. 8 in Cawnpore, and that of extra-good quality, Rs. 9.

**Uses.**—It is even still an important ingredient in gunpowder, owing to the large volume of oxygen it contains, the ease with which it parts with its oxygen, and the fact that it does not readily absorb moisture from the air. On the other hand, sodium nitrate is preferred for the manufacture of nitric acid because it is cheaper and yields about 7 per cent. more acid. In India, saltpetre is used in association with certain animal dyes, such as lac and cochineal. In MEDICINE it is sometimes prescribed because of its diaphoretic properties. Its merits as an antiseptic in preserving fish and meat are well known. As a MANURE it is much appreciated, especially for wheat and tobacco (see p. 771; also c.f. Agri. Ledg., 1893, No. 10; 1897, No. 8, 171), and in India it is sometimes used as a flux in glass-making.

**Production and Trade.**—According to Holland, the returns are so imperfect, being considerably below the amounts of export, that these must be taken as the only satisfactory index of the extent of production. For the period which he reviews (1897–1903), the average annual exports, including those across the frontier, amounted to 382,333 cwt., valued at £262,592. He further states that a comparison with the figures returned for the past twenty years shows that there has been only a slight reduction in the amount exported, in spite of the discovery of large deposits of sodium nitrate (now being extensively utilised in America), of variations in tariff, and of wholesale changes in the substances used for manures and in the manufacture of explosives. For the six years 1878–1883 the average quantity of

For the six years 1878–1883 the average quantity of...
Trade in Saltpetre

Saltpetre exported amounted to 405,505 cwt a year, whilst for a similar period ten years later, 1888-1893, the average annual exports were 389,989 cwt. The highest values, ranging from £600,000 to nearly £900,000, occurred at the time of the American Civil War from 1860 to 1864, but saltpetre was then an essential constituent of explosives and India had almost a monopoly of supplies.

The actual figures of the exports of saltpetre during the five years ending 1906-7 were as follows:—1902-3, 410,622 cwt., valued at Rs. 43,27,283; 1903-4, 392,114 cwt., valued at Rs. 40,75,364; 1904-5, 348,741 cwt., valued at Rs. 36,23,823; 1905-6, 336,429 cwt., valued at Rs. 38,52,919; and 1906-7, 353,378 cwt., valued at Rs. 41,42,527 (= £276,168). In the last year the largest quantities were distributed as follows:—United States, 105,034 cwt.; United Kingdom, 98,804 cwt.; China (Hongkong), 78,499 cwt.; Mauritius, 26,174 cwt.; etc. Practically the whole of the exports go from Bengal (348,263 cwt. in 1906-7). Holland (Rev. Min. Prod., in Rec. Geol. Surv. Ind., 1907, xxxvi., 81) shows the average value per cwt. for the past five years as 14.5 shillings, and he points out that the importance of the industry may be inferred from the fact that in Bihar (during 1906) there were 50,469 workers employed.

Only very small quantities are imported into India by sea, averaging about 19 cwt. during 1901-5, but in 1905-6 the quantity suddenly rose to 4,848 cwt. (owing to the importation into Bengal of 4,820 cwt. from China), and in 1906-7 fell to 28 cwt. Considerable quantities, however, are annually carried across the frontier, almost entirely from Nepal. The actual figures of Trans-frontier imports for the period 1900-5 were as follows:—1900-1, 4,590 cwt.; 1901-2, 11,352 cwt.; 1902-3, 2,758 cwt.; 1903-4, 4,429 cwt.; 1904-5, 2,872 cwt.

Sansevieria

Sansevieria Roxburghiana, Schult., f.; S. zeylanica, Roxb., Fl. Ind., ii., 161; Fl. Br. Ind., vi., 271; Hæmodoraceæ. The Bowstring Hemp, marul, murva, murga, murgali; gorachakra, chaga, etc., the Sanskrit for it being apparently marura (Jones, As. Res., iv., 271).

A stemless bush with a rosette of succulent radical leaves, each ending in a long spine. It is by some persons held to be indigenous to India, by others, like the remaining members of the genus, to be African. But if not a native of India, the vernacular name murva must have been adapted to it from some other plant which in ancient times afforded the murva string of the warrior caste (Institutes of Manu, ii., 42, 44). One or two species are fairly extensively grown in Indian gardens as ornamental shrubs, and here and there occasionally raised on account of the fibre. From the succulent leaves, the fibre is extracted and is much valued, because of its elasticity and consequent suitability for bow-strings. The reader will find much useful information on this subject in The Agricultural Ledger (1896, No. 30), where it will be found murva fibre has been recommended as a catch crop with tea. (Cf. Roxburgh, Obs. on Substitutes for Hemp and Flax, 1801, No. 12; Dodge, Useful Fibre Plants of the World, 1897, 975
THE SANDAL-WOOD TREE

SANDALUM ALBUM, Linn. ; Roxb., Fl. Ind., i., 442; Talbot, List Trees, etc., 1902, 293; Gamble, Man. Ind. Timb., 685-8; Prain, Beng. Plants, 1903, ii., 913-4; Watt, Ind. Art at Delhi, 1903, 147-53; SANTALACEAE. The Sandal-wood, known in Indian vernaculars as chandan, chandal, sandal, sukhad, gandha, gandada, suket, sukhud, sundel, srigandam, santiagu, etc., etc. A small evergreen tree met with in the dry regions of South India (Mysore, Coorg, South Marathá, Hyderabad, Karnátak), and in North India chiefly as a cultivated plant. It affects open forest lands with grass and patches of other trees, usually frequented red or stony soils. It is a root parasite on a long series of host plants, and hence apparently the difficulties experienced in systematic plantations where provision has not been made for this requirement. On rich soil the plant grows well, but the wood is deficient in odour, consequently inferior commercially.

History.—Sandal-wood has been known in India from the most ancient of classic times, the Sanskrit authors distinguishing various woods according to colour. Chandana might be spoken of as the collective name for the series, srikanda the true (or white sandal), and pitachandana the inferior (or yellow sandal), both being derived from Santalum album. They distinguish two kinds of red sandal or raktachandana, namely Pterocarpus santalinus (see p. 909) and Ceyalpinia Sappan (see p. 194). So, in a like manner, these various woods were known to the early Arab traders who visited India and China. Avicenna (ii, 649) gives the medicinal properties of the true sandal. Serapion (De Simpl., 340) describes white, yellow and red sandal, and speaks of the finest qualities coming from Sini (China), an opinion doubtless due to the well-established circumstance that the traders from China were in the habit of treating India as a half-way house and exchanged some of their Chinese wares for Indian products and manufactures, and on arrival at Arabia all the goods ultimately disposed of came to be spoken of as Chinese, because of the traders having come from China, just as in the further distribution of these self-same wares they received the names of the coast towns of Arabia from which they were finally distributed to Egypt and Europe. [Cf. Paulus Aegineta (Adams, transl. and Comment.), 1847, iii., 448-9.]

Marco Polo, in the 13th century, makes frequent reference to Red Sanders Wood and to Sandal-wood, and Garcia de Orta (Col., xlix.) says the white and yellow kinds grow in Timor, where it is called chundana and by the Arabs sandal, and the other kinds in the Malay Islands, a special red form known as vermelho being obtained in Tenasserim. [Cf. with recent information regarding kalamet (Mansonia Gagei), Journ. Linn. Soc., 1905, xxxvii., 250-62.] Sandal is described by Acosta, Linschoten, Pyrard, Matthiolus, Bonitus, Hove, etc., and for Indian writers consult the following:—Abul Fazl, Ain-i-Akbãri (Blochmann, transl., i., 81; Jahangir, Memoirs (Price, transl.), 14, 63; Foster, E. I. C. Letters, 1817, v., 267; vi., 163, 170; Alexander Hamilton, New Acc. E. Ind., 1727, i., 309; Jones, Sel. Ind. Pl. As. Res., iv., 293; Milburn, Or. Comm., i., 291; Rama Rao, Ind. For., 1908, xxxiv., 17-21.

Cultivation.—John Scott, Curator of the Royal Botanic Gardens, Calcutta, showed that sandal-wood was a root parasite on many plants (Journ. Agric.-Hort. Soc. Ind., 1871, ii., 287). Barber (Ind. For., 1902, xxviii., 340) urged that a careful study of this circumstance might lead to much-needed reforms in the methods of cultivation, as also to the true explanation of the peculiar disease known as "Spike." Brandis followed this up by a review of the literature on the parasitism of sandal (Ind. For., 1903, xxix., 3-6). Rama Rao (Ind. For., xxix., 386-9) has furnished full details of the parasitism, also excellent illustrations, and given a list of some 100 host plants upon which the sandal had been found. Lastly,
Barber contributed a further paper (Ind. For., 1904, xxx., 545-8; 1905, xxxi., 189-201), which supplies details of his microscopic studies of the haustoria and their preferences for certain hosts. Lushington (Ind. For., 1902, xxviii., 139-40), Rama Rao (I.e., 1904, xxx., 248-67, 357-62, 397-402) and other officers of the Forest Department have also devoted much careful study to the cultivation of sandal, more especially in relation to the production of the maximum percentage of rich-scented wood. Lushington observes: "On the whole I am inclined to think that the best way of aiding the reproduction of sandal-wood artificially is to increase the scrub, and this is best effected by merely keeping out fire and grazing. As soon as the scrub reaches two or three feet, sandal reproduces naturally from seed dropped by birds, and this may perhaps be further assisted by dibbling," Rama Rao urges that weeding is dangerous, and that only surface pruning when the scrub becomes too dense should be indulged in. Lushington mentions 8 inches growth in girth per ten years as a safe average, and the exploitable age of the trees as forty years, the minimum size being then 32 inches at 4 feet from the ground.

**DISEASE OF THE SANDAL.**—In 1892 attention was drawn to the appearance of a disease among the sandal-trees which was attributed to borer beetle (Lehmann, Ind. For., 1901, xxvii., 97). Stebbing (Ind. For., 1903, xxxix., app.) furnished a useful account of the insect enemies of the plant. In the Forest Administration Report of Coorg for 1903 it was stated that 20,800 diseased trees had been uprooted. Similar reports exist regarding other districts, while many writers affirm that the extermination of affected trees has not checked the spread of the disease. Mr. McCarthy, Deputy Conservator of Forests, would appear to have been the officer who first recorded the disease, and who apparently gave it the name "Spike." The diseased branches seem to shoot up, forming narrow, thick, stiff leaves, reduced in size as the disease advances. The disease spreads to branch after branch, no flowers are formed, and finally the tree dies. Both Butler and Barber have examined with care diseased trees, but have failed to discover a fungus or other micro-organism present in or upon the diseased tissues. The roots of diseased trees have been traced from the stem to their ultimate fibrils, and, long before their parasitic haustoria were reached, these roots were very frequently found dead. Butler suggested that the disease somewhat resembled "Peach yellows," and, acting upon this idea, experiments were performed to test whether it could be communicated by budding. This was found impossible. It would thus seem that as yet no satisfactory explanation of the disease has been ascertained, but most officers appear to consider that it proceeds from imperfect nourishment due to the insufficiency or unsuitability of the associated plants upon which sandal-wood is parasitic.

**Sandal-wood Oil and Perfume.**—It is a somewhat surprising circumstance to learn that in the region of greatest success in sandal-wood production the manufacture of the oil has hitherto proved a failure financially, and is only practised on a small scale and by a very inferior process (Holmes, Pharmaceut. Journ., 1885-6, 3rd ser., xvi., 819-22; Sawyer, Odorography, i., 315). As matters stand, the sandal-wood oil of India is mainly, if not entirely, produced at Kanauj in Oudh.

From official correspondence it is learned that according to Mr. S. Ali Husain, sandal-wood oil was formerly distilled by several firms in Lucknow and Jaunpur, where the preparation of sweet-scented essences is a recognised industry. For some years past the industry in these towns has declined, and it has become the practice to purchase the oil from Kanauj. The method of preparation described by the Lucknow and Jaunpur men was as follows:—Two kinds of sandal-wood, red and white, are known in these provinces. The former is used medicinally and in dyeing, while the latter alone is employed for the extraction of the oil. Trees are found here and there growing in the provinces, but good wood can alone be obtained from the Bahraich forests. Until the last ten years wood from
these forests was used largely, but latterly (owing to the low yield obtained from the local wood) supplies have been imported from Bombay which are believed to have been derived from Mysore and Malabar. The best wood for the perfume trade is held to be that from the damper tracts of the latter—it being assumed that a higher proportion of oil is present, depends on both the dampness of soil and climate of the country of production.

The wood is first reduced to a powder, about 40 to 60 lb. of which are soaked in clean water for 48 hours, then placed in a copper still. The water, carrying the oil evaporates and is condensed in the usual way, when, on cooling, the oil floats on the surface and can be collected. It is then refined in various ways—filtered, or kept for a year until the sediment of impurities has settled at the bottom, etc. It is believed that the water has an important function to perform, since certain waters are superior to others. Kanauj is supposed to soften the wood and facilitate the liberation of the oil, while that of Jaunpur improves the quality of the oil. The Kanauj manufacturers, however, attribute their success to their skill and not to any special property possessed by the water.

It is said that the yield in Kanauj is about 2½ to 3 seers of oil to one maund of wood. The oil that comes off first from the still is the best quality. The following rules are recognised by the manufacturers:—(1) the heat must be uniform; (2) the receivers must be removed directly they are full; (3) cleanliness is essential. If the timing of the interior of the still is worn out, the oil gets greenish in colour from copper; (4) all joints must be steam-proof. There are various qualities of the oil—that made at Kanauj is called malleagiri; inferior kinds are kothri wala and jahazi. But the inferior oils are believed not to be made at Kanauj, and to be used by the traders for adulteration. The annual output at Kanauj is about 100 maunds of the oil; but the production is said to be declining, the reason given being the increasing price of good wood, which now fetches Rs. 30 to Rs. 35 a maund. The scarcity of fuel is given as another reason of the decline, and the adulterations practised by the dealers as a third reason. Ordinary quality of Kanauj oil sells at about Rs. 17 a seer (≈2 lb.). [Cf. Foster, E.I.C. Letters, 1611, v., 339; Gildemeister and Hoffmann, Volatile Oils, 1900, 338—45; Pharmacop. Ind., iii., 232—4; Hare, Caspary and Rusby, National Stand. Dispens., U.S.A., 1905, 1104—5; Hooper, Repl. Labor. Ind. Mus., 1903—4, 27.]

Trade.—The sandal-wood of Mysore and Coorg has not only been known from the most ancient times, but has ranked as the finest quality for centuries. It is somewhat surprising, however, to read in Stein (Ancient Khotan, 447, 452) of a comb found at the Kara-dong ruins (8th century) said to be made of sandal-wood. If that determination be correct it would point to an Indian trans-frontier traffic of a more varied and extensive kind than hitherto contemplated, as existing at that early period. The Indian supply of the true sandal-wood is drawn from Southern and Western India, and there is nothing to show that this was not always the case. The earliest European writers on the modern traffic refer to the sandal of Macassa, and a supply from there is still recognised in the markets of the world. A third grade is designated West Indian, though it is in reality procured from Venezuela. According to Gamble, the average annual sales of Mysore amount to 1,841 tons; Coorg, 102 tons; Madras Presidency, 75 tons; and the Bombay sales a still smaller quantity—or, say, a total annual output of 2,000 tons, valued at £40,000. Speaking of Mysore, Pigot (Mysore Sandal-wood, 1899) says the wood is found in a continuous belt, about 240 miles long by 16 broad, running from the north-west to the south-west of the province. A second and much smaller and less important zone lies farther to the east. The total area of both belts is about 5,450 square miles. This, therefore, is the chief sandal area of the world, since Mysore produces about seven-eighths of the total annual supply. Pigot classifies the grades and materials into some eighteen sections, ranging in size from billets not less than 20 lb. in weight (vilayat budh), the finest grade, down to the sawdust obtained in sawing up the
THE SOAP-NUT TREE

The former is the Soap-nut tree of Northern India and the latter of Central, Western and Southern India. They are collectively described by the Natives of India under the vernacular name *rihô*, and in Sanskrit by the names *phenila* and *urista*. Other vernacular names are, however, used, such as *rihia*, *rita*, *ariha*, *dodan*, *kannar*, *tô*, *ud-rak*, *prunanga*, *puwandi*, *kunkudu*, *thali*, *thalay*, *chena*, etc. The fruits of the North Indian form come into market about January or February, and of the South Indian a little later, say about March to April. From time immemorial these "nuts," cr. rather, dried fleshy berries, have been employed as detergents, and by the dyers of India are supposed to possess special merits as a preparation (if not mordant) for certain dyes. In Kashmir the soap-nut is preferred for washing shawls to European soaps. In other parts of the country they are specially valued for washing silk, and by the Indian jewellers are resorted to for the restoration and brightening of the silveriness of plate and ornaments tarnished by exposure.

As one of the many curious uses of these nuts, it may be said that they are sometimes employed in washing and bleaching cardamoms, and are supposed not only to improve the colour but also the flavour of the spice (see p. 515). The soap-nut is used medicinally, both by the Hindus and Muhammadans, and its properties are detailed in the *Makhan-i-Adwiyâ* and the *Taleef-Shereef*. More up-to-date details will be found in the *Pharmacographia Indica* (i., 367-70), and in the *Materia Medica of Madras*, by Moodeen Sheriff (112-4), etc., etc. Mr. A. Storey of Oodeypore pointed out that the honey of the flowers of these trees was poisonous to bees (*Journ. Bomb. Nat. Hist. Soc.*, 1890, v., 423). The soap-nut is much used in China for the same purpose as in India (*Hosie, Prov. of South'yan*, 1904, No. 5, 31).

Quillai Bark (the bark of *Quillaja saponaria*; *Kew Bull.*, 1904, 1-4) is sent to Europe from Chili as a soap substitute, and a demand has arisen for the same, which suggests the possibility of a foreign trade in the Indian soap-nuts—the above species—as also the pods of *Aesculus concinna* (see p. 14).

The plant is easily raised from seed, but is usually propagated by layers or cuttings. The fruit is a 3-celled capsule, each cell with a single seed, surrounded with a thick greasy substance—the so-called vegetable Tallow. In China this is used in place of animal tallow for the manufacture of candles and soap, also in dressing cloth. In addition to the solid fat, the seed-kernel yields about 50 per
SCHLEICHERA
TRIJUGA
Lac Tree

Oil.

THE COSTUS OR KÚT PERFUME

cent. of a brownish-yellow Oil, which is employed medicinally, also as a burning-

oil and in the preparation of umbrella varnish. Efforts have been made to utilise

tallow in India, but the labour and expense involved in extraction are said to
be far in excess of the value of the product. In the Annual Report (1901-2)
of the Industrial Section, Indian Museum, mention is made of a sample of

kerneis obtained from Kangra Valley which contained 63.6 of fat. Gamble says

"experiments have been made by Babu Birbal at Dehra Dun and the wax was

extracted and made into cakes, but the process was tedious and the result not
very satisfactory, so that the culture of the tree for wax is not recommended." 

Further details regarding the manufacture, chemistry and trade in vegetable

tallow will be found in The Agricultural Ledger. The leaves afford a black Dye
about which little is known. The Wood is white and moderately hard. It is

made into bedsteads, tables, toys, and has been suggested as suitable for printing-

blocks. [Cf. Braunt, Pract. Treat. on Anim. and Veg. Fats, 1888, 321; Andés,

Veg. Fats and Oils, 1897, 201-2; Kev Bull., 1897, 10, 54; 1899, 216-9; Thorpe,

SAUSSUREA LAPPA, C. B. Clarke; Fl. Br. Ind., iii., 376;

COMPOSITE. The Costus, kút, pachak, post-khái, rusta, ouplate, kostum,

chandal, sepuddy, etc. A tall, stout herb, indigenous to the moist, open

slopes surrounding the valley of Kashmir, at an elevation of 8,000 to 9,000

feet, and found also in parts of the basins of the Chenab and Jhelum, at

10,000 to 13,000 feet.

Costus root has been held in high repute as a medicine from remote
times, but its origin was for long obscure and was erroneously referred to Costus speciosus.

As with many other articles of merchandise, it came to be spoken of as obtained

from regions that were only emporia, not localities of production. Thus Garcia

de Orta (1563, Coll., xvii.) states that it grows in the region between Bengal,

Delhi and Cambay, and comes also from Chitore, whence it is brought to Cambay

and Ahmadábad and exported to Europe and parts of Africa. The roots are

actually dug up in large quantities in Kashmir, cut into small pieces and sent to

Calcutta and Bombay, whence the drug is exported chiefly to China and the Red

Sea. In Kashmir its collection is a State monopoly. Lawrence (Valley of

Kashmir, 1895, 77) says: "Every year a large amount of the roots of the Suas-

surea Lappa is demanded by the State, and the villagers are obliged to bring a

certain weight, for which they receive Rs. 4 per kharwár from the State.
The root, which is known as chob-i-kot, is exported to India, and at present the monopo-

ly in chob-i-kot is farmed out to a contractor for Rs. 45,000 per annum."

In addition to its medicinal properties it is a valuable perfume and largely

used in China as an incense. It is also said to be a good hairwash, having

the reputation of turning grey hair black. In Kashmir it is much employed

by shawl-merchants to protect their fabrics from moths and other insects. The

absence of this particular perfume was for some time made the test for

imitation shawls. [Cf. Chuiss, Hist. Exot. Pl., 1605, 204-6; Pharmacog. Ind.,

ii., 296-303; iii., 165, app.; Henry, Econ. Bot. China, 1893, 19; Rept. Ind.

Hemp Drugs Comm., 1894, iii., 94; Ann. Rept. Ind. Mus. (Indust. Sec.), 1894-5,

33; Dutt, Mat. Med. Hind., 1900, 180-1.]

SCHLEICHERA TRIJUGA, Willd.; Fl. Br. Ind., i., 681;

Gamble, Man. Ind. Timbs., 1902, 194-5; Brandis, Ind. Trees, 1906,

189-90; SAPINDACEÆ. The Lac Tree, Kosumba, or Ceylon Oak, kosum,

gausam, gosham, júskú, rodtanga, paka, págá, pulachi, ságá, chendala,

kassum, kusumb, gyó, etc. A large deciduous tree, in the "dry chiefly

deciduous forests in the greater part of India, Burma and Ceylon, but

apparently absent from Bengal and Assam" (Gamble). Recent in-

vestigations have shown, however, that the tree does occur in Bengal

(especially Chota Nagpur), though not in Assam.

The most valuable product of this tree is the Oil yielded by the seeds, which

is used for culinary and lighting purposes, also as a hair-oil and in Native medicine.
THE MARKING-NUT TREE

It is said to be an efficient agent for cleaning and promoting the growth of the hair, and is reputed to be the original Macambar oil. Recently there has been a considerable demand from abroad for the seeds (Hooper, *Agri. Ledg.*, 1903, No. 1). A large quantity of seed was found to be available in Indiā, but owing to its being edible, jungle tribes would, in times of scarcity, gather the fruits for their own consumption rather than for trade purposes. It is also said that none of the oil is sold or exported in any of the districts specially investigated. The tree is noteworthy from its being one of the most highly valued plants of the Lac insect. As a lac-yielding tree it is especially prevalent in Raipur and Bilaspur in the Central Provinces. The Wood is hard, strong and durable and used for making pestles, cart-wheels, axles, ploughs; also for rollers of sugar-mills, and of cotton and oil presses. [Cf. *Pharmacog. Ind.*, ii., app., 138-9; *Journ. Soc. Chem. Indust.*, 1900, xix., 254, 672; Thorpe, *Dict. Appl. Chem.*, 1900, iii., 31; Wright and Mitchell, *Oils, Fats, etc.*, 1903, 542; Hooper, *Rept. Labor. Ind. Mus.*, 1904-5, 26; *Trop. Agrist.*, Oct. 1906, xxvii., 309-10.]

It yields by tapping the stem an acrid, viscid juice from which a varnish is made (see *Melanorrhoea*, p. 779), but the most important product of the tree is the fruit, the pericarp of which contains a bitter and powerful astrigent principle, universally used in India as a substitute for marking-ink. It gives a black colour to cotton fabrics, but before application must be mixed with limewater as a mordant. In parts of Bengal the fruits are also used as a dye, either alone or with alum, while throughout India they hold an important place in Native medicine. The fleshy cups on which the fruit rests, and the kernels of the nuts, are eaten as food. [Cf. Acosta, *Tract. de las Drogas*, 1578, 323; PISO, *De Med. Bras.*, 1648, 57-9; also *Mant. Arom.*, in *Ind. Utri re Nat. et Med.*, 1658, 193-4; Moensgraf, *Hist. Pl.*, in PISO, *De Med. Bras.*, 94-5; BOYMN, *Fl. Sin.*, 1856, c.; Labat, *Nouv. Voy. aux Isles de L’Amer.*, 1724, ii., 385-7; *Paulus Eginus* (Adams, transl. and Comment.), 1847, iii., 450; *Pharmacog. Ind.*, i., 389-92; Mooden Sheriff, *Nat. Med. Hind.*, 1900, 141-2; ACHART, *Quinze Cents Plantes dans l’Inde*, 1905, 385-7.]

SESAMUM INDICUM, *DC*.; *Fl. Br. Ind.*, iv., 387; HEUZE, *Les Pl. Indust.*, 1893, ii., 142-50; SEMLER, *Trop. Agrik.*, 1900, ii., 472-84; WIESNER, *Die Rohst. des Pflanzer.*, 1903, ii., 765-78; *PEDALINEÆ*. Gingelly (or Ginge|li) or Sesame Oil, *til, tir, tal, krishna- or kala-tél, rasi, sunsum* or *sin-sim, khasa, tilmin, mithā-tél, bhunguru, kunjad, kala katea* (black), *purbīa* (red), *nallennny* (oil), *numvulu*, *achchellu*, *kwan*, etc. An annual plant cultivated throughout the tropical regions of the globe for the oil obtained from its seed. In India, however, it might be more correctly described as a crop of the warm temperate or sub-tropical tracts, being grown as an autumn or even winter crop in the warmer parts, and as a summer one in the colder.

History.—Botanical evidence alone might lead to the supposition that the *Sesamum* of sub-tropical agriculture was originally a native of Africa, in which continent there are some eight or nine truly wild forms, and where the present species is known to have been cultivated from remote times. De Candolle is of opinion that the plant was introduced into India from the Sunda Isles at a period prior to the Aryan invasion. “Rumphius,” he says, “gives three names for

981
the sesame in three islands, very different one from the other and from the Sanskrit word, which supports the theory of a more ancient existence in the Archipelago than on the continent of India.” He also adduces the fact that a plant found wild on the mountains of Java was determined to be *S. indicum*. If this were so, however, we might expect to discover some trace of the Sunda name in the languages of India. Instead we find a singular uniformity throughout the most diversified tongues in the names for the plant, its seed, and oil, which are clearly of unmixed Sanskrit origin. Moreover, the name enters into the early primitive conceptions of domestic life and religious ceremonial, and even assumes a generic from a specific significance, becoming “oil” ("ñaila") in more recent times on the discovery of other oil-yielding plants. Sesamum is frequently mentioned by the Greek and Latin authors. Indeed some of the Indian names given to it come from Arabic or Persian; few or none belong to the aboriginal languages of India.

In this connection may be mentioned the names gingen, jengzip, and jinjili or jinjali, which Dr. Rice derives from the Arabic *chul-chulun*, and Yule and Burnell from the Arabic *al jiljilun*. There is, moreover, no reason to doubt that the *tila* of the Sanskrit authors is the *til* of India to-day (Dutt, *Mat. Med. Hind.*, 216–7).

Though sesamum has not hitherto been recorded as found wild in any of the warmer tracts of Central Asia, it is cultivated everywhere in the Himalaya, in Afghanistan, Persia, Arabia and Egypt. There would, therefore, seem little evidence opposed to the statement that, if not originally native of the warm temperate tracts of India, it was probably brought to India before it found its way to Egypt and Europe. But it is certainly very remarkable that few, if any, of the early European travellers in India, such as García de Orta, Linschoten, etc., etc., make mention of this plant or of its oil. In the *Ain-i-Akbari* (1590) frequent reference is, however, made to both the black and the white-seeded forms, so that there is abundant evidence of its having been an important crop in India for at least the past 300 years. (Cf. Paulus Egineta (Adams, transl.), 1847, iii., 331; Varthéma, *Travels* (ed. Hakl. Soc.), 86–7; Camerarius, *Hort. Med. et Phil.*, 1588, 159, t. xiv.; Prosper Alpinus, *De Pl. Egypt.*, 1592, 38–9; Munting, *Phyt. Curiosa*, 1696–1702, 46, t. 239; Milburn, *Or. Comm.*, 1813, i., 292; Heyne, *Tracts on India*, 1814, 206; Taleef Shereef (Playfair, transl.), 1833, 59–60; Buchanan-Hamilton, *Stat. Acc. Dinaj.*, 1833, 174, 183; Hobson-Jobson *(ed. Crooke)*, 1908, 373–4; Joret, *Les Pl. dans l’Antiq.*, etc., 1904, ii., 269–70, 338; Hanausek, *Micro. Tech. Prod.* (Winton and Barber, transl.), 1907, 380–4.)

**CULTIVATION.**—Sesame is grown as a pure crop all over India, and in certain localities, such as the United Provinces, also as a mixed crop. According to the *Agricultural Statistics*, the area in British India under the crop in 1904–5 was 4,023,847 acres. An estimated area for the same year, excluding Burma but including the Native States of Bombay and Sind, was stated at 4,178,700 acres for the pure crop with a yield of 300,400 tons; 600,000 acres for the mixed crop with a yield of 35,000 tons, the latter being in the United Provinces. In that year also the area in the Native States (as officially returned, but excluding Hyderabad, Kathiawar and Baroda) is stated to have been 487,277 acres. In Noël-Paton’s *Final Memorandum* on the sesamum crop for 1905–6 mention is made of the area in Hyderabad having been 780,000 acres in 1904–5 and 431,200 acres in 1905–6. For the ten years ending 1905–6 the annual average area in British India, including Burma, was 3,904,000 acres, of which Burma had 930,000 acres; the Central Provinces, 832,000 acres; Madras, 737,000 acres; and Bombay with its Native States of Kathiawar and Baroda, 633,000 acres. For the years 1905–7 the estimated area and yield (excluding Burma) were:—1905–6, 3,914,200 acres (pure) yielding 344,800 tons, and 700,000 acres (mixed) yielding 45,000 tons; 1906–7, 3,844,100 acres (pure) yielding 441,100 tons, and 775,100 acres (mixed) yielding 90,000 tons.

There are two crops, a *rabi* and a *kharif*, and various cultivated forms of the plant, some specially suitable for growing in the *kharif* season,
others as early rabi crops. Two, at least, of these are easily recognised—one with white seeds (sa jed til), the other with black (kala til). The latter is much the more common form and is reputed to yield a superior oil.

The rabi crop is most extensively grown on black or medium black cotton soil in alternation with cotton or jüdr. If sown in September it is ready in January. The kharif crop is usually sown with other crops, such as jüdr, bøjra and cotton, but is sown by itself in some localities. It ripens in October or November. A good average crop from black soil is said to yield about 450 lb. of seed per acre (Imp. Gaz., 1905, iii., 38-9).

**Bengal, including Eastern Bengal.**—The estimated area and yield in 1904–5 were 493,700 acres and 59,000 tons. The actual area, however, was 414,200 acres. The largest areas (indicated by the returns for 1904–5) ordinarily are:—Maimensingh, 74,300; Pabna, 39,000 acres; Angul, 34,500 acres; Midnapur, 29,100 acres; Hazaribagh, 27,700 acres; Backerganj, 25,000 acres; Jessore, 22,500 acres; Noakhali, 13,600 acres; Tippera, 13,200 acres; Bogra, 13,000 acres, etc. The supplementary *Final Memorandum* for 1906–7 estimates the area for 1906–7 at 292,100 acres with a yield of 39,600 tons in Bengal, and at 221,800 acres with a yield of 25,400 tons in Eastern Bengal.

According to Roy, the best soil is an alluvial loam, high and well drained. The black variety is taken after ākus paddy, the white after ākus or aman paddy. In Dacca only white til is grown. The land is ploughed and harrowed in February and April and the seed then sown "6 seers per acre." The crop is harvested in May–June, and the average yield is about 15 maunds per acre." In Orissa, the land is prepared and the seed sown for white til in June–July, and the crop harvested in November–December; for black til, the seed is sown in September–October and the crop harvested from January to March. [Cf. Basu, *Agri. Lohardaga*, 1890, pt. 2, 35; Banerjei, *Agri. Cuttack*, 1893, 89–90; Mukerji, *Handbook Ind. Agri.*, 1901, 274–5; Roy, *Crops of Bengal*, 1906, 82–3.]

**Assam.**—The area in Assam proper in 1904–5 was 8,376 acres and the chief localities Sylhet, Nowgong and Kamrup. There are reported to be three different crops, viz. the crop sown in February–March in Sylhet, the August–October crop of the Brahmaputra valley, and the May–June crop of Manipur and Nowgong. According to F. C. Henniker (*Assam Crop Exper.*, 1900–1, app.) the average outturn in 1900–1 was found to be 283 lb. per acre. [Cf. Allen, *Assam Dist. Gaz.*, 1905, ii., 120–1.]

**United Provinces.**—As already indicated, sesamum is largely grown as a mixed crop in these provinces. The total area of the pure crop in 1904–5 was 304,097 acres, and the outturn (estimated) 13,900 tons; of the mixed crop (estimated) 600,000 acres, and the outturn (estimated) 35,000 tons. The principal districts (according to the returns for 1904–5), where the crop is grown alone, are:—Agra: Hamirpur, 115,119 acres; Jhansi, 105,404 acres; Banda, 35,164 acres; Mirzapur, 17,663 acres, etc. The supplementary *Final Memorandum* on the crop for 1906–7 estimates the area under the pure crop at 309,200 acres with a yield of 36,200 tons, and under the mixed crop at 775,000 acres with a yield of 90,000 tons. It is a kharif crop, sown at the commencement of the monsoon and harvested in October and November. The method of cultivation is very rough. "The seed is sown broadcast after two or three hurried ploughings, and ploughed in. When grown with millet or cotton, it gains the benefit of the care which these crops receive. It is in this case either sown broadcast,
the seed being mixed with that of the principal crop before sowing, or it is disposed in parallel lines running across the field or along its margins. When mixed with other crops the amount of seed sown to the acre varies, of course, with the inclination of each individual cultivator. When grown alone, from 8 to 12 seers of seed are used."

"Under the circumstances of its cultivation it is obviously impossible to frame any reliable estimate of its outturn per acre, which varies very greatly with the amount of seed sown. From 25 seers to 1½ maunds are commonly gathered when it is sown with juár or cotton. When grown alone from 4 to 6 maunds is the average return to the acre." [Cf. Dutthie and Fuller, Field and Garden Crops, ii., 35-7 and t. xlii.]

**Central Provinces and Berar.**—The estimated areas in 1904-5 in the Central Provinces and Berar were 779,600 acres and 111,500 acres, while the estimated yields were 58,900 tons and 10,100 tons respectively. The actual areas were 858,664 acres in the Central Provinces and 111,718 acres in Berar. In the Central Provinces the chief districts were:—Sambalpur, 103,401 acres; Nimar, 98,785 acres; Rajpur, 98,680 acres; Hoshangabad, 78,487 acres; Jabalpur, 68,992 acres; Chânda, 59,800 acres, etc.; in Berar:—Wun, 67,307 acres. The supplementary Final Memorandum for 1906-7 estimates the area at 783,900 acres and the yield at 69,600 tons.

Fuller (Note on Outturn of Land under Crops in C. Prov., 1894, 22-4) says "it can be grown on almost the poorest land in cultivation, but is also a profitable crop on good soils, and is commonly sown on newly broken lands during the first two years of the reclamation. It requires a light monsoon rainfall and in this respect resembles cotton, the til and cotton harvests generally agreeing in character. Though classed as a monsoon crop, til is largely grown during the cold weather in the southern and eastern districts, good land in this case being devoted to it and a larger outturn gathered than is usually yielded by monsoon til." With regard to outturn, he states that "the present standards are 150 lb. per acre for the three northern districts, 250 lb. for Wardha and Nagpur, and 200 lb. for all others. They rather overstate the produce, save in the case of the Nerudda and Nagpur districts, where they are decidedly too low." [Cf. Rept. Land Rev. Settl. Nagpur, 1899, 63; Hoshangabad, 1905, 28.]

**Panjâb and North-West Frontier.**—The estimated area and yield in the Panjâb for 1904-5 are given as 158,000 acres and 16,000 tons. The actual area subsequently returned for that year in the Panjâb was 113,300 acres, and in the North-West Frontier Province 4,901 acres were returned as under the crop. The largest areas in the Panjâb (in 1904-5) ordinarily occur in Gurdaspur, 30,479 acres; Multan, 13,295 acres; Kangra, 10,255 acres; Amritsar, 5,709 acres; Gurgaon, 5,242 acres; Hoshiarpur, 5,231 acres, etc. The supplementary Final Memorandum for 1906-7 estimates the area in the Panjâb at 94,400 acres with a yield of 8,600 tons.

In the Gazetteer for Multan (1901-2, 217) it is stated that "the outturn is from 3 to 3½ maunds per acre, and the produce fetches the zamindar some 10 seers to the rupee, or Rs. 4 per maund. The crop gives fair returns and costs less to cultivate than most, as it can do with a light soil and moderate moisture, can be sown late, and requires very little looking after. The sowings take place in July, and the crop is cut in November." Lawrence (Valley of Kashmir, 340) says it is a very common crop, sown
in April, and ripens shortly after rice. It is a delicate crop, injured by cold winds.

**Bombay and Sind.**—Estimated areas, including the Native States, were given in 1904–5 as 793,900 acres in the Presidency and 83,700 acres in Sind, with yields of 52,700 tons and 5,300 tons respectively. The area actually surveyed in the British districts alone was 302,600 acres in Bombay and 79,772 in Sind. In Bombay (1904–5) the largest areas were Khandesh, 80,812 acres; Nasik, 54,989 acres; Panch Mahals, 46,768 acres; Ahmadabad, 33,524 acres; Kaira, 18,681 acres; Ahmadnagar, 16,731 acres; Dharwar, 16,446 acres, etc. In Sind—Upper Sind Frontier, 46,894 acres, etc. Although no returns are available for the year named, the crop is known to be very important in Kathiawar, Baroda and other Native States. The supplementary *Final Memorandum for 1906–7* estimates the area and yield in Bombay (including its Native States) at 1,020,400 acres and 182,400 tons, and in Sind (with its Native States) at 62,100 acres and 4,700 tons. The method of cultivation is fully described by Mollison: “The *khari* crop requires,” he says, “a totally different soil to that found most suitable for the *rabi* crop. *Til,* as a rain-crop, likes a sandy soil or light soil, whereas the crop which is sown in August–September, or later, grows best on black soil or on such soils as are retentive of moisture.”

The Kaira cultivation, he further says, is typical for the *khari* crop. It is sown subordinate to *bájra* on sandy loam soils. Other subordinate crops are the usual pulses and fibre-plants. “The *til* seed rate is 1/2 lb. or less per acre.” If sown as early as possible in the *khari* season, harvest should commence in September–October. A good outturn as a subordinate crop he estimates at “80 to 120 lb. per acre.” As a *rabi* crop it is grown extensively alone on black or medium black soil. The rotation crops are cotton and *juár.* The field is repeatedly ploughed and harrowed during June, July and August. If sown in September, the crop is ready in January.

With regard to outturn, he estimates that a good crop in Khandesh yields from 320 to 360 lb. per acre, and the seed is worth 15 to 18 lb. per rupee. From a seed-rate of 1 lb. per acre, a crop experiment at Surat in 1895–6 gave an outturn of 372 lb. per acre, worth Rs. 25–13–3. The cost of cultivation is rated at Rs. 10–6–0 per acre. [Cf. Mollison, *Textbook Ind. Agri.*, iii., 90–4; *Crop Exp. Rept. Bombay Pres.*]

**Madras and Mysore.**—The estimated area and outturn were 674,200 acres and 55,100 tons, but the actual area in Madras during 1904–5 was 755,475 acres. In Mysore the area was 90,623 acres. The chief districts of Madras in 1904–5 were Godavari, 83,939 acres; Vizagapatam, 83,337 acres; South Arcot, 68,218 acres; Tinnevelly, 56,938 acres; North Arcot, 56,873 acres; Salem, 55,429 acres; Coimbatore, 47,334 acres, etc. The supplementary *Final Memorandum for 1906–7* estimates the area and yield in Madras at 583,500 acres and 48,000 tons. In Godavari, it is stated that mixed or sandy soil suits the plant best. The land is prepared about the month of April and the seed sown in May or June. The crop is ripe about three months after sowing. In North Arcot it is said to be an early crop, being sown, if the rains are sufficient, in April or May, and reaped four months later. It is sometimes irrigated, and is then sown as early as January or February. [Cf. Cox, *Man. N. Arcot*, 1895, i., 271–2; Rice, *Mysore Gaz.*, 1897, i., 122; Francis, *South Arcot*, 1906, i., 114, 122.]

**Burma.**—The area in 1904–5 was 976,361 acres in Upper Burma;
THE GINGELLY OR SESAME PLANT

Burma

60,317 acres in Lower Burma. The largest areas were as follows:—Myingyam, 241,355 acres; Magwe, 185,386 acres; Lower Chindwin, 128,398 acres; Sagaing, 127,634 acres; Meiktila, 94,954 acres; Minbu, 77,176 acres, etc. The following facts regarding Myingyan (Carey, Settl. Rept. Operat., 1901, 34), where the largest area is ordinarily grown, may prove instructive. “Early sesame is sown in May and June and is reaped in July and August. Late sesame is sown in October and November and is reaped in January and February. The early sesame seeds are the thadunbyu (white), boktaung (red), shan hnan (large seed), and the late sesame varieties are the hnangi-net (black) and hnangyi-phu (white). The same quantity of seed is sown for both crops. The late crop is the safer, but the early crop gives the larger yield. Invariably 2½ pvis of seed are sown to the acre, and whereas the early crops yield from two to twelve baskets (both extreme figures), the best late crops seldom exceed six baskets. A basket of seed gives 5 viss of oil, the value of which varies from Rs. 3 to Rs. 5 per viss, but Rs. 3–4–0 is the average normal sale value.” [Cf. Settl. Operat. Repts. for Parllett, Sagaing, etc.; Max and Bertha Ferrars, Burma, 1900, 51, 149.]

Expression of Oil

MANUFACTURE AND USES OF THE OIL.—As indicated, there are at least two easily recognised forms, one with white, the other with black seeds. The latter is the most abundant and yields the best oil. It is extracted by expression in mills, by the same process as that for mustard-oil. It is clear and limpid, varying in colour from pale yellow to dark amber. Has no smell and not liable to become rancid. Adulteration with ground-nut oil is frequent. In India it is largely used for culinary purposes, in anointing, in soap manufacture, and as a lamp-oil. It is also frequently employed as an adulterant of ghi (see pp. 479, 481). In England it is chiefly used in making soap. In many of its properties it resembles olive-oil, and is accordingly similarly utilised. The oil from the black variety is generally stated to be more suitable for medicinal purposes than the white. It is also extensively employed in the manufacture of Indian perfumery, and for this purpose the perfume is frequently extracted by the seeds direct—layers of the seeds being placed between layers of flowers, etc. (see p. 820). The white-seeded form is largely eaten as an article of food, more especially in certain sweetmeats. The oil-cake, left after expression of the oil, is in demand all over India as a cattle food, and in times of drought and scarcity is often eaten as food by the poorer classes. As a manure the cake is of less value than castor and other oil-cakes. In Madras tanguctic bark (see p. 290) is said to be added to the seeds before being pressed for oil. [Of Pharmacog. Ind., iii., 26–33; Agr. Ledg., 1893, 1895–7, 1901, 1903–4; Basu, Agr. Lohardaga, 1890, pt. 1, 131; Banerjej, Agr. Outack, 1893, 197; Blount and Bloxam, Chem. for Engin. and Manuf., 1900, ii., 233; Merek, Digest., 1900, No. 7; Ludwig Hesse, Physiolog. and Therap. Import. of Iodipin in Pharm.—Centralhalle, 1906, No. 1; Thorpe, Dict. Appl. Chem., 1900, iii., 377–8; Leach, Food Inspect. and Anal., 1905, 420; Leather, Mem. Dept. Agric. Ind., 1907, i. (Chem. ser.), No. 2.]

Trade—Internal.—The returns of oil seed carried by rail were in 1902–3, 4,590,935 cwt.; in 1903–4, 4,675,014 cwt.; in 1904–5, 3,627,307 cwt.; in 1905–6, 2,956,419 cwt.; and in 1906–7, 4,326,524 cwt. The chief importing centre is Bombay port, which in 1906–7 drained its supplies chiefly from the Central Provinces, Rajputana, Nizam's Territory and Bombay Presidency, viz. 2,738,978 cwt. Calcutta follows next with a total of 453,979 cwt., received from the Central Provinces and Bengal; then come the Madras ports with 384,156 cwt., derived from the Nizam's Territory and Madras. The traffic of Burma is not given in the returns of railborne trade, but it is doubtless mainly toward Rangoon and the other chief towns of the province.

The total exports by coast of sesame seed in 1905–6 amounted to 479,169 cwt., valued at Rs. 37,69,577, and during the period 1900–5

986
TRADE IN GINGELLY

averaged about 400,000 cwt. The chief exporting centres, coastwise, are Madras and Bombay, and the chief importing province is Burma. It is thus very significant that Burma, though it is the largest single producing area, drains an annual supply from India.

Foreign Exports.—In the foreign trade statistics the figures are returned under two headings—(1) Oil and (2) Seeds. The quantities of Sesamum Oil exported during the years 1902-7 were as follows:—In 1902-3, 212,728 gallons, valued at Rs. 3,33,489; in 1903-4, 285,711 gallons, valued at Rs. 4,24,403; in 1904-5, 547,456 gallons, valued at Rs. 7,22,158; in 1905-6, 308,310 gallons, valued at Rs. 4,44,293; and in 1906-7, 165,877 gallons, valued at Rs. 2,79,644. Almost the whole quantity goes from Bombay, and the chief markets in recent years have been Mauritius, Arabia, Aden, Ceylon.

During the period 1900-7 the exports of Seed were:—In 1900-1, 1,844,194 cwt., valued at Rs. 1,55,58,575; in 1901-2, 2,447,149 cwt., valued at Rs. 2,14,39,368; in 1902-3, 3,732,685 cwt., valued at Rs. 2,90,93,614; in 1903-4, 3,512,650 cwt., valued at Rs. 2,42,89,443; in 1904-5, 2,516,757 cwt., valued at Rs. 1,73,71,691; in 1905-6, 1,685,208 cwt., valued at Rs. 1,46,93,032; and in 1906-7, 2,740,815 cwt., valued at Rs. 2,53,79,919. It will thus be seen that a considerable fluctuation has taken place. Commenting on this subject, Noël-Paton (Rec. Trade Ind., 1905-6, 43) observes: “The shortage in rape-seed led to an acute internal demand for sesamum and occasioned great embarrassment to shippers; and, since in this case also the favourable nature of the crop prospects had led to depletion of available stocks, the exports, which declined by 28 per cent. in 1904-5, underwent a further contraction of 33 per cent., making a total of 52 per cent. in the two years. The average value rose by 26·3 per cent.” The condition mentioned was, however, entirely changed by the recovery of the foreign transactions in the year following. Bombay exports almost the entire quantity consigned from India (in 1901-2 its share came to 2,366,144 cwt.), and the chief markets were:—France, 1,060,589 cwt.; Belgium, 862,117 cwt.; Germany, 311,553 cwt.; Austria-Hungary, 191,795 cwt.; Italy, 158,316 cwt.; Egypt, 110,515 cwt.; and by way of contrast it may be added that the United Kingdom took only 3 cwt., valued at Rs. 24. But, as already observed, while Burma is the largest single producing province, it exports practically no sesamum seed. The production must be locally consumed, and hence to Burma this is relatively a much more important product than it is to the people of India. In Burma this oil doubtless plays very largely the part of ghi in India.

The imports of sesamum oil and seed are small and unimportant, amounting, in 1906-7, to 384 gallons of oil and to 14,549 cwt. of seed, chiefly derived from the Straits Settlements and Ceylon, and consigned to Burma.

According to a recent volume of Prices and Wages in India, the wholesale price of sesamum seed in Calcutta in January of 1906 was Rs. 5-10-6 per maund of 82·286 lb.

SESPLANIA ACULEATA, Pers.: Fl. Br. Ind., ii., 114; Prain, Beng. Plants, 1903, i., 402-4; Leguminosae. The jayanti, brihat-chakrane, dhanicha, dhunuchi, gadoreji, ran-sheurd, bhuauali, erra jiluga, nyach, etc. A suffruticose annual met with often in a cultivated state on low-
THE ITALIAN MILLET

lying land on the plains of India, from the Western Himalaya to Ceylon and Siam.

The stems of this plant have long been employed locally in various parts of India to yield a strong and useful fibre, which is used as a substitute for hemp. It is considered to be very durable under water, and is much esteemed by fishermen for making drag-rope for nets. It is sown after the first showers of April or May, and the crop is ready to cut in September or October. The expense of cultivation is about Rs. 9 per acre. The method of preparing the fibre is similar to that for san (Crotalaria juncea). The stems are also commonly employed as stakes for pān (Piper belle) gardens. Recent experiments at Sibipur and elsewhere have shown that it makes a good green manure. [Of. Banerjici, Agri. Outtac, 1893, 88; Dodge, Useful Fibre Plants of the World, 1897, 294; Exper. Farm Rpt., Sibipur, 1897–8, 10; Repts. Dept. Land Rec. and Agri., Bengal; Admin. Rept. Bengal, 1901–2, 20; Dept. Agri. Mad. Bull., 1905, iii., No. 52.]

SETARIA ITALICA, Beauv.; Fl. Br. Ind., vii., 78; Rhede, Hortic. Mal., xii., t. 79; Dutthie, Food. Grass. N. Ind., 15; Dutthie and Fuller, Field and Garden Crops, 5, t. xxv.; Panicum italicum, Linna., Roxb., Fl. Ind., 1, 302; Gramineæ. The Italian Millet, kängnī, kāngni, rāla, kirangi, kora, koni, kaon, kākūn, china, chena, shāli, shol, tāngun, kher, gal, teñni, naoni, sat, etc.

Cultivation.—This millet is extensively grown in India both on the plains and the hills up to 6,000 feet, and is distributed to most warm temperate and tropical countries. It is interesting, for example, that the discoveries made at Ancient Khotan, by recent explorers, show that it was cultivated in Eastern Turkestan during at least the 3rd century of our era. Stein, for example, calls it tarigh, and mentions specimens of the grain found at Niya and also at Kara-dong which had been identified at Kew. It was perhaps somewhat significant, however, that no reference should be made to it in The Bower Manuscripts, discovered at Kucha, seeing that two other millets are mentioned, viz. Panicum crus-galli (var. frumentaceum, see p. 843) and Eleusine coracana. The Italian Millet has often been claimed as an Indian wild plant, but the majority of writers now regard it as an exotic though cultivated from ancient times. It has, in fact, been grown from time immemorial in Asia, and has been recognised in the deposits of the Swiss Lake dwellings. De Candolle thinks that the species existed thousands of years ago in China, Japan, and the Indian Archipelago. The kāngni of modern writers undoubtedly denotes this grass, and it is cultivated here and there all over India, and even in Burma and the Shan and Kachin hills. It delights, says Roxburgh, in an elevated light dry soil, and two crops may be sown on the same field, two separate sowings being made, and harvested in September and January. It is grown as a kharīf crop mostly, and there are two well-marked varieties, one straw yellow, the other reddish yellow. Sen (speaking of Dacca) says it is very sensitive to stagnant water. If rain-water stands on the field for twenty-four hours the crop may be lost. Roy tells us that in Orissa it is generally grown by the hill tribes and confined to the jungle-lands. Mollison (Textbook Ind. Agr., iii., 90) says that this millet is cultivated all over India, but in no part is the cultivation very important. "In Bombay Presidency the crop is annually becoming more popular and the area has considerably increased." "The total area for the Presidency exceeds 200,000 acres annually." It is a "quick-growing plant and a suitable crop to grow after a period of famine or scarcity." Mollison then adds that a Dharwar crop tested in 1894 yielded the following results:—Seed-rate 63 lb.; grain 843 lb. and straw 2,631 lb. an acre.

Diseases.—In Madras the crop is very much attacked by a fungus, known as Scierospora graminicolora, some account of which is given by Barber in a paper on the diseases of Sorghum in Madras (Dept. Agri. Mad. Bull., 1904, ii., No. 49), and by Butler (Mem. Dept. Agri. Ind., 1907, ii., 14; also Maxwell-Lefroy, 1908, ii., 1–13).

Food. —The grain is much esteemed as an article of human Food in some parts of the country, and is eaten in the form of cakes or of porridge. In Madras it is specially valued as a flour to be used in making pastry; and when boiled with milk it constitutes a light and pleasant meal for invalids. It is also much valued as a food for cage-birds and for poultry, and added to beer it is said to make the
SHELLS

Beverage more intoxicating (see p. 700). Church gives the nutrient ratio as 1 : 7-4 and the nutrient value as 91. As Fodder, the straw is not reckoned very nourishing and is often only used as bedding or for thatching houses. [Cf. Sen, Rept. Agri. Stat. Dacca, 1889, 37; Banerjea, Agri. Cottuck, 1893, 76-7; Roy, Crops of Bengal, 1906, 60; Lawrence, Valley of Kashmir, 1893, 327; Mysore Gaz., 1897, 1, 116-7.]

SHELLS.—Three groups of shells are of industrial value in India:

(a) Cowries or shells used as money; (b) Conch and other shells used for artistic and industrial purposes; (c) Shells, freshwater and marine, utilised as sources of lime; and (d) Ornamental Corals.

Cowry.

Cowry.—kauri, kavadi, kaparda—the small white shell of Cypraea moneta. From time immemorial this has been employed in the currency of Southern Asia, more especially in China. The use is alluded to by Ma'bud (943 A.D.), by Marco Polo, and by many other writers, more especially of the Maldives, South India and Bengal. In India they are rapidly disappearing, though in the rural parts of the country they are still employed as money. Their value appears to be 0.144 to the rupee. But in addition they are largely employed as articles of adornment for horses, cattle, etc. The imports in 1901-2 came to 17,568 cwt., valued at Rs. 56,892; and five years later (1905-6) 21,405 cwt., valued at Rs. 81,710; and 1906-7, 18,638 cwt., valued at Rs. 68,845. The bulk of these foreign supplies came from East Africa and were imported into Bombay mainly, then Calcutta, Karachi, and last of all Madras. A considerable local supply is also obtained from the Laccadive and Maldives Islands. [Cf. Watt, Ind. Art at Delhi, 1903, 206.]

Conch or Chank, Mother-of-Pearl, Etc.—Thomas, Pearl and Chank Fisheries, 1884; Thurston, Mad. Bull., 1894, No. 1. The sacred chank, conch or sankha (Turbinella rapa), is procured by divers in the Gulf of Manar, opposite Jaffnapatam in Ceylon, and off the coast of Travancore, Tuticorin, etc. Formerly the traffic in these shells was a State monopoly, to-day the Ceylon fisheries are regulated by an Ordinance. And so far as India is concerned, a notification is simply given when the sales will occur at Tuticorin. As much as a lakh and a half of rupees’ worth is often disposed of at one time. But so long ago as the 16th century Garcia de Orta spoke of the trade with Bengal in these shells having declined, and Bocarro in the 17th century made special mention of the manufacture of bracelets from them. A right-handed chank (that is to say, one with the spiral opening to the right) is much prized by the Hindus to be used at their temples, and being exceedingly rare often fetches a high price. Bracelets, armlets, charms, etc., are made of the ordinary conch shell, and these have been used in India from time immemorial, such bracelets being known as sankhhas and the workers as sankharis. It is somewhat curious that the chief centres of this trade are all remote from the localities of production—namely Dacca, Patna, Dinajpur, Rangpur, Bardwan, Balasore, Bankura, Sylhet, etc. Many of the smaller and more ornate shells are specially collected and used for personal adornment, or are worked up in fancy goods.

Mother-of-Pearl is procured at both the pearl and the chank fisheries. The shells are largely exported from Tuticorin, and used up in inlaying both wood and stone at Kota, Bharat and Aga (see goods). Shells, Coral, Etc., used as sources of Lime (see p. 712).

Coral.—murjan, munga, sangi-marjan, galli, paxadal, pooydan, etc., is mainly of interest to India in the form of coral-reefs—modern or ancient—and hence as sources of lime. Very little can be learned regarding indigenous ornamental corals. Mason, writing of the coast of Burma, mentions an elegant species of Actinia and of Memandria found in Amherat and Mergui. He also refers to a scarlet coral composed of cylindrical tubes united together (Tubipora muscosa): a star-coral and tree-coral as plentiful on the coast of Tavoy. Black coral (Antipatharia) is also met with, of which beads are made and traded in from the Mergui Archipelago. Speaking of Tenasserim, Mason alludes to a tree-coral two feet long being of a deep scarlet often sold under the name of “Red Coral.” There are no properly constituted coral fisheries in India or Burma, and it cannot accordingly be said that we possess the information to decide whether or not any of the Indian species are of industrial value. The Indian trade in ornamental coral accordingly centres around the imported kinds, which, being foreign products, need not be dealt with in this work further than to mention the other shells, used as sources of lime (see p. 558).
THE SAL TREE

SHOREA ROBUSTA

extent of the traffic. In 1868-9 India imported coral to the value of £93,126. For the past five years the traffic has marked a decline in quantity but a rise in relative price. In 1902-3 India received 283,580 lb., valued at Rs. 5,47,258 (£36,484); and in 1906-7, 98,172 lb., valued at Rs. 3,27,773 (£21,832). The traffic is almost entirely from Italy and to Bengal.

The Sāl tree, sāl, sākhu, sarjum, sakva, tāvur, kāndār, gūgāl, kābbu, enkāyān, etc. A large gregarious tree, of which Gamble says: "The sāl tree occupies two principal regions in India. The first is a belt at the foot of the Himalaya and running into its valleys and up its lower hills to 3,000 or 4,000 feet, and exceptionally, as for instance at Lansdowne, to a still higher altitude." "The second is the Central Indian belt, and the sāl country begins on the Ganges near Rajmahal and passes through the Sonthal Parganas, Rewah, Chota Nagpur, the Central Provinces, Orissa and the Northern Circars, ending in the Pallonda range of Vizagapatam and the forest of Jeypur."

Seed.

Famine Food.

Timber.

When tapped, the tree exudes large quantities of an aromatic Resin, whitish at first but becoming brown when dry. The method of tapping usually employed is in the month of July to cut out three to five narrow strips of the bark, according to the size of the tree, and about 3 or 4 feet from the ground. In about twelve days the grooves have filled up with resin. This is gathered and left to fill again. They give three yields, amounting in the best trees to as much as 10 lb. The first is the best in quality. A second yield in October and a third in January are also obtained from the same cuts, but small in quantity and inferior in quality. The resin usually occurs in small rough pieces, nearly opaque and very brittle, but Gamble states that in some parts of the Upper Tista forests, large blocks, 30 to 40 cubic inches in size, may be found in the ground at the foot of the trees. It is used chiefly to caulk boats and ships, as also an incense and in medicine. Hooper (Rept. Labor. Ind. Mus., 1903-4, 25) says that it has a much lower acid value than pine resin, viz. 20 to 22, in place of 137 in imported pine resin and 124 in the Indian article.

The bark is said to yield a red and black Dye and to serve as a TAN. Recently an investigation into the value of sāl bark as a tanning material was undertaken at the Imperial Institute, at the request of the Forest Department, and a report (Imp. Inst., Oct. 7, 1904) was submitted by Dunstan to the Under-Secretary of State for India. Analyses proved that the bark derived from young trees was richer in tannin than that from old trees; moreover, that the young bark contained as much tannin as is present in oak, hemlock, and other barks commonly employed as tanning materials. Analyses of Indian-made extracts, however, showed these products to be of poor quality. Filtrates were better than solid extracts, both as regards solubility and tannin content, but "the best contained only 21 per cent. of tannin, whereas the ordinary tanning extracts in use in Europe contain at least 30 per cent." Experiments in tanning, both in the laboratory and on large-scale trials, were carried on by Dunstan at the Imperial Institute. In summing up his report, he observes that the results recorded show that it is quite possible to prepare from the bark of Shorea robusta an extract which, when employed as a tanning material, may furnish leather both of good texture and colour. It remains, he adds, to be seen whether the process devised by him can be successfully employed on a manufacturing scale in India. [Of. Hooper, Agri. Ledg., 1902, No. 1, 15-6.]

The seeds ripen at the commencement of the rains and are collected and eaten as Food, especially in times of scarcity. The Agricultural Magazine (1904, No. 5) will be found a paper by Reinherrz on the seeds of Shorea as a famine food. He gives a map showing the chief localities where the seeds are eaten, viz. in Chota Nagpur, the Sonthal Parganas, Gaya, Bhagalpur, Jalpaiguri and Orissa in Bengal; Gorakhpur in the United Provinces; Central India; and Chatrapur in Madras. The tree, however, is best known for its Wood, which is the most extensively

S. rhombifolia, the yield per acre found to work out to 5 maunds 19 seers cleaned fibre. It was stated that the plant did not grow well but was branchy, hence it was difficult to extract the fibre and the machine used could not deal with it properly.
SILK
BOMBYX
Mulberry

added (upon what authority is not shown) that "the retting process is not suitable for it." The ultimate fibres were found to be 1-5-2 mm. in length, and to be similar to jute in their reactions. It was, however, softer and more uniform. Chemically it showed a high percentage of cellulose (83-0 as compared with jute 75-0). [Cf. Cross, Bevan, King and Watt, Indian Fibres, 1887, 41-2; Watt, Sel. Rec. Govt. Ind., 1888, 277-82.] The most recent opinion is that given by Mr. Robert S. Finlow (Pusa, July 25, 1907) in a report on experiments: "Sida is undoubtedly a fibre of very high class; it is far superior to jute; indeed it probably ranks nearer to flax and rhea. It is a common plant all over India, but it grows especially well in the moist climate of Assam. I have sown plots at Rajshahi this year, which are doing well" (Rept. Agri. Dept. E. Beng. and Assam, 1906-7, app. ii.). Samples were sent to the Imperial Institute, and valuations ranging from £12 to £18 a ton were obtained (Imp. Inst. Tech. Repts., 1903, 59). The opinion given by Just Brothers of Bielefeld seems the rational one, namely that until a consignment of 400 lb. to 500 lb. of the fibre has been spun and woven, no definite conclusion can be arrived at.

SILK.—In perhaps no other country of the world does the necessity exist so pressingly as in India to treat the subject of silk and the silk industries under two distinct sections, viz. BOMBYCIDE, the Domesticated or Mulberry-feeding Silkworms; and SATURNIDAE, the Wild or Non-Mulberry-feeding worms.

I. THE MULBERRY OR DOMESTICATED SILKWORMS.

The terms mulberry and non-mulberry-feeding are more accurate than domesticated and wild, since certain of the so-called wild insects have existed for centuries, both in India and China, under what must be characterised as a degree of domestication; but, on the other hand, all the silkworms that live on the mulberry are not necessarily domesticated. "Wild silk" denotes, as a rule, the product of non-mulberry-feeding insects.

Habitat and Domestication.—The mulberry silkworm seems to be indigenous to the warm temperate regions of Northern China, and perhaps also of the adjacent countries. It was, for example, found by me in Manipur (during the Burma-Manipur Boundary Commission of 1882–3), under conditions that perhaps justify the suspicion that it may be indigenous, as well as long domesticated, in that little frontier State, if not of some parts of Bengal as well. But if it be not a native of certain warm temperate tracts of India proper, it occurs immediately beyond the Himalaya, more especially toward the eastern extremity, and at a very early period was successfully acclimatized on the extreme west in a tract of country just beyond the Kashmir frontier known as Khotan.

History.—In Buddhist Burma, where the objection to taking life prevails so strongly, a formidable barrier opposed any great extension of the industry, even although the Burmans for centuries past have been very partial to silk garments. Moreover, the silkworm exists on the hills of Burma and a distinctive race has for long been there reared—a fact that points to a considerable antiquity for the crafts of domestication of the worm, the reeling of the cocoons, and the weaving of silk. Moreover, a special tribe of people are identified with silkw—The Yabais.

Turning now to China, it is customary to read of the silkworm having been reared from a vast antiquity (2,000 to 3,000 B.C., cf. Du Halde, Hist. China, 1734, ii., 355–6), and of the secret of its value having been carefully guarded until well into the Christian era, when a princess, who married the Chief of Khotan, succeeded, at the risk of her life, in carrying off to the country of her adoption, seed of both the mulberry plant and the silkworm. This is reported to have taken place in 419 A.D., and in this way originated the silk industry and trade of Central Asia. A century and a half later, from Khotan a knowledge in silk was diffused to Persia on the one side and Greece and Rome on the other. The silk production of Central Asia became, in fact, the envy of Europe, and led to the formation of the silk-roads which were designed to facilitate the traffic in silk toward Rome. Procopius (De Bello Gothic, iv., 17, in Yates, Text. Antiq., 1843, 231) tells the story of the monks of Serind (according to Yates—Khotan) having successfully carried the eggs of the silkworm to Constantinople (530 A.D.) at the invitation of the Emperor Justinian. This was desired so that the Romans might be able to produce the raw silk themselves instead of having to purchase it from their enemies, the Persians. A slightly different version of this story is told by Sir Thomas Herbert (Travels, etc., 1677, 183–4), viz. “From the Seres or Regio Serica (part of Scythia towards Indus blunt) this worm first came into Persia, not long before Alexander’s time; but until the Emperor Justinian’s time it was not known in Europe; the first being presented by the Persians unto the Emperor at Byzantium as a rarity.” A curiously interesting confirmation of the tradition of the introduction of silk into Khotan has recently been brought to light by Stein (Ancient Khotan, 1907, 259–60) in the form of a painted wooden tablet found in the sand-buried ruins of Dandán-Uliq, which Stein interprets as depicting the story of the Princess who carried off from China the silkworm eggs. There seems every reason for concurring that the tablet dates from the closing decades of the eighth century. One attendant is pointing to the headdress in which the eggs were secreted, and also to the basket of cocoons obtained therefrom, while a second is shown working at a silk-loom. The strongly Persian, in place of the Chinese, expressions of the faces is perhaps due to the stronger Iranian than Chinese influence at Khotan during that period, perhaps to some extent a direct consequence of the trade that had been by then established in silk. In Japan the domestication of the silkworm is perhaps very nearly as ancient as in China.

In India the mulberry worm has been systematically reared for many centuries, though it seems probable there have been two independent sources of the knowledge and stock possessed by India, viz. (a) Northern India, very possibly from Central Asia (Khotan) and Persia; and (b) Assam and Bengal, possibly from across the Chinese frontier, in all likelihood via the little State of Manipur. But it is curious and partly suggestive of the date of introduction into Northern India, at all events, that in the Periplus it should be stated that the silk came down the Indus (from beyond Bactria) and was conveyed to the great emporium Barygaza (the modern Broach), while no mention is made of locally produced silk. This is apparently, moreover, the first mention of the great
silk manufacturing industry of West India—an industry that subsequently drew upon Bengal for its supplies of raw silk. It would also seem highly probable that all the early references to silk by the Sanskrit authors denote one or other of the non-domesticated worms, not the true silkworm of modern commerce.

Briefly, then, it may be said that the domesticated silkworm has been carried to all the countries of the globe where it has been found possible to grow the mulberry plant. But just as there are several distinct species, and under these many very different races of mulberry, so there are numerous forms of the silkworm. Some of these are confined within narrow limits, both as to locality and food-plant, others are less restricted and have adapted themselves to a wider range of climatic conditions and food-plants. The Roman attempt at rearing the silkworm does not, however, seem to have made much progress, for the domesticated insect of modern commerce is commonly believed to have been conveyed to Europe somewhere about the 13th century, and has since been widely diffused. There were, however, repeated efforts at domestica-

SOILK BOMBYX RACES OF INSECT

sions. For example, the worm was conveyed to Italy by King Roger II. of Sicily, who brought it from Greece along with Greek silkworm rearers, whom he compelled first to settle in Palermo. So again, it was in 1440 carried from Naples to France. It is now met with in Italy (Lombardy), France (Central and South), Spain, Sweden, Russia, Turkey, Algeria, Egypt, Syria, Armenia, Central Asia, Persia, Afghanistan, Kashmir, India, America and Australia, in addition to Burma, Siam, China, Japan, Corea, etc. It everywhere thrives best and gives the finest silk where the climate is temperate and its food-plant one or other of the races of *Morus alba.* Under skilled treatment, both of the food-plant and of the insect itself, immense improvements have been effected in Europe, also in Japan, so that it is commonly said both China and India have fallen below the modern level of quality.

As manifesting a common origin, the recurrence of the Tartar name *ser* and the Corean *sir* in many languages may be mentioned. Thus the Chinese *tsao* (cocoon), *tsi* (silkworm), and the Burmese *tsa*; also the *ser* in Greek; *sericum*, Latin; *seiden*, German; *soie*, French; *sheolk*, Russian; *scele*, Anglo-Saxon; *silke*, Icelandic; and *silk*, English. On the other hand, there seems little or no connection with these words and the names for the silkworm and silk in both ancient and modern India. The synonym *urna* (generally translated silk) occurs in the *Rig Veda*, but there is nothing to establish belief that it denoted mulberry silk. Another Sanskrit synonym, *patta*, gave origin doubtless to the modern Assamese and Bengali *pat* and the Tamil, *pattu,* for mulberry silk. In fact, *pat* occurs here and there throughout India and even in Kashmir, and uniformly denotes silk. So also the Sanskrit *pundarika* (silkworm) lives in the caste name of the silkworm rearers, the *pundari-kakshas* or *pundas.* The very common Indian name *resham* (silk) is derived from the Persian *abresham,* and is thus closely connected with the Hebrew *meshi* and *demeshek,* as also the Arabic *damatso* and *kus.*

**Names.**

**Life-history.**—While the forms made specifically by Hutton have by modern authors had to be reduced to races under the species *Bombyx mori,* the forms in question denote important industrial assemblages, which it is essential should be here briefly indicated.

It may be as well to sketch very briefly the life-history of the silkworm itself. Needless to say it exists first as an egg, then as a worm (or cater-

**Generations.**

pilar), which later on spins a cocoon within which the chrysalis stage is spent, and lastly from the cocoon in due course emerges the winged moth, which, after coupling, lays eggs and dies, thus originating once during its lifetime the cycle above briefly indicated. The four stages (egg, caterpillar, chrysalis and moth) thus constitute one generation, and insects that take a year to pass through these stages are called *univoltine.* Occasionally special breeds are met with that are *bivoltine,* that is to say, a first batch of the eggs germinate almost immediately after being laid, thus allowing time for two generations in the year. The *bivoltine* insect of China was perhaps first introduced into Europe by the Genoese, but *trivoltine* insects occur in Tuscany, and even *quadrivoltine* forms are met with in many countries.
In India a still more complex condition prevails, where the heat of Bengal and Assam causes the insects to become multivoltine. The boropol (barapalu) insect (Bombyx textor) is univoltine, but the deri (B. fortunatus), the madras (B. casti), the chotapat (B. sinensis), and the ngapaw (B. aracanensis) all pass through a succession of generations in the course of the year, which sometimes amounts to as many as eight in number.

The crop of silk produced by a generation of worms is called a band. In Bengal the ordinary crops or bands are known as the November band, the March band, and the July band, but there is occasionally a fourth band attempted after the close of the July one, by such rearers as have sufficient leaf.

Aristotle gives an interesting account of the silkworm, but he was not accurately acquainted with the four stages in its life. He does not say that it was reared in captivity but simply that Pamphile, daughter of Pilaeus, was reported to have been the first to weave silk at Cos. Aristotle describes the spine or horn at the anal extremity of the worm, a fact that proves fairly conclusively, however, that it was the same species as the mulberry-feeding insect of to-day. But St. Basil (370 A.D.), a native of Asia Minor, gives full particulars of the stages and mutations of the silkworm, and he was the first to mention the popular suggestion of the parallelism of the escape of the worm from the chrysalis with the resurrection after death. Pausanias (in the 2nd century), also a native of Asia Minor, furnished particulars of the rearing-houses used in summer and those employed in winter by the silkwormers. Thus, when we first make acquaintance with the life-history of the silkworm, it had probably been by then as fully domesticated as it is to-day.

The first scientific writer who can be traced is Andrug Libavius, who bred silkworms at Rothenburg and published his observations in 1599. He lays stress on the horn-like tail as the most distinctive character of the domesticated mulberry worm. But to the student of Indian sericulture a much more interesting publication appeared nearly a century later. In 1689 the Rev. J. Ovington wrote his Voyage to Surat, in the Appendix to which there is given Observations concerning the Nature of the Silkworms (see pp. 1017, 1020). This was apparently framed as an account of the silk of India generally and not of Surat alone, but it deals exclusively with the mulberry worm. It leaves the suspicion, therefore, that it may have had special reference to an attempted Surat industry of rearing silkworms, fully two centuries ago. He gives the utmost details as to the seasons of each band, then concludes—"This is the Nature of the Silk-worms in the Indies where the Heat of the Sun renders them much more fruitful than with us: for in India the Worms breed and spin their Silk six times in the Year, and in England only once." He likewise they are sooner brought to perfection, and begin to work sooner, viz., 28 days after they are hatcht, but in England not until the 40th. Where also they are by a third part more tedious in breaking out of their Houses from the first day of their Spinning than they are in the East, which is there done in ten days, but here only in fifteen." Herbert (Travels, etc., 1677, 183-4) gives a highly instructive account of the domestication of the silkworm in Persia. It was a univoltine insect fed on white mulberry, and he says, "In most Villages and Cottages we saw sheds filled with laborious People minding their enriching Silkworms."

**Races of Insects.**—The following may be given as the chief races:

(a)—B. mori proper, the European Silkworm.

It is customary by writers on the Indian silk production and trade to class all the races of the European worm as one, perhaps because under the Indian conditions the differences that exist become immaterial. Mukerji gives many interesting details regarding the directions under which the rearing of certain grades of the European worm become possible in the plains. The eggs require to hibernate under considerably lower temperatures than those for the barapalu (below)—viz. 30° to 40° F. But there are certain disadvantages, such as the fact that these worms usually die of flacherie if reared from April to August. They do not as a rule make good cocoons if fed on the ordinary shrub-mulberry of Bengal. They require to be fed on leaves gathered from trees. Where large mulberry trees are available it may be profitable to rear European cocoons. In
INDIAN MULBERRY SILKS

Races of Insect

fact the opposite condition also prevails, namely the chhotapalu (presently to be described) do not make good cocoons if fed on leaves from tree mulberries. The reader desires of full particulars of the methods to be pursued in rearing European silkworms in Bengal should consult Mukerji's work (l.c. 162-70).

In Kashmir, largely through the great personal interest taken in the subject by Sir Walter Lawrence and Sir Thomas Wardle, much progress has been made in acclimatising the European silkworm (see p. 1016). [Cf. Note on Sericult., in Kashmir, Baluchistan and Quetta, in Agri. Journ. Ind., 1907, ii., pt. iii., 286-7.] More recently similar efforts have been made in Assam (p. 1015), in Baluchistan (pp. 1016-7), and in Mysore (p. 1018).

D.E.P., vi., pt. iii., 111.

Journ. Agri.-Hort. Soc. Ind., 1871, i., 125; Rondot, L'Art de la Soie, 1887, ii., 483; Geoghegan, Silk in Ind., 1880, 133-8; Liotard, Memo. Silk in Ind., 1883, 59; Manuel, Journ. Agri.-Hort. Soc. Ind., 1886, vii., 291-307; Cotes, Ind. Muse. Notes, i., pt. iii., 162; Allan, Agri. Ledg., 1896, No. 26; Cooke, Silk Indus., in Yamethin, Agri. Ledg., 1897, No. 11; Handiman, Monog. Silk in Burma, 1901, 26-30; Quajat, Del Bozols, 1904, 115. The nympaw of the Burmans. This is a multivoltine silkworm. Apparently the earliest notice of it occurs in a letter from Major Bogle and referred to by Fytche, Assistant Commissioner, Arakan (Journ. Agri.-Hort. Soc. Ind., 1850, vii., 281-5). The best description of it, however, is that written by Mr. R. A. Manuel. It lives on the mulberry and the following are its stages—in the egg, 8 days; in the worm, 15-23 days; in the cocoon, 8-10 days; and in the state of moth, 2-3 days. Its cultivation in Burma, he further says, is careless, slovenly and dirty. No separate rearing-house is provided and the trays are never changed, the excreta never removed, nor the refuse food cleared out. It is no wonder, therefore, that the mortality is very high. The manipulation of the silk and the manufacture of the resulting fibre are alike indifferent, so that the industries connected with this special worm can hardly be regarded as more than of very local interest. The districts chiefly concerned are Tharawaddi, Prome, Thayeitmyo and Toungoo. Breeding is confined to the higher tracts of the Pegu and Arakan Yomass. Still, the existence of a special breed of B. mori may either point to a great antiquity or denote the comparatively recent domestication of a peculiarly Burmese insect which with more careful inquiry may be found to exist even to-day in a wild or feral state, much as in the neighbouring State of Manipur.

B. crassil. Hutton, Trans. Entom. Soc., 1864, ii., 312; Cotes, Ind. Muse. Notes, i., pt. iii., 151; Quajat, l.c. 113. This is the nistri or nistari or madrasri, a multivoltine insect reared chiefly in the Marchi and rains bands of Bengal and Assam, where it is second in importance to the desi variety. It produces a succession of crops throughout the year, most of which are only reared for seed. But unlike the desi, however, it thrives in the hot weather. Cotes (Journ. Agri.-Hort. Soc. Ind., 1891, ix., 155) says the only real distinction between desi and madrasri is that while the former thrives best in the cold weather, the latter prefers the hot season. The cocoons are generally yellow, at least externally, and are larger than those of the desi, but the fibre has less elasticity and brilliancy. The moth is milky white in colour and the caterpillar has two black spots on each segment. Blechynanden (Journ. Agri.-Hort. Soc. Ind., ix., 156) suggests that the name nistri is due to these spots, the comparison being to the goddess Kali, an alternative name for whom is Nistari. Hutton says that it goes through all its changes from egg to cocoon in twenty-five days but in cold weather it takes thirty-five days.

Perhaps the earliest account is that given in the Minutes of the Bengal Board of Trade in 1819 (cf. Reports, etc., of Cotton, Silk, and Indigo (pub. E.I.C.), 1836, app., 48-51). It is there stated that there are several distinct forms of the nistri worm, such as the "madrasri, soonamooky, and the orange." As to the origin of these insects, it is stated that the "Board are not able to speak with the degree of precision it were to be wished." They are peculiar to Commercoolly district, except the madrasri, which is also found in Bauleah, Soonamooky and Malda. The Resident at Commercoolly was of opinion that the finest stock of nistri was that of Soonamooky. The madrasri are inferior but next to these. They all produce a silk of a greenish hue much inferior to that of the desi, but are much sought after as they yield a large amount of silk. It is a hardy insect, requiring little care and not at all choice in its food.

The Resident at Malda wrote in the same papers that the madrasri silkworm is distinguished from the desi by a black mark under the throat. He then adds,
"It is a great comparative defect is that it cannot be kept in store (in these nurings at least) longer than a few days without total destruction, whereas the desi may be kept in well- aired cocoones even twelve months without material injury." Speed. (Agri.- Hort. Soc. Ind. Tran., 1839, iii., 21) speaks of this as the maddrasi or China pu1u, from which it may be assumed as possible that n. sinensis or sina (China) insect may be a degenerate state of the maddrasi, the two names sina and maddrasi having in Bengal come to be accepted as synonymous. This insect may or may not be the case, but it cannot be too strongly urged that the early writers recognised several distinct forms of nistri, of which the maddrasi was one and by no means the best.

(4)---B. fortunatus, Hutton, Trans. Entom. Soc., 1864, 312; Wardle, Wild Silks of India, 1881, 3; Rondot, L'Art de la Soie, 1885, i., 312; Cotes, Ind. Mus. Notes, 1889, i., pt. iii., 150-1, t. viii., c; Quajat, Desi Rossoh, 1904, 114. The desi, choto polo, palu or pâd insect—the November or cold-weather band.

As the name implies, this is viewed by the people of Bengal as an indigenous insect, though it is probable that it is in reality only so much anterior in its acclimatisation as to be viewed as relatively indigenous. Perhaps the first definite account of this insect occurs in the volume of official papers (E.I.C., i.e. 40-7). It is there stated to be produced throughout the year but to vary in estimation and value, according to the season of production and the nutritious nature of the mulberry-leaf upon which fed. "Hence, the worms of the cold-weather or November band, and that of the dry-weather or March and April bands, is superior from the more favourable state of the weather." Speed (Agri.-Hort. Soc. Ind. Tran., iii., 20) speaks of this silkworm as of a small size but as yielding cocoons five times a year at periods of from 40 to 110 days. Hutton points out that the longer period occurs in the November band, hence its superiority. The official papers (E.I.C., i.e. 41) speak of the "Commercially" chassara formerly raising no cocoons except the desi until the year 1799, when two sorts of nistri were introduced by Mr. B. Becher. It is, however, observed that the desi is the best of all the silkworms. The broods are October, November, March, April and June or July. The first is the best in point of quality, but the second the most productive. The Resident at "Cossimbazar" (E.I.C., i.e. 42) describes the November band of desi silk as the largest in the year, but he adds that in his opinion the annual worm is as far superior to the desi as the latter is to the mixed breed of desi and China insect. He then remarks that in Cossimbazar the April band is mostly the China insect. Similar reports are given from "Hurrrippal, Junghpora, Malda, Radhagore, Soonamockey and Bauleah," thus showing the wide distribution of this insect at the beginning of the last century. Of Hurrrippal, it was stated in 1819 that the desi had only just been introduced. In Soonamockey, on the other hand, the yield of silk from this insect in 1813 was 1,040 maunds of silk, and the Resident in Malda speaks of the produce from this particular insect having been in 1811, 2,708 maunds. He then adds that the cocoons produced in Bauleah and the vicinity in the November band alone, if a favourable one, are about 60,000 maunds.

Cleghorn recommended that in breeding the desi worm, it was imperative to select dusky moths. This observation regarding the dark-coloured insects and worms will be found to have a peculiar bearing on Hutton's opinion regarding the original form of B. mori, more especially when it is added that Muckerji, while experimenting with certain cocoons furnished by Cleghorn, arrived at the opinion that they "were a cross between the country breeds and B. mori of Europe." The domesticated and wild insects seen by me in Manipur would appear to belong to the desi race, a fact of no small importance in support of the belief that it is there indigenous (see below, p. 1015). [Cf. Allen, Monog. Silk Cloths of Assam, 1859.]

(c)—B. sinensis, Hutton, Trans. Entom. Soc., 1864, ii., 313; Cotes, Ind. Mus. Notes, 156. This is the sina (Chinese) or chota pâd insect of the Indian sericulturists. It is a small multivoltine silkworm, which produces cocoons inferior to both the desi and the maddrasi. In Bengal its cultivation has been almost abandoned, though it would appear to be grown successfully on the hills and seems to be the chief multivoltine insect of the plains of Assam. Hutton, speaking of Mussourie, says it was in his hands very prolific and yielded crop afer crop up to the middle of December. The cocoons vary in colour from being white, yellow, or greenish coloured. Unlike the other Indian races, which hatch slowly during the morning (from 6 to 12 o'clock), the sina worms come forth all in a batch, hatching day and night till all are out of the eggs. In the volume of official papers (Board of Trade, Bengal, 1819) there are several passages that deal with
this insect; the reports are unfavourable, and speak of the breed having degenerated in Bengal. Of Cossimbuzar, for example, it was observed that there had been a great intermixing of desi cocoons with the China stock. The latter predominates in the April band, the distinctive mark being the length and thinness of the cocoon. This is considered by the rearers as the most inferior kind and is called the "distinctive species." (ii. E. F. Baker, Notes, Trans. Entom. Soc., 1884, ii., 313; Wardle, Wild Silks in India, 1881, 2; Louis, A Few Words on Sericult. in Bengal, 1880, 20; Rondot, L'Art de la Soie, 1885, i., 320; Quajat, Dei Bozzoli, 1904, iii.; Cotes, Ind. Mus. Notes. 1889-91, i., 154; Mukerji, Handbook of Sericult., 1899, 155-62.

The boro polo or barapalu—Large Pât—the annual silkworm of Bengal. Speed (Agri.-Hort. Soc. Ind. Trans., 1839, iii., 19-20) fixed the date of the introduction of this insect into India, viz. 120 years before the date of his paper, etc. He further says that it came from Italy. There is no confirmation of these views in any of the records I have been able to consult.

Cotes speaks of this as an annual mulberry silkworm, larger than either the desi or the madras. In the official papers issued 1819, it is stated that in the district of Cossimbuzar this insect predominated in the March band; moreover it was added that in the Cossimbuzar factory that band was second in quantity but first in quality of all the bands in the year. Of Bauleh it was remarked in 1817 that not a cocoon of this description was produced. On the other hand, the Resident at Hurripaul spoke of it as the most valuable and as yielding the best silk in the March band. Of Jungypore, it was stated that notwithstanding every exertion, the production of this cocoon had become exceedingly precarious and uncertain. Radnagore reported that in a good season this insect was very abundant and profitable and produced in the proportion of at least two to one of the other species. The Resident of Soonamooky observed that the eggs are brought out for hatching about the end of January and in 40 to 45 days the cocoons are complete. This insect, he added, is, however, most difficult to rear and is much more delicate than the others. But the silk is of fine fibre and strong, and ought to be very mellow to the feel and of clear yellow colour with some white. The yield is about 103,500 khauns, which ought to yield about one hundred and fifty factory maunds of silk.

It is at present occasionally reared in Assam and Bengal, but owing to the fact that it produces but one crop of cocoons in the year and that its eggs do not hatch simultaneously, its cultivation has now been almost abandoned. To-day Mukerji deplores the decline in production that has taken place. "The Barapalu is reared," he says, "by very few people. There are two reasons for neglecting such a superior class of cocoons: (1) The eggs of the Chhotapalu, the Nistripalu, or the Cheenapalu take only eight to ten days to hatch, but the eggs of the Barapalu hatch after ten months; (2) Barapalu go on hatching for seven or eight days or still longer, while the eggs of the other varieties of Bengal silkworms hatch completely in two or three months, when once the hatching does commence." Mukerji makes the practical suggestion that if arrangements could be made for hatching barapalu eggs in certain central establishments and distributing hatched worms to villages instead of eggs, the rearing of barapalu could be made to assume some importance. Mukerji (L.c. 159) gives many useful particulars regarding the methods of storing and hatching the eggs, and shows that by subjecting them to a fairly low temperature for a fortnight, followed by a similar period of warm temperature, the eggs may be caused to hatch at any time desired, thus producing pseudo-broods as leaf may be obtainable. Naturally, they hatch in January and the cocoons are obtained in February, and from them four pseudo-broods may be taken, viz. a second brood in March, a third in September, and a fourth in October. Rondot writes that this variety spins a white cocoon smaller than that of B. mori and differing from it both in form and structure, being generally pointed at both ends, a little soft, the silk not closely wound and containing comparatively little gum.

MULBERRY-PLANT CULTIVATION.—(see Morus, pp. 784-5). In the temperate tracts of India various forms of Morus alba, Linn. (the mulberry of the European silk-producing countries), are grown specially as food for the silkworm. This is the case in many parts of the plains of Northern India, Baluchistan, Afghanistan, Kashmir, and along the Himalaya at altitudes up to 11,000 feet. The other species even more largely grown

998
for the Indian silkworm is *M. indica*, Linn., of which there are many distinctive varieties or races. This is the most common mulberry of Bengal and Assam, as also of the Nilgiri hills. The plants are usually raised under what is called the bush system, the standard or tree system being hardly if ever seen in these localities. It is, in fact, only in Bengal that shrub mulberries are produced systematically and at a cost of Rs. 20 to 25 per bigha (one-third acre). There is but one advantage of this system, namely that the leaf produced is preferred by the *chhotapalu* insect. Mukerji strongly recommends that mulberry trees should also be grown within or around the plantation, and for that purpose he suggests *M. alba*, var. *atropurpurea*. It is a fast-growing plant; the leaves are large and thick and at the same time smooth, tender and succulent.

*M. serrata*, Roxb. (the karun or kimu), *M. tawigata*, Wall. (the kimbu and *tawpeesa*), though wild, the former on the western and the latter on the eastern Himalaya and the mountains of Assam and Burma, are not to any material extent employed as food for the true silkworm.

Buchanan-Hamilton (*Stat. Acc. Dinaj.*, 210–3) gives particulars of the method of cultivation of the mulberry and the feeding of the worm that prevailed in Bengal during the closing decade of the 18th century. In the volume of official papers on the cultivation of mulberry, issued by the Bengal Board of Trade from 1813 down to 1836 (l.c. 63–113, 130–163) will be found a special report by Roxburgh entitled *Observations on the Indian Mulberry Tree, M. indica*, Linn. (l.c. 69–71), and also a similar paper by Wallich (l.c. 130–3, in which he describes *M. indica*, *M. atropurpurea*, *M. leptostachya* and *M. serrata*). These reports give a full record of the early experiments at improving the Indian silk by the production of better food for the worms, and are exceedingly instructive and valuable. Mukerji (*Handbook of Sericult.*, 1899, 1–4; also *Monog.*, l.c. 5–9) deals with present methods and opinions. "All varieties of mulberry are not equally suited," he says, "for rearing every kind of silkworm. The mulberry tree which we usually see in gardens, which yields large-sized black-coloured and luscious fruits is *M. nigra*. The leaves of that tree are rather coarse and not quite suitable for rearing silkworms." He then says that if the *chhotapalu* worm be reared on *M. nigra* it readily takes the disease flacherie, and the other forms of the insect, if reared on the black mulberry, yield a less proportion of silk and that of an inferior quality. Mukerji then adds that *M. multicaulis* may be regarded as the best for rearing silkworms. He doubtless means the Chinese and Philippine plant described by Perrotet, and which Rafinesque discusses in detail. [Cf. *American Manual of Mulberry Trees*, 1839, 64–6; also *Fl. N. America*, 1836, pt. iii., 48.] The attention of the Madras Government was drawn to this species of mulberry by Col. Sykes in 1839, and a supply was procured by Wight and grown in the Horticultural Society's gardens, Madras, about 1840, and a little later was taken to Bangalore and the Nilgiri hills. The leaves are large and tender. They are thick but not coarse. The tree grows fast and attains a greater height than other varieties. The internodes are short and the yield of leaf accordingly high. It is doubtless one of the many varieties or races of *M. alba*. As a curiosity it may be added that the American Osage orange (*Maclura aurantiaca*, Nutt.) has been introduced into India and found useful for rearing mulberry silkworms of all kinds.
SILK BOMBYX

Mulberry Plant

But in the early stages of the life of the worm it may be fed on the tender young leaves of the *pipal* (*Ficus religiosa*). This fact is of considerable practical value when in spring the mulberry of Bengal is in a backward state.

Diseases of Mulberry.

*Diseases of the Mulberry.*—Mukerji (l.c. 121–7) discusses the diseases to which the mulberry trees are liable. The most serious appears to be tukra. This is caused by a minute scale-insect (*Dactylopius bromeliac*). When attacked by this disease the leaves become curled up and the tender shoots swollen. When eaten they are shortly after voided by the silkworms, and if consumed to any material extent cause *flacherie* or *grasserie*. *Tukra* accordingly does much harm to the silk industry from January to June, and the only cure is the application of kerosene emulsion. Another somewhat similar disease is known as *naicha*. This is also caused by a member of the Coccidæ. It would seem the case that bush mulberries are much more liable to these diseases than tree mulberries. Mukerji observes that all the silk districts are not equally affected by *tukra*. In Murshidabad it prevails to such an extent that if it had not existed, there could have been obtained at least a third more leaf and therefore a third more cocoons. In Malda, Birbhum and Bogra very little damage is done by *tukra*—due possibly to greater intelligence in cultivation. Tree mulberries once started require little attention and are much less affected by dry, hot weather or disease.

*Butler* (Agri. Journ. Ind., ii., pt. i., 97–8) gives useful particulars regarding a fungal disease seen on the mulberries of Kashmir. The State plantations near Srinagar had been seriously attacked. The disease is found on old trees without causing appreciable damage, but does great harm to the young plants in the nurseries. It attacks the seedlings in their second and subsequent years, does not kill them outright, but they have to be cut back below the diseased parts, thus losing several years’ growth, even if they are not attacked again. The disease is caused by a parasitic fungus (*Coryneum mori*) which invades the wood or the branches, and comes to the surface to form spores. Butler adds, after his detailed description of the fungus, that it has previously only been found in Japan, where it was first described in 1904. It is thus probable that it was introduced into India during one of the attempts made to apply Japanese methods in Indian sericulture.

Rent of Mulberry Lands.—Some share in the decline of the Bengal silk industry has been attributed to the high and differential rents charged for mulberry land. Insufficiency of nourishment, due to dearness of mulberry-leaf, was, it has been said, one of the chief causes of the low yield and low quality of the silk. But Mr. Finucane (in an official paper) argues that the land usually placed under mulberry is valued for growing sugar-cane, tobacco, potatoes, and that accordingly if mulberry cannot hold its own in popular favour against these and such like crops, it would be unwise and pernicious to “prop it up by factitious encouragements.” He then continues, “There can be no doubt that the rates of rent for high land on which mulberry is grown are higher than for low rice land, which is of a different quality; but the real question is—are the rates charged when mulberry is grown, higher than the rates which would be charged for the same land if sown with sugar-cane or potatoes or other upland crops?” He then answers that question by showing that in some districts an illegal practice does prevail of charging special rates for mulberry...
cultivation. But the position of affairs is summed up by the opinion that such special rents are not general, and that they have "not really had much effect in bringing about the depression in the silk industry in Bengal."

Diseases and Enemies of the Mulberry Silkworm.—From 1865 to 1870 Pasteur devoted himself to the study of the diseases of the silkworm, and the remedial measures which he recommended have since been not only widely adopted in Europe but throughout the silk-rearing regions of the world. Even in India, thanks to the energy of the late Mr. N. G. Mukerji and his coadjutors, the selection of seed by the aid of the microscope has become an every-day practice of the ordinary cultivator, who may be said fully to recognise the value of specially selected seed in the curtailment of disease. A voluminous official correspondence exists in the Annual Reports of the Dept. Land Rec. and Agri. and in the Proceedings of the Govt. of Bengal on the subject of the diseases of the silkworm, especially the papers for 1894 and 1895.

The chief diseases are:

(a) Pebrine.—This is known in Bengal as kata, or, in an aggravated form, toli, and characterised by the presence of microscopic corpuscles of an oval shape found within the tissues of the worm, but also in the moth and egg. Though not always fatal, this disease damages the quality of the silk very greatly. Besides being contagious, it is also hereditary. The cure is to breed only from eggs laid by healthy females (established by a microscopic examination) and general sanitary precautions to prevent infection. This is the worst of all the diseases, and, according to Mukerji, it was unknown in India twenty-five years ago (l.c. 42, 53-4). The final conclusions and recommendations deserve to be most carefully considered and enforced. [Cf. Fisher, Ind. For., xv., 165-7; Arbouset, On Silk and Silkworm (Engl. trans.), 1905, 203-6.]

(b) Flacherie or Gattine.—This is known in Bengal as kata shira or shafla, and is characterised by the presence of 'chain ferment within the digestive tract of the worm and pupa.' The disease is contagious, and to a certain extent hereditary, in that the larvae of moths that show symptoms of flacherie have a predisposition to the disease. The remedy is as above, namely, for breeding purposes to reject all eggs obtained from moths found by microscopic examination to manifest signs of the chain ferment. [Cf. Mukerji, l.c. 95-109; Fisher, l.c. 167-9; Arbouset, l.c. 206-11.]

(c) Muscardine.—This is known in Bengal as chuna (or chund-kilti) a name that indicates the resemblance to lime—and is caused by a fungus, which appears as a white efflorescence on the body of the worm some hours after it has died of the disease. It is contagious but not hereditary, and though the affection may be so slight as not to interfere with the spinning of the cocoon, the chrysalis almost invariably dies, and thus never emerges as a moth. The disease is spread by the spores produced on the efflorescence, so that the speedy removal of all dead worms is an efficient preventive to a dangerous outbreak. Next to pebrine this does the most harm in Bengal. [Cf. Mukerji, l.c. 74-87; Fisher, l.c. 167; Arbouset, l.c. 195-202.]

(d) Grasserie.—This is the disease known in Bengal as rasa. It is of little importance, and is never hereditary. Following muscardine, it does, however, considerable damage to the worms in Bengal. In Europe it is not looked upon as serious, but in Bengal it becomes often epidemic. It invariably follows a heavy downpour of rain, if that succeeds to a long period of drought and high temperature, especially if the worms be then in their last stage of growth. Worms fed on mature leaf first, and tender leaf afterwards, are liable to take grasserie. The means of checking the disease is the propagation of large mulberry-trees. Whenever there is a sudden shower of rain, leaves from trees, not shrubs, should be given. [Cf. Mukerji, l.c. 87-95; Fisher, l.c. 109-70; Arbouset, l.c. 192-4.]

(e) The most serious pest is the Tachinid fly, Tryantlyum bombycis (Ind. Mus. Notes, i., 83-8). This parasite lays its eggs upon the body of the worm. Those eggs on hatching produce a grub that lives within the body of the worm and finally kills it. [Cf. Mukerji, l.c. 112-21.]

Influences of Climate.—It may be briefly said that in no essential feature are the mulberry worms of India different (as far as liability to disease is concerned)
from those of Europe, America or the Colonies. Perhaps the chief difference lies in the climate enfeebling the insect by causing it to produce too many broods in the year. But the prevalence of certain of the above-mentioned diseases uncontrolled is doubtless the chief cause of the decline of the Bengal industry. Mukerji (i.e. 41–53), in an introductory chapter, discusses the general aspects of the diseases of the Bengal worm, and makes many highly practical recommendations. About 60 per cent. of the silkworms, he says, die immediately after spinning a cocoon and after having eaten the full quantity of leaf. On this account the silk-rearers have for the past twenty-five years or so (in other words, subsequent to the appearance of pebrine) been steadily giving up their ancestral craft and taking to ordinary agricultural pursuits. There would seem no great reason why this wave of unpopularity could not be stemmed by vigorous efforts to assist and educate the rearers in the methods essential to the control of the plague.

Mukerji gives many interesting details (i.e. 128–50) regarding the construction of rearing-houses, where the selection and improvement of stock might be conducted, and the elimination of disease by the microscopic selection of eggs. The grainage, he urges, should be established close to a large tank or river; should be surrounded by mulberry trees; should be one mile away from cocoons-rearing villages, filatures or cocoon godowns; and should be in a village where a sufficient community exists conversant with the picking of ripe worms, handling moths and planting mulberries. It is not possible to conduct sericulture under hired labour, if the workers are not drawn from the hereditary silkworm rearers. This point is of vital importance, as it takes many years' careful training to acquire the expert knowledge essential to success.

II. THE WILD SILK-WORMS—THE SATURNIIDAE.

Out of the long lists of wild insects that have been published by writers on this subject, only three Indian and two Chinese and Japanese species are of commercial importance. These are:—Indian-Tasar silkworm, Antheraea paphia; the Muga, A. assama; and the Eri, Attacus ricini: Chinese-Tasar, Antheraea pernyi; and Japanese-Muga, Antheraea yamamai. The last two insects are only mentioned here because they come into trade in opposition to the corresponding Indian insects, and on that account have been classed by the trade as forms of tasar and muga silks.

Names.

Tasar silkworm of India, a name which in English commerce is often written "tussur" or "tisser," and in French "tussore." It is usually said to mean a shuttle, and to be derived from tasara or trsara in Sanskrit, but neither of these words are employed by the older authors to designate a particular form of silk. Mr. A. Yusuf Ali points out that the letter "t" in the word for shuttle is the soft dental, while in the word tasar silk it is the sharp palatal "t"—two letters that are not often inter-
changeable. The English rendering *tussur* (if pronounced *toosewir*) would be quite unintelligible to the Natives of India. Equally absurd are the renderings *tussah*, *tusseh* and *tusha*. [Cf. Milburn, *Or. Comm.*, ii., 158, 244.]

Rumphius gives an interesting account of this insect, and appears to be the first European to call it *tasar* (or, as he wrote it, *tesser*), and the word must even then (1691) have been well known, seeing that he was able to contrast the insect of the Moluccas with that of Bengal. James Petiver (who died in 1718) gives a picture of the cocoon, and speaks of obtaining specimens from Madras through Edward Bulkley and Sam Browne. [Cf. *Phil. Trans.*, 1701, No. 271, 843; *Yule, Diary of William Hedges*, ii., app. cexx.] But an even earlier usage of the word denotes a fabric of striped silk and cotton, the silk being either *tasar* or *muga*. Thus, for example, in the *Min-i-Akbari* (1590) we read of *tasar* selling at Rs. ½ to Rs. 2 a piece.

Other vernacular names are used to denote this insect, or, rather, special forms of it. We read of the *tasar* found in Bengal on the ber-tree (*Zizyphus*) being called *bugky*; that found on the *asam*-tree (*Terminalia*) being the *jarvo*; in Manbhum, the *tasar* insect is known as *dasa*, *daba*, and in Santali it is *humam*, *lumang*; in Bhagalpur and Dinajpur (according to Buchanan-Hamilton) it is *jaru*; in the United Provinces it is *koa* (cocoon), and the insect that lives on the *ber* is called *kuswari*, and that on the *asam* the *tasar*; and in Assam it is often distinguished as the *katkura*, while in the Deccan the name *kolissura* is sometimes given to it. Roxburgh calls the insect *bugky*, and the silk spun from its cocoons *tusseh*.

**Habitat and Races.**—According to Sir George Hampson it is a native of China, India and Ceylon. It may be spoken of as a denizen of the upland forests inhabited by the Santhal, the Kol, the Khond and the Gond, extending west and south-west of the Gangetic alluvial basin. In other words, commencing at the Rajmahal hills, it stretches through Karackpore, Chota Nagpur, Orissa, the Central Provinces, the Northern Circars to Hyderabad. It has thus the Ganges for its northern boundary, the Godavari for its southern, the coast ranges of Orissa to Rangar in Hyderabad for its south-eastern, and the Nerbudda river and the Kaimur mountains for its north-western boundary. But it crosses these limitations at various points, as, for example, it passes the Ganges and enters Nepal, Sikkim, Assam, Manipur and Chittagong. It has also been recorded in Mysore. Beyond the special tract indicated, it is everywhere else more a curiosity than a commercial product.

There are several varieties or races of this insect (*Fa. Br. Ind.*, l.c. 19):

—"The form *mylitta* is the most yellow; *paphia* is pale brownish-yellow; *nubulosa* greenish-brown, clouded with fuscous as far as the postmedial line; while *eingalesa*, from Ceylon, is a dark brownish-yellow form."

**Semi-domestication.**—The term domestication can hardly be applied to the method of rearing this insect pursued in India, and still in many localities it is not strictly speaking wild. The chief districts of production are Bhagalpur, Chota Nagpur and Orissa in Bengal, and Chattisgarh, Nagpur, Nerbudda and Jabalpur in the Central Provinces. But the experiments performed some years ago at Poona proved that, so far at least as Western India was concerned, the expectations often advanced
of greater success from special cultivation over restricted areas, as compared with collection by the ordinary method from wild sources, were misleading. The semi-domestication that ordinarily prevails is to endeavour to grow (or rather to encourage the natural growth), within a certain tract of country, the tree or trees on which it is intended to rear the insect. The seed cocoons are collected from the jungles and tied on to the trees. Thereafter men and boys, armed with pellet-bows, guard the insects, as far as may be possible, against their enemies—chiefly flocks of birds that would greedily devour the caterpillars. In some few localities specially selected cocoons are reserved from last year's supply for the purpose of seed, and it is even occasionally the practice to allow the moths to make their escape from the cocoons under confinement, and to retain the females as prisoners in a position where they may be visited by the wild males, and thereafter to tie the little cages or baskets containing the eggs on to the trees. But it has been proved beyond dispute that the worms will not feed properly in captivity. The pairing of the moths and the production of the eggs may be accomplished under cover but the feeding must be done in the open air. Moreover, the worms are very timid, and must not be disturbed while feeding. In some localities they are carried from one tree to another when the supply of leaf runs short, but even this degree of interference is resented, and the worms seem never to form proper cocoons when any such interruption has occurred during the vigorous feeding stage.

For more than a century continuous efforts have been made in India to improve and extend the traffic. In 1796 Michael Atkinson (a correspondent of Roxburgh's) wrote: "This species cannot be domesticated. I am informed that the Natives cannot even retain any of it for seed. The hill people say that they go into the jungles, and under the byer and asseen trees they find the excrement of the insects; on which they examine the trees, and on discovering the small worms, they cut off branches sufficient for their purpose, with the young brood on them; these they carry off to a convenient situation near their houses and distribute the branches on the asseen tree in proportion to the size thereof, but they put none on the byer." The Board of Trade of Bengal published in 1819 a series of reports on the "tasarah" silks, one of which is entitled Models of rearing the Gutis (gootee = cocoon). "The seed is purchased from the jungle people, who collect it in August. Plots in the forest are appropriated for rearing where the ashan, sal and sejah trees predominate, particularly the first, which constitutes the best food. These spots are carefully cleared of other trees and shrubs annually. Just before the perforation, the seed cocoons are tied on to the trees. The rearers live in huts erected on the plot, keeping guard night and day with pellet-bows to drive away kites, crows and other birds."

These two passages may perhaps suffice to show that a century ago the system pursued was in every detail that followed to-day. But, as already mentioned, some thirty years ago Major Coussmaker conducted, on behalf of the Government of Bombay (Admin. Rept. Bomb., 1876-7; 172; Coussmaker, Rept., March 14, 1883), extensive experiments in order to ascertain how far the Native system might be simplified and improved. He made many important discoveries and solved most of the obscure problems of the life-history of the insect, but at the same time his results demonstrated conclusively that in Poona at least, the insect could not, under any degree of domestication, be reared profitably. Accordingly his final report expressed the opinion that systematic tasar silk-growing would not pay. Another practical investigator, Mr. W. Coldstream, though he formed a slightly more favourable opinion than Major Coussmaker, admitted that the future of the industry would depend on whether it could be made to pay. Coldstream, moreover, worked with a view to discover if tasar silk production could be engrafted on the village industries of the Panjab, rather than the establishment of a large commercial industry. Mr. H. C. Cookson wrote a monograph on The Silk Industry of the Panjab (1887), which republishes, as an appendix, Coldstream's report of his experiments. Later on a second monograph on The
FOOD-PLANTS OF THE TASAR

Silk Industry of the Panjab was written by W. M. Hailey (1890), which once more reviewed Mr. Coldstream's experiments.

The insect lives essentially in the forests remote from the railways and centres of commerce, and in tracts of country unsuited to European life. Even to the Natives, the occupation of tasar silk rearing can hardly be viewed as a favourite one, for in addition to having to leave their homes and to take up temporary residence in the jungles, they have to submit to austerities enjoined by religion that make the occupation a punishment rather than an enjoyment. Moreover, the advances of agricultural occupation are daily pressing the area of possible tasar silk production farther and farther away, hence it can easily be understood why the cocoons, even when collected from purely wild sources, can hardly be conveyed to the nearest railway station at a price at all likely to command a ready sale. Mukerji suggests that the most practicable way of introducing the tasar-rearing industry in a new locality is to settle a number of Sonthal families, acquainted with this industry, in the new locality. The Sonthals have a hereditary affection for the tasar caterpillar and certain notions regarding its treatment, acquired with this industry, in childhood. This affection and these notions enable them to watch patiently the worms all day and at all seasons. They have also the conviction that they are personally liable to supernatural visitations boding evil if they neglect any of their traditional rules regarding the rearing of tasar silkworm.

All this is quite different with the Chinese tasar (Antheraea pernyi). It is a native of the warm temperate tracts of China, feeds on oak-leaves (see p. 912), and has been semi-domesticated for centuries. Moreover, it is a bivoltine insect; that is to say, it gives two crops in the year. A domesticated insect that can be reared with ease on a plantation within an accessible locality can hardly help proving more profitable than a wild one, the collection of the cocoons of which over an extensive inhospitable tract of country entails considerable labour and expense. The capabilities of A. pernyi in China are as different from those of A. paphia in India as any two subjects of inquiry could possibly be. The one is a denizen of a salubrious and invigorating richly cultivated temperate country, the other of encraving tropical jungles infested with disease and animals inimical to human life. The inhabitants of the one country are industrious and energetic, of the other apathetic and enslaved by religious restrictions and obligations that make the collection of tasar cocoons distasteful and unpopular. It is one thing to say the insect is "found in the forests of all parts of the Indian continent and to be had for the trouble of collection." It is quite another matter to make that wild insect tractable to the necessities of commerce, or even to overcome the religious prejudices of the agents who have to be primarily employed in the development of the trade.

FOOD-PLANTS OF THE TASAR WORM.—The following are the chief trees on which the Indian tasar silkworm feeds:—

Anogeissus latifolia, dhaura (pp. 70-1).
Bassia latifolia, mahua (pp. 116-7).
Bauhinia variegata, kanchan (p. 121).
Bombax malabaricum, semul (pp. 108-9).
Careya arborea, kumbi (p. 269).
Carissa Carandas, karaiand involved (pp. 270-1).
Celastrus paniculata, mal kangni (p. 292).
Chloroxylon Swietenia, billu (p. 294).
Dodonaea viscosa, samata.
Eugenia Jambolana, jāman (p. 526).

Crops of Tasar. —The tasar silkworm has generally two crops, but instead of being bivoltine in its wild state, it is most probably quadri-voltine. According to the Rev. Dr. Campbell, there are often three crops. The cocoons are procured in May and June, from persons who collect them in the jungles. The larger ones are generally female and as much as 8 to 10 cowries apiece are paid for these, while the smaller male ones fetch much less. From these moths emerge, and the 1st crop of caterpillars

1005
SPIN COCOONS IN SEPTEMBER; 2ND CROP (A SMALL PORTION OF 1ST) EMERGES IN
OCTOBER AND SPINS COCOONS ABOUT JANUARY; THE 3RD CROP, MOTHS EMERGE
FROM COCOONS OF THE 1ST AND 2ND CROPS ABOUT JUNE, WHICH BRINGS US BACK
TO THE FIRST CROP AGAIN. A PROPORTION OF THE SEPTEMBER COCOONS ONLY
EMERGES IN THE FOLLOWING AUGUST.

THE GOVERNMENT OF INDIA IN A RESOLUTION, DATED NOVEMBER 23, 1875, FUR-
NISHED PARTICULARS OF THE MORE IMPORTANT INVESTIGATIONS THAT HAD BEEN CONDUCTED
BOTH IN INDIA AND EUROPE. THE CHIEF DIFFICULTY DEPENDS ON AN INHERENT DEFECT IN
THE FILAMENTS SPUN BY THE WORM. IT IS EXPLAINED THAT THE SILK IS PRODUCED BY
THE INSECT FROM A DOUBLE SPINNERET, AND THAT THE RESULTING FILAMENTS ARE NOT PARALLEL
BUT SPIRALS THAT TOUCH EACH OTHER AT THE EXTERIOR POINTS OF THEIR CURVES ONLY, AND
ARE HELD IN THAT POSITION BY THE NATURAL GUM IN WHICH EXUDED. IT IS TO THIS
PECULIARITY THAT SOME OF THE SPECIAL PROPERTIES OF TASAR SILK, SUCH AS ITS ELASTICITY,
ARE DUE. IT IS NECESSARY THAT THE DEGREE OF CROISURE SHOULD BE EXERTED TO BRING
THE FILAMENTS INTO A ROUND THREAD. THIS COULD ONLY BE OBTAINED IN FULLY EQUIPPED
FILATURES, AND NOTHING BUT STEAM COULDENSURE THE UNIFORMLY HIGH TEMPERATURE
INDISPENSABLE. AT THE PERIOD HERE INDICATED IT WAS ACCORDINGLY REGARDED THAT
THE COMPLETE REELING OF TASAR SILK IN THE FORM THAT WOULD COMMAND A LARGE EURO-
PEAN MARKET COULD NOT BE ACCOMPLISHED AS A VILLAGE INDUSTRY. A FURTHER RESO-
LUTION OF THE GOVERNMENT OF INDIA BRINGS THE KNOWLEDGE OF THIS SUBJECT UP TO THE
DATE OF FEBRUARY 1879; THE RESOLUTION AND ITS ENCLOSURES WILL BE FOUND RE-
PRINTED IN THE INDIAN FORESTER (1879, V., 77-101). COTES BROUGHT THE INFORMATION
UP TO THE DATE OF 1890, AND FURNISHED MOST ADMIRABLE ILLUSTRATIONS OF THE WORM,
THE MALE AND FEMALE MOTHS, AND THE COCOONS. MUKERJI (HANDBOOK OF SERICULT,
INDIA) AFFORDED MUCH USEFUL ADDITIONAL INFORMATION REGARDING TASAR, BUT HE
MAY BE SAID TO HAVE BEEN SPECIALLY CONCERNED TO MAKE THE MERITS OF THE JAPANESE
AND CHINESE WORMS KNOWN. DEWAR, ON THE OTHER HAND, OBSERVES THAT THE MERE
FACT THAT TASAR REARING, SPINNING AND WEAVING ARE VILLAGE INDUSTRIES, OFTEN
COMBINED WITH AGRICULTURAL PURSUITS, GIVES THEM AN INTEREST TO THE ADMINISTRATOR.
THE ABORIGINAL OR LOW-CASTE PEOPLE WHO REAR THE TASAR WORM AND GATHER THE
COCOONS LIVE IN THE MOST REMOTE AND JUNGLY VILLAGES. THE WEAVERS FORM
COMMUNITIES IN THE TOWNS WHICH ARE NOT TOO FAR FROM THE JUNGLE TROADS. DEWAR
REMARKS, IN HIS CHAPTER DEVOTED TO THE HISTORY OF TASAR, THAT THE Earliest RECORD
OF ITS APPEARANCE IN THE CENTRAL PROVINCES "WOULD SEEM TO BE THAT OF CHANDA
DISTRICT, WHERE IN 1775, UNDER THE MAHRRATTAS, THE MONOPOLY OF REARING SILK-
WORMS AND MAKING TASAR-SILK WAS FARMED OUT BY THE RULING POWER, JUST AS IS
STILL DONE IN SOME FEUDATORY STATES." SAMBALPUR AND CHANDA ARE THE CHIEF
DISTRICTS IN THE PRODUCTION OF TASAR, WITH RAIPUR AND BILAEPR TAKING GOOD SECOND
PLACES. DURING THE LATTER HALF OF THE 19TH CENTURY THE GOVERNMENT OF INDIA
MADE REPEATED EFFORTS TO EXTEND AND IMPROVE THE PRODUCTION IN THE CENTRAL
PROVINCES, BUT WITH LITTLE PRACTICAL RESULTS. DEWAR REVIEWS THE VARIOUS EFFORTS
THAT WERE PUT FORTH, AND HIS MONOGRAPH WILL BE FOUND OF SPECIAL VALUE AND INTEREST
IN THAT RESPECT. PARANJE (IND. FUR., 1902, XXVIII., 192-6) GIVES A
SKETCH OF THE LIFE-HISTORY OF THE TASAR-WORM IN BHANDAR.

EUROPEAN COMMERCE.

Mukerji (Monogr., I.C.) observes that there are several classes of cocoons which go by the generic name tasar. Those recognised in commerce, according to the quality of their silks, are:—(1) The Yamamai cocoons of Japan (Antheraea yamamai); (2) the China tasar (A. pernyi); (3) the muga of Assam (A. assamana); and (4) the Bengal tasar (A. paphia). All the other wild silks, he tells us, are in Bengal grouped under the name bharus. Of the commercial forms mentioned, the Bengal tasar has the greatest length of fibre, though it is inferior to that of the other three. The Yamamai is so highly prized in Japan that, by law, capital
punishment may be meted out to any person exporting the seed-cocoons or eggs.
INDIAN RESULTS

The silk afforded by its cocoons is almost as good as mulberry. The China tasar cocoon is smaller than the Bengal, and the average length of its fibre is 550 metres as compared with 700 metres in Bengal. The amount of waste is much greater with the Bengal than the China, though the amount of silk is higher—8 per cent. in Bengal tasar, as compared with 5 per cent. in China tasar.

"The Bengal tasar cocoon has a few other advantages over the China tasar cocoon. The tenacity of the base (i.e. the double fibre as it comes out of the mouth of the silkworm) is 28½ grammes, as compared to 18 grammes, which is the tenacity of the base of the China tasar. The elasticity of the base is 21¾ per cent. as compared to 19 per cent., which is the elasticity of the base of the China tasar. The Bengal tasar also loses less of its weight in bleaching; the China tasar losing as much as 21 per cent. while Bengal tasar loses only 11 per cent. The Bengal tasar is, however, more difficult to bleach and dye than the China tasar."

Indian Results.—Mukerji (Rept. Inquiry into the State of the Tasar Silk Industry, Beng., 1905) tells us that he visited all the more important centres of tasar production and manufacture and discussed personally with those interested the issues of importance. The report opens with the following:—"The tasar silk industry is declining almost everywhere, although the demand for tasar cloths has been on the increase in Bengal, owing to the general revival of agriculture in this province, which has brought into prominent notice tasar cloths as well as silk cloths." He then enumerates the chief centres of tasar manufacture, and concludes that there are 6,500 families of weavers, or nearly 25,000 individuals, more or less dependent on tasar-weaving in Bengal. Of the Central Provinces, he remarks that it is purely a village industry, except in Sambalpur and Bilaspur, but that there are probably not more than 2,500 tasar weavers all told. The weavers, he explains, are entirely dependent on a supply of cocoons for the continuance of their industry, but that the rearers are agriculturists who give but a portion of their time to the production of cocoons, and the number so engaged fluctuates very greatly.

Roughly, he estimates that the number of persons concerned in tasar-cocoon rearing may be about eight times the number of those engaged in tasar-weaving. There would be in Bengal, therefore, by that estimate, 200,000 persons, and in the Central Provinces 20,000 persons who obtain at least some portion of their annual earnings from tasar silk.

Mukerji then concludes with numerous practical deductions, amongst which the following may be mentioned:—

1. That the wild cocoons are the richest in silk.
2. That Singhbhoom is the district best suited for tasar-silk rearing. Further that the wild barra muga worm of that district is the best of all, followed by the muda muga, also of Singhbhoom, then by the muga of Mourbhanj.
3. That even in the wild state, Chanda and Bhandara cocoons are inferior to those of Raipur, Bilaspur, Sambalpur, and of the Bengal tasar districts, while the home-grown cocoons of Chanda and Bhandara are the worst of all.
4. That the deterioration is more marked in the case of banela than in muda cocoons.
5. That the main cause of the decline of the industry is the disease known as grasserie, which affects weak worms more than strong ones, and worms feeding on low bushes more than those feeding on high branches of trees.
6. That grasserie being caused by irregularity of season, such as heavy showers following long-continued drought, it cannot altogether be avoided even by the use of good seed.
7. That degeneracy of tasar worms runs mainly along two lines, inferior cocoons (small size and flimsy in structure) being purposely reserved for seed, owing to the superior cocoons fetching a higher price; and semi-domestication and the use of home-grown cocoons for seed instead of wild ones.
8. That the cocoon-rearers are sometimes helpless, as wild cocoons are often not readily found.

Lastly, as measures calculated to revive the industry, Mukerji proposes the establishment of two model tasar-rearing nurseries in Bengal; the propagation of sain trees (Terminalia) in the tasar village areas; and the reservation of certain forest tracts for the wild stock only from which the model establishments would periodically obtain fresh seed supplies. With a statement of continuous research and of vigorous efforts, such as is implied by the numerous reports thus briefly indicated, it can be hardly fair to affirm that the backwardness of the Indian industry is a direct expression of the apathy of all concerned.
SILK
ANTHERÆA PAPHIA
Tasar

**MANUFACTURE OF TASAR.**—Mukerji (Monog., I.c., 1903, 104) points out that it is strange the cocoons should be gathered in the jungles of Singhbhum, Manbhum, Sonthal Parganas, and even of Assam, and brought down to the filatures of Murshidabad for reeling. To secure improvement the *tasar*-silk reeling and weaving industries should, as far as possible, be estranged from the corresponding mulberry industries, and be developed on their own lines. There should, for example, be no difficulty in establishing *tasar* factories in *tasar*-growing districts, where labour and fuel (both coal and wood) are abundant and cheap. He then adds, “A *tasar* reeling and weaving company organised on European principles and working in the *tasar*-growing districts is likely to have a very prosperous career before it.”

In exemplification of these views he then deals with the industry district by district. Of **Murshidabad**, he says the *tasar* cocoons are reeled in European filatures, chiefly at Bajarpura and Narsyanpur factories. Of **Hughli**, Jahanabad Sub-division, he speaks of some 350 families being engaged in *tasar* and mixed *tasar* and cotton weaving. Of **Bardwan**, *tasar* spinning and weaving are carried on by some 228 families. A certain amount of weaving is also practised for which yarn is imported. Of **Midnapur**, he observes that cocoons are found in the jungles, especially at Moubhanj and Dhalhbum—the hardest kind are preferred. The cocoons are reeled locally and also spun and woven. Of **Birbhum**, he says the *tasar* industry is followed by some 300 families, the cocoons being reeled and the cloth woven locally. **Bankura** has long been famous for its silk industry, but the *tasar* manufactures are not very extensive. The most important fabric produced is known as *kethe*. This is made from pierced cocoons, is coarse but cheap. Of **Bhagalpur**, the cheap *bajta* cloth is far better known than the *kethe* of Bankura. About 2,000 weavers (both Hindu and Muhammadan) gain a livelihood by producing various *tasar* textiles. The cocoons are imported from the Sonthal Parganas, etc., and sold at Nathnagar at rates of 8¢ to 250 to the rupee, according to quality—pierced cocoons fetching only from 100 to 400 to the rupee. The yield is about one tola of *tasar* silk from 15 to 20 cocoons—and eight to ten tolas of *tasar* silk will bring in about a rupee. In the *bajtas* the woof is usually cotton and the warp *tasar* silk. Of the Sonthal Parganas, Mukerji says that the cocoons are reared throughout the district for export to Murshidabad—the local reeling, spinning and weaving are practised to some extent, especially in the Godda Sub-division. Of **Hazaribagh**, Ranchi and **Palamau**, he remarks that there is no *tasar* weaving, but that a considerable industry exists in rearing and exporting the cocoons. The pages devoted to these districts will accordingly be found to contain many useful particulars regarding the methods and seasons of the operations concerned. Of **Singhbhum**, he remarks that there are only a few *tanti* (*tasar*) weavers, and the cocoons are reeled by hand by the weavers themselves. The *dhutis* or *saris* so made are largely exported to Dacca and Lower Bengal, and fetch from Rs. 3 to Rs. 4. But if weaving be unimportant, the rearing of *tasar* cocoons is an industry of considerable magnitude in Singhbhum. The *tasar* weaving of **Manbhum** is, on the other hand, of considerable value. There were at the last census 12,911 *tantis* or *tasar* weavers, and Raghunathpur is the most important centre. The *tasar* weaving of **Gaya** is also fairly important, though the cocoons are
no longer locally produced owing to the curtailment of the forests. Of Balasore, Puri and Cuttack, Mukerji observes that the industry of tasar weaving is not an important one, though the rearing of the worms and production of cocoons are largely pursued.

This is the muga (munga) silkworm of Assam, a name said to have been originally given because of the amber colour of the fibre, and hence frequently used to denote any wild silk—thus eri-muga, tasar-muga and kalkari-muga. It is met with chiefly in Assam, but its area extends east to the Naga hills, including Sylhet and Cachar, and south to Tippera and the mountains of Burma. It has also been recorded as far to the west as the valleys of Kumaon and Kangra, and a special insect mentioned from Pondicherry, and named *A. perotteti*, has been accepted as a form of muga.

**Historic Records.**—It seems probable that the first mention of this silkworm and of its silk occurs in 1662 in connection with Mir Jumla. But it must long anterior to that date have been known in India, since Tavernier (*Travels Ind.*, 1676 (ed. Ball), ii., 281) makes special mention of the Assam silkworms that remain on trees all the year; and he does not suggest that fact as being a novelty, but rather implies that it was well known. He may, of course, be alluding to the tasar silk, but in that case the locality Assam would hardly be correct. The collection of official papers issued by the Bengal Board of Trade in 1819 makes mention of the "moopa" being "the most common and plentiful, the thread coarse but winded easily. *The gutis* are sold direct from the forests." This is mentioned separately from "tussah," "terrah," "bonbunda," "debbu," "buggy" and "carroy" silks, so that it very possibly was intended to denote the muga proper. In the *Dictionary* will be found numerous references to papers by Buchanan-Hamilton, Jenkins, Hugon, Helfer, Brownlow and Stack—all of whom have afforded interesting particulars regarding this silkworm and Assam silk generally.

**Domestication.**—The muga exists in a state of even more complete domestication than is the case with the tasar—the eggs are hatched and the cocoons spun within doors, and while feeding on the trees the worms are carefully supervised and protected from their enemies. When they have finished eating they are removed from the trees and carried off to the rearers' houses in order to spin their cocoons. The worm is multivoltine, has five generations during the year, but of these only two or at most three are used by the rearers. The people of Upper Assam annually import their seed-cocoons from Kamrup for their cold-season and spring crops owing to the fact that the worm soon degenerates in the Sibsagar district, and hence no seed-cocoons are retained from the last brood of the season. This is said to be due to the fact that in Lower Assam the insect is fed mainly on *Litsea polyantha*, the svalu or house plant. [ Cf. *D.E.P.*, vi., pt. iii., 176; Allen, *Monog.*, l.c. 14-5.]

**Food-plants.**—The muga worm feeds on a fairly extensive series of leaves, the most important being species of laurel, such as the *sum*, *Machilus odoratissima*. But other trees may be mentioned:—*Cinnam-
**SILK**

**ANTHERAEA ASSAMA**

Muga

*Momum obtusifolium*, *Michelia Champaca*, *Symphlocos grandiflora*, and several species of *Litsea*. In Lower Assam it is also largely bred on the *suva*, *Tetranthera monopetala*. The most important of these food-plants is the *sum* (*Ind. For.*, 1879, v., 35-9, 202-21).

**Life-history.**—The cocoons intended for breeding are placed in trays and hung up safely in the house. In a fortnight’s time during the warm months, and three weeks in the cold season, the insects come forth. The females, recognised at once by their bulkier bodies, are immediately secured by a thread passed round the thorax behind the wings and tied to a short length of straw hooked on to a line stretched across the room. The males are left free, but usually sufficient number consort with the female prisoners. Each female produces 250 eggs in three days. All eggs laid after then are rejected, and the moth dies about the fifth day. The pieces of straw, with their attached eggs, are then taken down and placed in baskets, covered with cloth, and the room in which stored is heated in winter, but kept dark as much as possible. In summer it is not necessary to retain the eggs within doors at all, and the straws may, therefore, be carried at once to the trees, due precaution being taken against undue exposure to sun, rain or dews. Generally, however, the worms are hatched indoors. They pass through four moultings, and, when full grown, measure about five inches long. While feeding, if the leaves get exhausted, the worms are picked off and carried to fresh trees. The worms of their own accord, in fact, descend from the tree and are caught by a trap of straw or plantain leaves tied around the stem, and thus are easily picked up and carried by the attendant to fresh trees. It is said that if placed on a tree the leaves of which have already been devoured, they refuse to ascend. When they have eaten all they desire, the worms are carried off and made to spin their cocoons in the rearers’ houses. Trees from three to twelve years old are considered the best; older are avoided, as they harbour ants, and the lichen and moss on their branches impede the rapid movements of the worms. But the greatest enemies of the *muga* are crows, kites and many other birds by day, and owls and bats by night; constant watching is thus necessary, and abundant and continuous employment thus afforded to the young, old and infirm members of the family.

The periods and stages of the insect’s life are as follows:—hatching, from 7 to 10 days; feeding, from 26 to 40 days; spinning, from 4 to 7 days; resting within the cocoon, from 14 to 21 days; and life as a moth, from 3 to 5 days. The variations in time indicated are largely a consequence of the season of the year or brood of worm under record. The cocoon is fawn-coloured, large, thin, devoid of the suspensor, so characteristic of the *tasar*; and the short period spent within the cocoon, when taken in conjunction with the more tractable habit of the insect generally, makes this a very much more desirable form of silkworm than the *tasar*. The cocoon is about 1\(\frac{1}{2}\) inch long and 1 inch in diameter. In colour it is of a golden yellow, but there is usually a percentage of dark cocoons in every brood, for which no satisfactory reason has been assigned.

**Reeling and Spinning.**—Reeling is simple. The insects within the cocoons are killed by exposure to the sun or by fire. Thereafter they are boiled in an alkaline solution. From 7 to 20 filaments are rolled together between the palm of the right hand, drawn across the thigh, while the left hand works the reeling apparatus. The whole of the silk may be unwound except the innermost layer next to the chrysalis.

1010
The quantity of silk afforded varies according to the brood. The coldweather insect gives the least, and is accordingly usually reserved for breeding, only the inferior cocoons being spun.

No part of the muga cocoon is, however, rejected as useless. The flax plucked off from the outer surface of the cocoon, before reeling is commenced, the shell that remains around the chrysalis, and the cocoons from which the moths have escaped in breeding, are all reserved to be carded and spun, and the by-product thus obtained is called eri and is often mixed with the eri silk—the product of the next species (see pp. 1013, 1021).

Manufacture.—The muga silk thread varies according to quality from Rs. 8 to Rs. 12 per seer, era or spun thread being sold at half those rates. The cloth woven from muga yarn has a bright-yellow colour and a pretty gloss. It stands washing much better than any other silk, keeping its gloss and colour to the very last. It is usually sold in pieces of 5 yards long and 4 feet broad, the price varying from Rs. 1–8 to Rs. 2 per square yard. There is no large market where either thread or cloth can be purchased, but the headquarters of the industry is the district of Sibsagar in Assam, more especially the Sub-divisions of Golaghat and Jorhat. The exports are mainly in thread, which go to Calcutta for local consumption or for export to Persia—it is too dear for the English and Continental markets—the price quoted being Rs. 6 to Rs. 12 per seer. There is no means of knowing the total production, but it has been estimated that the exports come to about 280 maunds a year.

The Champa and Mezankuri mugas are only the silks of the worm obtained from insects fed on the trees of these names—Michelia Champaca for the former and Litsaea citrata for the latter. Morian is the chief locality for the mezankuri silk. The champa silk seems almost quite forgotten to-day, but it was the fine white silk worn by the Ahom kings and nobles of Assam in former times. Buchanan-Hamilton (in Montgomery Martin, Gaz. of Assam, 1838, iii., 679–80) speaks of the meandering silk constituting the dress of the higher ranks, "most of which are dyed red with lac but some are white." Until quite recently it could be said that the muga silk was the material of dress with the middle classes of Assam.

It may be said that commercially this silk is obtained from Assam, though Roxburgh and Buchanan-Hamilton speak of it as if in their time it had been confined to Dinajpur and Rangpur. To-day it is found throughout Eastern Bengal in the districts Purnea, Bogra, Jalpaiguri, in addition to Dinajpur and Rangpur. It is also not uncommon in Darjeeling, Nepal, Kumaon, Gaya, Shahabad, Chittagong, Puri, and its cultivation has recently been attempted in Upper India.
The textile sold in India under the name “Assam Silk” is almost invariably the produce of the insect here indicated, though of course muga silk is very much more restricted to and characteristic of the valley of Assam. This is the silk with which the poorer people of Assam used formerly to be almost exclusively clad, while the muga silk (which in India is often classed as a special grade of tasar silk) was that (as already mentioned) employed by the middle and upper classes.

**Early Mention.**

**Spun.**

**Brownlow.**

**Hot Water Injurious.**

**Wardle.**

**Food-plants.**

**Life-history.**

**Multivoltine.**

**Seasons.**

**Stages.**

**Crop.**

Mukerji estimates that from an acre of castor-oil plants it would be possible to obtain from 60 to 90 seers of pierced cocoons a year.
The price of these would be about Rs. 60. But in this way it will not pay. It is when grown on odd bits of land and the worms reared and the cocoons spun by the women, during their spare moments, that the industry becomes profitable. Until the price rises materially, it will probably not pay as a separate industry. But as a supplementary crop it is very remunerative, and the insect is more easily reared and is less expensive than the mulberry worm. Since the cocoons cannot be reeled, there is no object in killing the insects within them. In every instance, therefore, they should be allowed to escape. Green *eri* cocoons, that is to say, cocoons with live chrysalids, sell for 500 to 600 to the seer (2 lb.). If they are killed and dried in the sun, 1,500 to 2,500 go to the seer. When the insects have escaped (pierced cocoons), 3,000 to 7,000 go to the seer. In other words, while a maund of pierced cocoons may fetch Rs. 100, the same weight with the chrysalids inside may only realise Rs. 20.

**Carding and Spinning.**—The *eri* cocoon, it is said, has been successfully reeled in Italy, but from time immemorial it has in India been opened out crudely, then spun. No sort of information can be furnished as to the extent of the manufactures nor the probable margin available for export. Mention has been made of a traffic in cocoons from Goalpura to Calcutta of 400 to 500 cwt. yearly. The spun thread, though coarse, is woven into textiles that are exceedingly durable (see pp. 1011, 1021). In fact *eri* silk is stronger than wool, cotton or mulberry silk. But the European trade demands white *eri* cocoons, and this somewhat restricts the supply.

**Manufactures.**—The thread and cloth are largely traded in all over Assam and Cachar, though the effect of the imports of Manchester cotton goods has been to largely displace *eri* as an article of clothing. Hugon speaks of large quantities of the cloth being exported to Lhasa by merchants known as "Kampa Bhotias," but he adds this trade has entirely died out. Stack says that throughout the whole range of the southern hills, from the Mikir country to the Garo, *eri* thread is in great request for the weaving of those striped cloths in which the mountaineers delight. The Mikirs, Kukis, and Garos cultivate the worm for themselves, but the handsome and durable cloths worn by the Khasias and Santengs are woven of thread procured from the Mikirs. T. N. Mukharji (*Agr. Ledy.*, 1894, No. 19) refers to the fact that within recent years a new market has been found for the cloth, in supplying suits of clothes for the Europeans and Natives of India. The supply, he adds, is not equal to the demand. Efforts have been made with that object in view, in many parts of Bengal and Assam and even in the United Provinces, but so far with indifferent success. A more recent, and in some respects fuller account of the *eri* silk industry, will be found in N. G. Mukerji's *Monograph*. He there gives details of the industry as it exists to-day in Bogra, Rangpur, Jalpaiguri and Mainensingh. Speaking of the increasing demand, he observes that this is now being met by imitation *eri*, made out of waste mulberry silk. He then adds, "At present little skill is brought to bear on the production of *eri* silks either in Assam or in Eastern and Northern Bengal. The spinning might be more uniform and the weaving more varied and artistic.

**Indian Silk Production and Manufacture.**

In official statistics of filatures and mills, all village industries are disregarded and returns furnished alone of factories, etc., that employ twenty-
five or more hands. This gives an unnecessarily low and imperfect conception of the interests involved, since here and there throughout India and Burma there is a fairly extensive village or domestic industry in rearing, reeling and manufacturing, entirely disregarded by official returns. Moreover, recent statistics would seem to mark a serious decline, whereas the explanation of the shrinkage shown is largely the discontinuance to chronicle certain factories.

Filatures, Mills, etc.—According to the latest volume of the Financial and Commercial Statistics, there were 75 silk filatures in India in 1904, employing 9,526 workers, all in Bengal. There were also in the same year 11 silk mills, employing 2,964 workers, distributed thus:—in Bengal, 8 mills with 1,465 employees; in Bombay, 2 mills with 1,299 employees; and in the Panjāb, 1 mill with 200 employees. According to the Imperial Gazetteer (1905, iii, 209) three large silk mills (two in Bombay and one in Calcutta) are worked by steam-power and are almost exclusively concerned in catering for the Burmese market, a trade that was formerly concentrated in Glasgow but is now mainly in the hands of Indian and Japanese manufacturers. “The Bengal factories of to-day largely work up tasar silk in place of preparing the korah silks formerly turned out by them; they are owned and managed by Natives and do not employ European machinery. Besides the registered mills and factories, numerous weavers own one or two looms worked by themselves and their families. Silk-weaving seems intimately associated with Gujarāt. From one end of India to the other Gujarati silk-weavers may be found, speaking a dialect of Gujarati or using Gujarati names for most of their appliances and for the textiles they produce.”

The extent and location of the silk interests may now be indicated:—

BENGAL (see p. 1019).—This, as already stated, is the great centre of the silk-reeling industry. Formerly a large trade also existed in the manufacture of corah (korah) silks—plain undyed silk piece goods, the demand for which has fallen off very greatly in consequence of the greater popularity of Japanese and Chinese silks; but at the present moment the traffic in the Bengal corahs seems reviving. [Of Indian Art at Delhi, 1903, 302–7.] Mukerji says, in his Monograph, that with the exception of Chittagong Division, all the other portions of Bengal have a silk-weaving industry. The following particulars may be given of the chief centres:—

Presidency Division.—The industry is confined to Murshidabad. Mulberry-growing, cocoon rearing and reeling, as also silk-weaving, are all practised, and the town of Mirzapur produces the most superior fabrics in the whole of Bengal; but Baluchar and other centres are also famous, especially for artistic and brocaded fabrics. The trade in reeling is mainly concentrated in Berhampur and Jeggan, and there the wealthy merchants reside. During the last decade the industry seriously declined, both in cocoon-rearing and corah-weaving. The census of 1901 shows 41,615 persons dependent on this industry in Murshidabad against 55,142 ten years previously.

Bardwan Division.—Silk-weaving is carried on in all the districts. Babu Sukumar Haldar gives an interesting historic sketch of the silk industry of Jahanabad, in the Hugli district, during the seventeenth century. In the Bardwan district silk-weaving is mainly carried on in Katwa and Kaina Subdivisions, but not in Raniganj. The cocoons reared in Midnapur, and even from all parts of Howrah, are utilised in the looms of Chandra Kona. In Howra the silk-rearing industry is of minor value, but the silk-weaving of Bankura is of great importance, even more so than the rearing of cocoons and the spinning industries. It is a curious circumstance that the East India Company should have striven for years to establish Hugli as the centre of their silk industry and have failed to induce the weavers to settle in that district.

Bhagalpur Division.—In Maldah, cocoon-rearing and silk-spinning are carried on more or less extensively throughout the district, while silk-weaving is con-
THE BENGAL INDUSTRY

centrated at Sahibganj, at Shalipur near Bholabat (silk factory belonging to a French Company), at Sajapur, near the ruins of Gour, and at Maldah. The silk industry of Maldah has in fact slowly but steadily improved during the last decade, and the census figures show 43,498 persons as employed in 1901, as compared with 42,896 in 1891, but this improvement, as in the case of Murshidabad, Rajshahi and Birbhum, has been mainly in the department of weaving.

EASTERN BENGAL AND ASSAM.—Rajshahi Division.—Mulberry cultivation, cocoon-rearing, silk-spinning and silk-weaving are still regarded as industries of very considerable importance. But to feed the European silk factories, cocoons are imported from Maldah as the local supply is insufficient. The chief centre of spinning and weaving is at Mirganj—and the best moula silks are turned out at Dakra. The principal trade centre for yarns and fabrics is a portion of the Sadra station of Rampur Boalia. Bogra cocoons-rearing (a greatly depreciated industry) depends entirely on the neighbouring district of Rajshahi for the disposal of its produce.

Assam Valley.—Busa (Agri. Journ. Ind., ii., pt. i., 22-32) reviews the results obtained with the experiments to acclimatise the European silkworm in Shillong. This was proposed by Sir J. Bampfylde Fuller in 1904 and has ever since been prosecuted with much energy. It has been proved that the winter colds have proved sufficient to check early and irregular hatching. "Three years' experience has shown that the climatic conditions of Shillong during April and the first half of May, which cover the rearing season, are not unfavourable to the healthy development of the silkworms." But prolonged wet weather is injurious, and it cannot, therefore, be said that the climate of Shillong during April and May is wholly free from danger. Great inconvenience has been experienced in drying the cocoons during the monsoon, which follows closely the rearing season. To safeguard this a drying-case has been used, and apparently with success.

Busa points out that a fairly large field exists for the extension of sericulture in Assam. A successful experiment has been performed in Kohima in the Naga hills. Manipur possesses a nascent silk-rearing and manufacturing industry (see pp. 903, 907). There is thus every reason to believe that the European silkworm might be raised in the greater part of the hilly country extending from Manipur on the east to the Garo hills on the west. All over the valley of Assam there are professional silk-rearers, who have only to be taken in hand and educated in the art of safeguarding their worms, in order to secure the foundation for a large and important industry.

UNITED PROVINCES OF AGRA AND OUDH.—Perhaps the earliest attempt to organise a modern silk industry in the Dun was made by Capt. Hutton of Mussorie in 1856 (Geoghegan, Silk in India, 101-19, 131-2). From time to time various subsequent endeavours were made, and finally Mr. H. G. Ross, Superintendent of the Dun, handed the industry over to Messrs. Lister & Co., Bradford, and it is well known that large sums of money have since 1879 been expended by that Company in their efforts to organise a large and profitable industry. Lloyd's (Memo. on Silk in India, 1883, 24-34) reviews all the experiments performed and the results obtained, and his paper will repay perusal. The story was carried down to 1890 by N. G. Mukerji (Rept. of a Sericult. Tour in the U. Prov., the Panjab and Kashmir, 7-14) in his vigorous review of the results attained by Messrs. Lister & Co. The next publication of importance is by Yusuf Ali (Monog. on Silk Fabrics, 1900, 9-25). This sets forth the ups and downs in the industry sustained mainly by Lister & Co., and the complete change which has taken place from the grande magnanerie to that of tenant rearing. A Savings Bank has also been started by them to protect the rearers from the money-lenders, and every effort put forth not only to improve the position of the tenants but to simplify the superior methods of silkworm-rearing that they were desired to pursue. To the energy and determination of purpose of the late Lord Masham (formerly Mr. Lister) has to be attributed the present position of the silk industry of Northern India.

PANJAB.—Baden-Powell (Pb. Prod., 1808, i., 101-77) gives a full account of the silk industry of this province during the period of which he wrote. In fact, though many writers have followed in his footsteps, very little additional information of any great value has been made public. In 1836 Dr. Gordon conceived the idea of extended silk production. He accordingly planted mulberry trees at Ambala, which still existed in 1858 (Geoghegan, i.e. 78-100). It would occupy many pages to enumerate all the experiments that were subsequently conducted. Mr. Cope made a vigorous effort, in 1854-6, to acclimatise the
Kashmir, where an abundant supply of leaves from standard mulberries were to be had. Passing over many other investigators and adventurers in sericulture, we come to the time when Lister & Co. commenced operations in Gurdaspur and Capt. Bartlett in Kangra. But all this has been already told so fully in the Dictionary that it seems only necessary to refer the reader to that work. (The following publications in sequence of date may assist the inquirer: — Liotard, I.c. 34-46; Cookson, Monog. on the Silk Industr. Pb., 1886-7; Mukerjji, Rept. on Sericult., L.c., 1890; Hailey, Monog. Silk Industr. Pb., 1899; Hoshipur Dist., Panjab Gaz., 1904, 135-8.)

**Kashmir.**—Lawrence (Valley of Kashmir, 1895, 367-9) says that Mirza Haidar in his history (A.D. 1536) alludes to the abundance of mulberry trees in Kashmir and to the leaves being used for the food of the silkworm. Adams (Wanderings of a Nat. in Ind. (ed. 1867), 198-9, 269) describes the silkworm industry as seen by him. Drew (Jummoo and Kashmir, 1875, 409) speaks of the silkworms of Gilgit being reared in small quantity and of the worm being smaller than that of Kashmir. Several writers mention a small wild insect seen on the mulberry trees of Kashmir, the cocoons of which were collected and sold. Liotard (Memo. on Silk in India, 1883, 46-55) traces the industry to his time and gives tables of statistics from 1869 to 1881. The effort made in 1880 by the Maharaja Rambir Singh to extend and improve the industry is mentioned by most of the writers on this subject. The cocoons raised in 1876 were valued at 1,70,064 (Indian rupees). But disease appeared, and the industry rapidly declined until taken in hand by Lawrence. In his address to the Society of Arts on April 26, 1896, he tells the story of the efforts that had been put forth to resuscitate the industry. This is followed up by a series of reports and official correspondence (Agric. Ledg., 1898, No. 10). In his report, dated September 15, 1900, addressed to Sir Adelbert Talbot, Resident in Kashmir, Mr. C. B. Walton, Director of Sericulture, narrates the work accomplished during the year. The crop attained came to 11,019 maunds of cocoons, which when reeled was worth Rs. 7,71,000, which represented 100 per cent. on the cost of production. N. G. Mukerji (Rept. Sericult., L.c. 1-17) gives many interesting details and practical observations. He mentions that he had procured for the State from Signor Susani of Italy, 100 ounces of purely cellular seed of the three best classes of cocoons. Lastly, Sir Thomas Wardle (Kashmir, Its New Silk Industry, 1904) tells in some 350 pages the rise and present position of the silk industry of Kashmir. He gives particulars of the supply of eggs personally procured, and of the machinery purchased on behalf of the State and which he had taken out to Kashmir and seen established in working order. He also affords details of the subsequent results attained. In a note written by the officiating superintendent of sericulture, Mr. H. D. Douglas, in 1906, it would appear that in 1903 the crop of cocoons was 10,000 maunds; in 1904, 13,000 maunds; and in 1905, 25,000 maunds. The net profit to the State in 1903 came to 1½ lakhs of rupees, and in 1906 to over 3 lakhs. In the year April 1905 to 1906, 600 bales of silk of 150 lb. weight were reeled. The price realised at the beginning of the year was about 12s. a lb., whilst later 15s. were obtained. Last year 10 looms were started to produce cloth in competition with Japan, and, those proving successful, 200 more looms had been ordered and arrangements made for these to be in working order by June 19, 1906. Thus the revived industry bids fair to be of the utmost value not to Kashmir alone but to the British Empire.

**Afghanistan.**

Very little information exists regarding the attempts that have been made to establish a regular silk industry on the Himalaya except at Dehra Dun, to which reference has already been made. Further to the west in Afghanistan and Baluchistan there has always existed a small industry. Thus Moorcroft (Travels, 1841, ii., 416) mentions that the town of Yang Arekh in Bokhara is supported chiefly by its filatures of raw silk. There are two kinds of silk, white and yellow, exported to Kabul and Peshawar. This is the survival of the early traffic from Central Asia to India (repeatedly alluded to in connection with Khotan) conveyed down the Indus river to Bombay and Surat.

Speaking of Baluchistan, it may be observed that the present industry is due very largely to Mr. Rogers, who, at his own expense, conducted in 1901 experiments at Kirani near Quetta. The silk produced was so favourably spoken of that efforts have been since put forth by Government to extend the adventure, the locality selected being Mustang in Khelát, where many villages were known to possess large numbers of mulberry trees. His Highness the Khan
(under the advice of Major Showers, Political Agent) has entered enthusiastically into the scheme of a new industry for his people. In April 1905 Showers wrote a long official report that not only gives the history of the Khelat experiment but the results hitherto attained, and the opinions of the brokers, as also of Sir Thomas Wardle, on the silk produced. These all combine to confirm the high expectations entertained regarding the future of the Baluchistan and Khelat silk industry.

BOMBAY.—The silk manufactures of Ahmadabad were famous alike during the time of its own kings and of its Muhammadan Viceroyes. The chief excellence lay in the bright colours of the plain stuff and the strength of the brocades. (For Ovington's account see p. 906, 1026). Under the Marathas (1735–1817), however, Dunlop wrote in 1817 that it was taxed when raw, as it passed through every process of manufacture, and again when ready for sale, and was thus so weighted that in competition with foreign silks, the local manufacture almost ceased to pay and all but died out. Geoghegan (I.e. 55–55) says that the first attempt at silk-rearing in Bombay was made in 1795 by Dr. H. Scott. Hose, the cotton expert, lived with Scott, but in his 'Tours for Scientific and Economical Research', written in 1787-8, no mention is made of silk. In 1679 the Governor of Fort St. George recorded in his Diary, of 5th December of that year, his having come across Gujarati silk merchants buying silk for Ahmadabad. It is thus highly likely that the raw silk exported from Western India was to some extent at least Bengal silk, seeing that there is no evidence of silk-rearing having been successfully established in Western India until well into the 19th century. As just stated, frequent mention has been made of a silk supply drawn to Western India from Central Asia, the route being down the Indus. The earliest record of cultivation in Bombay Presidency is in 1823, when the worm was discovered from Mulsoor to Dharwar. Shortly after (in 1827) Mr. Gibeon planted his garden at Dhubra in Khandesh and Signor Mutti opened out his silk farm at Poona in 1829. During the first year of British occupation of Ahmadabad (1818) the import of raw silk amounted to 11 tons (300 Indian mounds), during the second year it came to 37 tons, and in 1847 stood at 109 tons. Since then the trade has witnessed extreme fluctuations. Numerous explanations have been offered, such as the rise of the cotton traffic—both local production and foreign imports; changes of fashion, more especially the decline of the demand for brocades by the Kathiawar chiefs; and lastly the growth of the trade in Chinese and Central Asiatic woven silks.

There are three chief classes of silk goods produced in Ahmadabad, viz. plain silks, brocades, and silk prints. The plain goods are also largely produced in Surat, and the markets for these are Kathiawar, Rajputana, Central India, Bombay, the Deccan, the Central Provinces and the Nizam's Dominions. The brocades, as also cloths of silver and gold, are much less used for robes nowadays than formerly, but are in demand for upholstery and elephant and other trappings.

Surat has for long years past been largely concerned in the supply of silks to Burma, and a Native of Surat, seeing the advantage of proximity to the Bengal silk supply and the facility of export to Rangoon, some years ago organised a silk factory in Cuttack to be run exclusively for the Burmese market. But for many years past the demand by Burma for Indian silks has shown a decided tendency to decline, and an inquiry was instituted as to the cause. It was pointed out that in the first instance the silk-weavers of Surat were primarily responsible, in that yielding to the recommendations of Native merchants in Rangoon, they had gradually lowered their price by reducing the quality until it was recognised in Burma that the locally manufactured silks, though more expensive, were infinitely more lasting and the colours and patterns more in accord with the prevailing fashion. It was also pointed out that the advances of European commerce and the necessities of the people had led to a substitution of cotton for silk goods.

MADRAS.—Brandt (Résumé of the Rec. of the Mad. Govt. relative to the Cult. of Silk in the Pres., Oct. 1871) says that no mention occurs of silk in connection with Madras prior to the year 1791—a statement that is hardly correct (see p. 1019). Tippu Sultan appears closely associated with the rise of the modern industry. A Native of Trichinopoly was by him sent to Bengal to learn the silk trade. But there must have existed an industry prior to that date, since we read of a present made to an Englishman, in 1793, having consisted of "kincobs" made at Trichinopoly. Dr. James Anderson, Physician General at Madras, established in 1771 a plantation of 5,000 white mulberry bushes from Hyderabad stock at Nungambakum—a suburb of

Mysore—In December 1790, after many failures, succeeded in acclimatising the Bengal worm. It would seem that this insect, subsequently conveyed back to Bengal, may have given origin to the name Madras, the alternative name for the nistri—the Bombyx crassus of Hutton. Dr. Anderson urged that the Peninsula, owing to its more equable temperature, had great advantages over Bengal. In consequence, a vigorous effort was made by the Madras Government to distribute Dr. Anderson's acclimatised insect to all parts of South India deemed likely to prove suitable new areas, and every encouragement was given to extend mulberry cultivation. Collectors, surgeons, paymasters, etc., became superintendents of Government plantations all over the Presidency. About this time Dr. Anderson reported a successful experiment to improve the Bengal silk worm, 10½ grains of silk being obtained as against 6 grains, the average outturn in Bengal. Cocoons were wound on the Piedmontese reel and ultimately a brilliant white silk was obtained. But it soon began to be believed that Dr. Anderson had taken a too sanguine view of the possibilities of the Madras Presidency in the rearing of silk. All parts of South India were not alike suitable, and a uniform climate, that might admit of breeding throughout the year, was soon realised as by no means a desirable state of affairs. This story of the Madras experiments is very largely that also of many other enterprises in India—ignorance of the conditions upon which alone success depends being the foundation of a superstructure of failure and disappointment greatly calculated to retard legitimate endeavours. The Madras Government spent £20,000 in four years, and a further sum of Rs. 78,736, for the filature constructed at Vellavedu. They shortly after advertised their plantations and property for sale, but obtained no offers.

Notwithstanding the failures and disappointments in the acclimatisation of the silkworm and the establishment of a silk-reeling industry, the manufacture of silk and satin made considerable progress in the Madras Presidency. And beyond the Presidency the silk brocades and the plain silks of Mysore are famous even to the present day. A century ago Buchanan-Hamilton (Journ. to Mysore, etc., i., 208, 222; ii., 263) gave an account of the industry that to this day has hardly been excelled for its fulness and thoroughness. Persons desirous of studying the subject of silk in South India could not do better than begin their inquiry by perusing Hamilton's account.

Mysore.—In Mysore and Travancore greater success was attained than in any part of the Madras Presidency proper. In 1849 Surgeon Smith published a report of the silk experiments of Mysore from the date of its introduction by Tippu Sultan to the date of his report. Coming down to recent times, the story of failure has to be replaced with a record of success. The late Mr. J. M. Tata started an experimental silk-rearing farm in Bangalore with a view to resuscitate the industry. In 1897 he personally visited Bangalore and chose the land for his plantation and rearing-houses. He then sent off to Japan to obtain the services of a superintendent and a selected number of trained operatives, both men and women. It was soon ascertained that the tableland of Mysore approached in climatic conditions very closely to that of the warm zone of Japanese silk culture. The services of Mr. T. Odzu were in 1889 procured as manager and the farm was started a little beyond the Basseynagudi extension at the village of Yediyur. A similar experiment was started by Mr. Partridge at Yellaranka near Bangalore. Henceforward we read of steady progress in the Tata Farm, the Mysore authorities having made it a grant of Rs. 3,000 a year in return for obtaining permission for its utilisation as a sort of school where the Japanese methods of growing the mulberry and rearing the insects might be taught to the people of Mysore. And it may be added that it soon exercised even a wider influence in connection with the proposed new silk farm of Pusa in Bihar. The Mysore farm was also visited by Major Showers, in order to study the methods pursued. That officer has since organised a silk industry in Khelat (official letter dated April 29, 1905), and says, "I may note here that about the best Indian silk that has reached London yet, is that produced at the Tata experimental silk farm at Bangalore. A sample of this silk was shown me by Mr. Frank Durant (Durant, Bevan & Co.), and he advised our taking that as a model at Mastung. This silk realised as much as 17s. a pound." Such high testimony is thus fully expressive of the great success attained by the Tata Farm.

The Silk Trade of India

Early Records of Indian Silk Trade.—Varthema (Travels, 1510 (ed. Hakl. Soc.), 38) speaks of the silk of Bengal being conveyed to Mecca. In a
further passage he discusses the cotton and silk goods of Cambay. In a third, makes mention of the silk being made in large quantities at a place identified as having been Masulipatam. These three statements thus exemplify the three great centres of the early silk trade of India. Sir George Birdwood and Mr. W. Foster published, in 1803, *The First Letter Book of the East India Company*, or a register of the official correspondence from 1660–19. We there read, in the Commission granted to the commander of the Company's second voyage (1605), of provision being made for the purchase of raw silk, but there is nothing to show that the entry in question denotes that the silk was to be procured from India. In subsequent commissions of other ships, such as of the date 1609, special mention was made of the Chinese and Persian silks. The former are spoken of as Lamking (Nanking) and Canton. Persian silk was sent in 1617 to Surat in exchange for sugar and other Indian commodities. It would seem that the Company's first efforts at silk manufacture were made in Surat, though everything points to the raw silk having had to be carried to the manufacturers of that town (see pp. 930, 1017). Mr. W. Foster, in a series of volumes entitled *Letters Received by the East India Company*, 1602 to 1619, affords many useful additional historic facts regarding the silk trade of India. We there learn that, disregarding letters that deal with China, Japan, Malay, Siam or Straits silks, one of the earliest mentions of Indian commercial silks occurs in a letter from Cambay, dated 1614. It is there stated that silk used formerly to be brought to that city from the interior. One of the earliest references to Bengal silk occurs in a letter from Sir Thomas Roe, written at Ajmir, December 1616, in which he discourses against the proposal then made to found special factories in order to purchase Bengal silks. He says that these are to be “had cheaper at Agra.” “I am of opinion your residences are sufficient and best chosen as they are.” He then adds that there exists “Silk of Bengal plenty at reasonable rates” (E.I.O., i.e. iv., 250). Subsequently, in 1619, a letter was issued from the factors at Surat to those at Masulipatam, in which an acknowledgment is made of “Musters of Bengal silke.” Foster (The English Factories, 1818–21, 153) furnishes a letter from Masulipatam, in which the following occurs, “I am in good hope after some small time to furnish you with good quantites of that sort of Bengal silk which Lawrence Walse was first, and Robert Young after, showed you musters of in England.” In a further letter, of date 1620, we read of Robert Hughes having been deputed from Surat and Agra to organise a factory at Patna. He purchased a maund of “serbandy” cocoons, for he adds it is “the cheapest and surest dealings to buy the serbandye and wynde it of my selfe.” Further on, doubt is thrown on the advantage of a filature at Patna, seeing that the silk cocoons had to be conveyed from “the cityye of Mucksoundabad (Murshidabad) where it is made, which would bee worth bothe labor and charge, for wee are assured that there it may be provided in infinite quanteties at least twenty per cent. cheaper than in any other place of India, and of the choystest stuffe, wounde off into what condition you shall require it, as it comes from the worms; where are also innumerable of silk wynders, experts workmen, and labour cheaper by a third than else where” (i.e. 229–30). Bernier (Travaux, 1656–8, 430–40) says, “There is in Bengal such a quantity of cotton and silks, that the kingdom may be called the common storehouse for those two kinds of merchandise, not of Hindoustan or the Empire of the Great Mogol only, but of all the neighbouring kingdoms and even of Europe.” Tavernier (Travaux in Ind. 1676 (ed. Ball), ii., 2–3) tells us that in his time Kasimbazar (“Cosembazar”), a village in the kingdom of Bengal, furnished about 22,000 bales of silk annually, each bale weighing 100 lb. “The Dutch,” he continues, “generally took, either for Japan or for Holland, 6,000 to 7,000 bales of it and they would have liked to get more, but the merchants of Tartary and of the whole Mogol Empire opposed their doing so, for these merchants took as much as the Dutch, and the balance remained with the people of the country for the manufacture of their own stuffs. All these silks are brought to the Kingdom of Gujarat, and the greater part come to Ahmedabad and Surat, where they are woven into fabrics.” “The crude silk of Kasimbazar is yellow.” Bernier says, “The Dutch have sometimes seven or eight hundred Natives employed in their silk factory at Kasem-Bazar, where, in like manner, the English and other merchants employ a proportionate number.” There would thus seem no doubt that long anterior to the arrival of the Dutch and English traders in Eastern Bengal, a fairly large silk industry existed, both in rearing the worms, reeling and throwing the silk, and in weaving all
manner of silken goods. The practical silence of Muhammadan writers on the subject is, however, significant, and tends to the conclusion that until the advent of the East India Company, little progress was made toward extending and improving the Native industry. Of the European traders, the Dutch were probably the first to find their way to the Bengal silk districts. It seems, in fact, to have taken the British the greater part of a century before their knowledge of the Bengal production took definite shape and they had assumed direct control. Most of the early books of travel, in discussing silk, speak either of the silks of Gujarat or of Masulipatam. Mandelslo (Travels, 1638, in Olearius, Hist. Muscovy, etc., 83) discusses the "Cotton and Linen Cloaths" and "Silk Stuffs" either conveyed to Surat or worked up there. In fact the British merchants seem to have striven hard to make Surat the chief centre of their Indian silk traffic, though they do not appear to have ever made the attempt to rear the silkworm there nor to build filatures at Surat. They carried the raw silk from Bengal to their looms. It is, therefore, surprising how Ovington could have written his most admirable account of the silkworm to which reference has been made above (p. 995).

Sir Henry Yule, in his Biographical Sketch of Sir Straynham Master (Diary of William Hedges, ii., app., ccxxxvi.), gives passages from a letter by Master descriptive of Kasimbazar, in which he speaks of all the country being planted with mulberry trees. Sir Henry fixes the Company’s establishment of an agency in Kasimbazar at 1658 (l.c. iii., excv.), though they had occasional agencies there as early as 1653. The reader will find much interesting information regarding the establishment of the East India Company’s silk industry in the late Mr. C. R. Wilson’s Early Annals of the English in Bengal (i., 39, 55, 375–8, 394; ii., 196, 228, 360).

EXPERIMENTS AT IMPROVEMENT OF INDIAN SILK.—Between the dates mentioned for the establishment of the agencies and the records of the Company’s erection of filatures in Bengal, there is a gap of a century of which we know little more than has been indicated. In the volume of Reports and Documents published by the East India Company in 1836 (to which repeated reference has already been made) much interesting information will, however, be found. It is there stated that the trade of the Company in raw silk was inconceivable in extent before the middle of the last century. The chief places where producing silk were "Cosimbazar, Commercilly and Rungpore." The class of silk procurable was described as country wound. But it was freely admitted that the fault of that silk was its inequality, some portions being single, others double or even quadruple. Accordingly, in 1757, Mr. Richard Wilder, a gentleman trained in every department of the silk industry, was sent to Bengal to examine into the cause of the defective quality of Bengal raw silk. Wilder continued in India until his death in 1761, and was enabled to lay the foundation of great improvements in the winding of silk. Mr. Joseph Pouchon was appointed to succeed Wilder, and his claims to the name of Bengal silk became equal to that of Italy or any other country. In 1768 the Court of Directors advised the Government of India that it was to be increased in raw silk that they looked chiefly for the means of bringing home their revenue. Subsequently the Court advised the Government that although there was no branch of their trade which they more ardently wished to extend than that of raw silk, still they could not think of effecting so desirable an object by any measures that might be oppressive to the Natives, and, therefore, no compulsory methods were to be adopted to increase the number of the silk-winders. With regard to planting mulberry, it was suggested that deductions from rent should be made on lands planted with it so as to amount to a bounty by rendering it more profitable than any other article of culture.

But complaints continuing to be made by the purchasers of Bengal silk, it was resolved to adopt the methods of winding practised in the filatures of Italy and other parts of the Continent. For this purpose the services of experts (both English and foreign) were secured and located at the Company’s agencies. For example, Mr. James Wiss, a native of Piedmont, was stationed at Commercilly with four Italians under him, engaged as drawers and winders. Mr. J. Robinson was stationed at Rangpur with three Italian experts under him. While Mr. W. Aubert, with three expert roellers from Languedoc, was appointed to another aurung, but Aubert died at Madras in 1771, and thus never reached Bengal. The first report on the silks produced was to the effect that Mr. Wiss had succeeded to admiration in drawing a tolerable silk from the most ungrateful
of cocoons, the sickliest of worms, and under the most unfavourable season possible. This led to recommendations to improve the stock, both of the worms and the mulberry, and a long correspondence ensued, in which ultimately Drs. Roxburgh, Wallich and Lush took part, and which culminated in the attempt to adopt the Italian standard method of growing the plant in the Bengal bush system.

The greatest difficulty in conveying live eggs from Italy to India seems to have suggested two alternatives:—1st, to get Italian eggs from St. Helenas as a half-way house; and 2nd, to obtain China stock. In 1771 eggs were accordingly procured from China, and at the same time the Chinese mulberry was brought to India. In 1774 it was reported that the Italian method of reeling had been so far successfully introduced that it promised in a reasonable time to fulfill all expectations. Wiss retired from India in 1776, but was appointed by the Company to a post in England by which he was enabled to afford much valued advice to the manufacturers in India. It would occupy too much space to follow the course of events farther. The purpose in view has been served, namely to exemplify the enlightened action of the East India Company and the far-reaching efforts which they expended in their endeavours to improve and extend the Indian silk production. It need only, therefore, be added that the Board of Trade in Calcutta established in 1832 an experimental station in Howerah for the purpose of instituting comparisons and experiments, with a view to improve the manufacture of raw silk. This was intended to guide the operations of the Company’s Residents in the chief silk-producing districts.

Under the fostering care, therefore, of the East India Company, the Indian silk trade prospered greatly. During the early years of its existence it had only Turkey, China and Japan to contend against. Gradually, however, the efforts to acclimatise the silkworm in Italy and France, and to engratiate itself with the regular industries of these countries, were crowned with success, and India had thereby to face formidable rivals. The East India Company gradually also found new and more immediate outlets for their enterprise, and silk, in consequence, passed into the hands of private persons. Discouraged by the lessen ing demand for Indian raw silk, the industry fell behind and degenerated until it was held that Indian silk could not compete with that of Europe.

Many writers had reported that the cocoons of the silkworm that feeds on the leaves of the castor-oil plant could not be reeled, but that the Natives of Assam carded these and spun them like cotton (see pp. 1011, 1013; also Roxburgh, Trans. Linn. Soc., 1804, vii., 45). Up to 1835 no advantage was taken of that fact in Europe, but in the year mentioned, the discovery was at last made in England that the silk waste and wild silks of India might be utilised in the manner mentioned. A new demand arose for these materials, and, in consequence, a complete change took place in the nature and location of the Indian silk trade. The waste silk of the village reeling business found a ready sale. A market was created for wild silks, and an export trade made its appearance in official returns under the heading of waste silk. Moreover, the reeled silk of India, about the period indicated, was recognised as possessing special features of its own for which a distinct demand existed. To Sir Thomas Wardle is due the credit of having urged, and successfully accomplished, the renewal of the efforts to improve the methods of reeling. He pressed for the introduction of better reeling machinery, even although M. Gallois had pointed out that he had some time previously introduced the Tavoletta concava machine, and found that the silk made by the ordinary process was quite as good. It has, however, been freely admitted that great improvements might be carried out by more care in reeling on the lines advocated by Wardle.

FOREIGN TRADE. Milburn (Rise and Prog. of the Silk Trade, in Or. Comm., ii., 244-60) gives the early returns of India. The first consignments of wound silk from India to England were made in 1772, and during the five succeeding years the returns of that nature averaged 180,000 lb. In 1785 they came to 324,307 lb.; in 1795, to 380,352 lb. About this time the Company’s purchases were made by contract, and it is recorded that a loss of £884,744 had been sustained. The total imports of Great Britain in raw and thrown silk were in 1773 returned as 777,373 lb., of which, under the heading of raw silk, were 145,777 lb. from Bengal; 203,401 lb. from China; 187,099 lb. from Italy and Turkey; and 6,190 lb.
from other parts; while under thrown silk, the total receipts were 234,906 lb. Twenty years later the corresponding figures were, total imports 1,261,963 lb., of which (raw silk)—Bengal supplied 736,081 lb.; China, 165,435 lb.; Italy and Turkey, 110,276 lb.; and other parts 8,216 lb.; with fully one quarter of the total consisting of thrown silk, viz. 241,954 lb. But shortly after a complete revolution took place. The silkworm was acclimatised in both France and Italy, and immediately thereafter the demand for silk in Europe not only increased very rapidly but the demand for the Indian fibre declined. The returns of the exports of raw silk from Bengal to England about this time began also to manifest a new feature, viz., it was referred to two sections, Company's and Private exports. In 1805 the total exports came to 835,904 lb., of which 460,303 lb. were made by the Company. In 1825 the total exports were 919,436 lb., of which the Company's share came to 699,230 lb. In 1835 the total exports of raw silk came to 727,535 lb., of which the Company exported 721,509 lb.

From 1857, when the utilisation of waste silk began to be understood and practised in Europe, the exports of India changed their character. The returns rapidly manifested a decline in value, due largely to the growth of the traffic in chasam (waste silk) and cocoons, in place of the reeled silk of former times. In 1867–8 the exports of raw silk from India were 2,226,201 lb., valued at Rs. 1,55,32,290. In 1877–8 the total exports from India were 1,512,819 lb., valued at Rs. 70,38,493; in 1880–1 they were 551,000 lb. reeled silk, plus 788,000 lb. waste silk and chasam, valued at 55 lakhs. Thus in twenty years from 1867–8, the exports declined from a valuation of 1½ millions to ¼ a million sterling. In 1900–1 the figures were 560,000 lb. reeled and 1,031,000 lb. waste, with a total value of 51 lakhs.

RAW SILK.

It is not always possible to refer the traffic in Raw Silk to the two important sections Wild and Domesticated, but where this can be done, the proportion which the former bears to the total will be exemplified.

Exports.—The following table exhibits the Foreign Exports for the past seven years, arranged under the three chief classes, viz. Reeled Silk, Chasam or Waste, and Cocoons.

</table>
Of these amounts, the Wild Silks were as follows: In 1900–1, the exports of reeled wild silks were 62,693 lb.; in 1901–2, 16,884 lb.; in 1902–3, 3,919 lb.; in 1903–4, 10,494 lb.; in 1904–5, 19,287 lb., in 1905–6, 26,904 lb.; and in 1906–7, 23,990 lb. The traffic in reeled wild silk has thus fluctuated very greatly. Of *chasam* or waste, the figures given are much higher, and seem to have been on the whole increasing, though in 1904–5 a shrinkage occurred. The figures were in 1900–1, 447,488 lb.; in 1901–2, 492,113 lb.; in 1902–3, 626,977 lb.; in 1903–4, 727,514 lb.; 1904–5, 350,514 lb.; in 1905–6, 634,593 lb.; and in 1906–7, 463,440 lb. So also the traffic in cocoons seems to have marked an expansion, though a shrinkage occurred in 1905–6. Let it be observed, however, the exports of this nature are almost entirely wild cocoons. The returns of wild cocoons exported were in 1900–1, 13,976 lb.; in 1901–2, 32,940 lb.; in 1902–3, 53,125 lb.; in 1903–4, 87,952 lb.; in 1904–5, 80,540 lb.; in 1905–6, 46,725 lb.; and in 1906–7, 36,965 lb.; which figures, it will be seen, leave very small balances annually that have to be accounted for as being domesticated cocoons.

Turning to the provincial transactions, it may be pointed out that practically the whole of the reeled silk exported from India goes from Bengal. Of the *chasam*, it may be said that two-thirds go from Bengal and one-third from Madras, the other provinces contributing negligible quantities. So also of the traffic in cocoons, two-thirds go from Bengal and one-third from Madras. Thus it will be seen the exports from the province of Bengal are by far the most important, since, as a rule, they amount to three-fourths of the total. Following Bengal come the Madras ports, which usually contribute from a fifth to a fourth of the total foreign exports. As manifested by the returns of railborne traffic, these Madras exports must be Mysore silk carried to the Madras port towns by rail, and then exported to foreign countries. But if anything, the Madras traffic seems to be declining, while the exports from Bombay are expanding. In 1900–1 the Bombay exports stood at 10,091 lb., while in 1906–7 they had expanded to 233,774 lb. From the returns of railborne traffic, the raw silk that drains into Bombay town (from which the foreign exports are largely made) appears to be mainly Panjâb silk, or silk conveyed into the Panjâb from across its land frontier—doubtless to some extent Kashmir silk. Of these foreign exports about three-fourths go to France and approximately one-fourth to the United Kingdom.

**Imports.**—Perhaps the most significant feature of this aspect of India's foreign silk trade is the circumstance that more raw (reeled) silk is imported by Bombay and Burma than is exported by Bengal. The figures for the years 1900–7 have been:—1900–1, 2,535,377 lb., valued at Rs. 1,01,69,402; in 1901–2, 2,128,483 lb., valued at Rs. 80,96,200; in 1902–3, 1,639,189 lb., valued at Rs. 55,16,149; in 1903–4, 1,544,315 lb., valued at Rs. 59,29,527; in 1904–5, 1,808,709 lb., valued at Rs. 73,41,121; in 1905–6, 1,645,696 lb., valued at Rs. 71,19,049; and in 1906–7, 1,422,467 lb., valued at Rs. 56,80,273. Of these quantities practically the whole comes from China and the Straits, the former furnishing about four-fifths of the supply. It has often been pointed out that this large import trade is mainly a consequence of the cheap freights by the return opium steamers to Bombay. But there would seem no doubt that Bengal for a century or more had failed to meet the demands of Western India.
The Bombay demand was, however, the incentive for the Gujarati silk merchants and weavers permeating the whole of India and forming the colonies that exist to-day all over the chief silk-producing localities of the Empire. It is needless, therefore, to add that out of the imports, Bombay takes by far the major portion, only about one-seventh going to Burma, while the other provinces take practically no share in these imports.

Thus while Bengal is the great producing province, Bombay is the chief distributing centre. By rail and river the Chinese silks brought to Western India are carried not only through the Presidency of Bombay, but very largely to the Panjáb and even to the United Provinces. Hence it may be said that while Bengal is the chief producing province, the Panjáb is the chief consuming province of India.

Re-exports.—It only remains to briefly indicate the re-export trade, practically the whole of which goes from Bombay, and is, in consequence, Chinese silk. The quantities of foreign silk re-exported during the period of 1900–7 were as follows:—1900–1, 97,519 lb., valued at Rs. 1,89,475; 1901–2, 59,941 lb., valued at Rs. 1,46,265; 1902–3, 85,249 lb., valued at Rs. 1,62,279; 1903–4, 68,131 lb., valued at Rs. 1,40,828; 1904–5, 54,522 lb., valued at Rs. 1,48,729; 1905–6, 69,330 lb., valued at Rs. 1,35,045; and in 1906–7, 105,288 lb., valued at Rs. 3,78,860. These re-exports go mainly to the United Kingdom and Arabia.

MANUFACTURED SILK.

Repeated reference has been made to N. G. Mukerji (Monog. Silk Fabrics of Beng., 45–82); his chapter on fabrics will be found to give every possible detail regarding the rise and present position of the Indian industry, the class of goods manufactured, and the extent of the trade. He mentions, for example, the Murshidabad silk manufacturers turning out many different classes of goods, such as gown-pieces, corahs, silk-muslins, handkerchiefs, mathas, imitation Assam silk, etc. The last mentioned was specially introduced by Mukerji himself as a relief measure, but the success attained has “given rise to a hope that under a fostering care the silk-weaving industry of Bengal may be developed in other directions also.” Speaking of the corahs, Mukerji observes that “these are the cheapest silk fabrics which form the staples of export to Europe, where they are used mainly for lining purposes. Corahs are generally woven 7 yards by 1 yard, and sold at a rupee (=1s. 4d.) per square yard. They are made out of unbleached and untwisted thread, and bleached in the piece after they are woven. Corahs are also woven 10 yards by 42 inches, like ordinary gown-pieces, and worn as saris by widows. Like gown-pieces, corahs are valued by the number of warp threads (called shándá), 2,400 warp threads per yard making the best gown-pieces and corahs, while 1,200 or 1,000 warp threads per yard make the poorest gown-pieces and corahs. The price of corahs varies from 6 annas to Rs. 1–8 per square yard.” In the Review of Trade of British India (1904–5, 38), the statement occurs: “The exports have steadily diminished during the last five years, the decrease compared with 1903–4 being 12 per cent., and what was once a trade of some importance is rapidly approaching insignificance.” This has reference mainly to the decline in the exports of corah silks, in which there seems some prospect of a revival. But at present the exports from India are “chiefly
TRAFFIC IN MANUFACTURED SILK

of tissues woven in Bengal from indigenous silks, for the Bombay mills employ imported silk and weave principally for the home markets."

Exports.—These again may be best arranged in tabular form under the chief classes—piece goods, silk goods mixed with other materials, thread, and other sorts.

</table>

The exports have thus in recent years been steadily decreasing, the value of the piece goods exported having shrunk during the years 1900–1 to 1906–7 to less than one-half. The total value of all manufactured goods has similarly shrunk from 12½ to a little under 7 lakhs. If, however, the comparison be carried farther back, the decline is manifested as even still more serious. For the five years ending 1895–6 the exports of manufactured silks of all kinds were valued at 19½ lakhs of rupees. The finer silk fabrics made in India are nearly entirely used up in the country. In 1904–5 the value of the Bengal exports of all kinds amounted to Rs. 5,76,390, or almost four-fifths of the total. The share of Bombay, which means chiefly imported silk for the home market, was Rs. 1,34,749, while the balance went from Madras and Burma. Turning to the chief markets, we find that in 1906–7 the United Kingdom imported Indian goods to the value of Rs. 3,44,850; France, Rs. 80,135; Arabia, Rs. 62,581; North Africa, Rs. 23,229; Straits Settlements, Rs. 55,348; Turkey-in-Asia, Rs. 33,715; and Australia, Rs. 12,013.

Imports.—These show a remarkable expansion. In 1876–7 they were valued at 58½ lakhs, five years later at 135 lakhs, and a decade still later (1890–1) 140 lakhs of rupees. Since 1900 the figures have been as follows:—1900–1, Rs. 1,66,58,108; 1901–2, Rs. 1,48,47,009; 1902–3, Rs. 1,63,23,232; 1903–4, Rs. 1,83,34,720; 1904–5, Rs. 2,11,81,502 (the highest figure yet attained); 1905–6, Rs. 1,90,15,100; and in 1906–7, Rs. 1,82,50,465. The largest quantities in 1906–7 came from Japan, Rs. 74,01,060; China, Rs. 33,97,558; France, Rs. 20,19,303; Italy, Rs. 19,84,466; the Straits Settlements, Rs. 1,02,307; the United Kingdom, Rs. 13,95,680; and Austria-Hungary, Rs. 3,06,661; while the chief
importing centre is Bombay, which takes almost three-fourths, the balance going chiefly to Burma. Reviewing the trade returns for 1904–5, Robertson (Rev. Trade of Ind., 1904–5, 17) says: "Piece goods of pure silk are chiefly of Chinese and Japanese make, the latter predominating, and jointly (including re-exports from the Straits Settlements) they amounted to 16.3 million yards, valued at 102 lakhs, out of a total of 18.9 million yards, valued at 12.4 lakhs. The value of the silk goods mixed with other materials, 43.8 lakhs, is 30 per cent. greater than in 1903–4. There is also an advance of 25.8 per cent. in 'other sorts,' of which the value rose by 51.7 per cent. to 42.9 lakhs. This includes warp and yarn of Italian silk imported into Bombay for hand-weaving." The expansion of the imports in mixed silk and other textiles and in thread, warp and yarn, is therefore a highly significant feature of the modern silk traffic that gives a useful hint as to the demands of the hand-loom workers.

Re-exports.—Have been increasing in recent years, and in 1904–5 were not far behind the imports in value. The figures for the period discussed were as follows:—1900–1, Rs. 5,33,749; 1901–2, Rs. 6,72,841; 1902–3, Rs. 7,33,519; 1903–4, Rs. 6,98,160; 1904–5, Rs. 6,01,942; 1905–6, Rs. 6,47,797; and 1906–7, Rs. 6,77,683. Bombay exports practically the whole amount, and the chief markets for these re-exported goods appear to be Natal, Arabia, British East Africa, Cape Colony and Persia.

Trans-frontier Trade.—Turning from the foreign to the Trans-frontier land trade, the returns may similarly be indicated under exports and imports of raw and of manufactured silks. Of Raw.—The exports during recent years have been as follows:—1904–5, 189 cwt., valued at Rs. 85,233; 1905–6, 190 cwt., valued at Rs. 93,586; 1906–7, 94 cwt., valued at Rs. 51,175. The chief markets are the South Shan States, Bhutan and North-East Afghanistan. The imports during the same period have been:—1904–5, 2,960 cwt., valued at Rs. 19,98,484; 1905–6, 4,121 cwt., valued at Rs. 29,37,592; 1906–7, 4,165 cwt., valued at Rs. 30,88,935. Kashmir and Western China supply practically the whole amount. Of Manufactures.—The following are the returns of re-exported silk goods:—1904–5, 667 cwt., valued at Rs. 8,97,079; 1905–6, 710 cwt., valued at Rs. 8,11,581; 1906–7, 969 cwt., valued at Rs. 9,36,406. The chief markets are the South Shan States, North Siam, North Shan States, South Siam and Tibet. The imports for the same period were:—1904–5, 196 cwt., valued at Rs. 4,72,833; 1905–6, 445 cwt., valued at Rs. 7,33,319; 1906–7, 250 cwt., valued at Rs. 5,01,206. The largest quantities come from North and South Siam and the South Shan States.
the shape and colour of the fruit, egg-shaped to an elongated pear or even cylindrical, while in colour it ranges from white through yellow to red and even dark purple. None are eaten in the fresh state but are cooked as vegetables.

**Cultivation.**—The seeds are sown at the beginning of the rains and the plants put out at the distance of a foot and a half apart. They come into season in August or September and bear till the end of the cold weather, certain varieties yielding till June and in Madras right through summer to October. In the suburbs of Calcutta, Bombay and Madras, in other words, in the vicinity of large towns, the *brinjal* is cultivated as a field crop. Full accounts of cultivation have recently been given by Mukerji and Roy for Bengal, and by Mollison for Bombay. The latter states that the varieties with purple fruits grow into much-branched shrubs about 3 feet high. The small-fruited forms are not so tall. The field varieties, he further adds, have prickles. The crop is grown chiefly in Gujarat, especially in the *goredu* or *besar* garden lands of Kaira and Baroda. The crop is obtained from transplanted seedlings. The seed-bed is carefully prepared in May, and the young plants are ready for transplantation in six weeks or two months. The field into which they are transferred is prepared as for chillies, i.e. ploughed two or three times and then harrowed till a fine tilth is obtained. Before the first ploughing, a dressing is given of not less than 20 tons old farm-yard manure per acre. The seedlings are planted two together in rows, 2½ to 3½ feet apart in both directions. When well established they should be earthed up, before which a top-dressing of 500 lb. of nitre or 1,000 lb. of castor-cake placed round the plants will be found very beneficial. Beds for irrigation and watering are arranged as in the case of chillies (*Capsicum*). Mollison gives a table showing the yield, cost of cultivation, and value of outturn per acre under fairly high-class cultivation. The table shows that nitre as a top-dressing has a remarkable effect on the crop. With a manure of dried fish and nitre, at the rate of 1,451 lb. of fish and 433 lb. of castor-cake placed per acre, the outturn was found to be 16,322 lb., cost of cultivation Rs. 138-6, and value of outturn Rs. 325-5 per acre.

In Bengal, according to Mukerji, the seed is sown at the end of March or early in May. The field to which the seedlings are transferred is prepared in December or January and should be ready for planting in May. The plants begin to bear in August. A variety, known as *kuli begun*, is sown in September and October; the seedlings are transplanted in October or November and the plants bear from February to June. He estimates the cost of cultivation at Rs. 60-8 per acre, and with an outturn of 150 maunds per acre, worth Rs. 90, the net profit would amount to about Rs. 30 per acre. Roy puts this matter more pointedly. There are two principal varieties, he says—(1) the winter and (2) the spring. The finest *brinjals* are known as *elokeshi* and *mukta keshi*. When grown as a spring crop *brinjal* follows *dus* paddy or jute. But where the rainfall is heavy it is grown in the *rabi* season.

**Uses.**—*Brinjals* are much eaten by the Natives whenever procurable, and by the Europeans during the early summer months, when other vegetables are not available. The Natives use them (a) in curries; (b) roasted in hot ashes and mashed with salt, onions, chillies, and lime-juice or mustard-oil; (c) cut into slices and fried in oil; and (d) pickled while young and tender with mustard-oil, chillies, salt, etc. By Europeans they
THE POTATO

SOLANUM TUBEROsum

Bengal

are usually prepared by being half boiled, the interior scooped out and mashed with pepper, salt and butter, then replaced and baked.

S. tuberosum, Linn. The Potato, alú, bilati álú, batata, wallorai, kilanu, utalay gudda, etc.

With reference to the indigenous habitat of the potato, De Candolle (i.e. 45-53) states that the only locality in which a species is found really wild, that could be accepted as representing the cultivated plant, is Chili, but that it is very doubtful whether its natural home extends to Peru and New Granada. According to Baker (Journ. Linn. Soc., xx., 489), however, undoubted forms of S. tuberosum have been found wild in Lima and in New Granada also, but the plant is everywhere one which occurs at a comparatively high altitude and in a dry climate, and is met with nowhere in the near neighbourhood of the coast. It is proved beyond doubt that at the time of the discovery of America the cultivation of the potato was practised with every appearance of ancient usage in the temperate regions extending from Chili to New Granada (Asa Gray, Scient. Papers, 1889, i., 317). In Europe it was introduced at some period between 1550 and 1585, first into Spain, thence to Portugal, Italy, France, Belgium and Germany. It had reached Ireland in 1585 or 1586 (Rozé, Hist. de la Pomme de Terre, Paris, 1898). The first mention of it in connection with India appears in Terry's account of the banquet at Ajmir given by Asaph Chan to Sir Thomas Roe in 1615 (Voyage E. Ind., 197). Fryer (1675, New Acc. E. Ind. and Pers. (ed. 1698), 104, 179) describes the gardens of Surat and the Karnátak as containing among other vegetables brinjals and potatoes. It would thus appear that within a remarkably short interval, after the discovery of the potato in America, it had been conveyed to India and was apparently at once taken up by the better-class Muhammadans as a desirable addition to the ordinary articles of diet.

CULTIVATION.—To-day, it may be said to be cultivated more or less in all parts of India. The methods pursued will, therefore, be now briefly indicated under provincial headings:

Bengal.—The chief potato-growing districts are Hughli, Bardwan, Rangpur, Jalpaiguri and Darjeeling. Full accounts have recently been given by Mukerji and Roy, as also in the publications of the Bengal Agricultural Department. Various kinds of the tuber are grown, of which the Patna, Naini Tal, and Cherrapunji are best known and most highly valued. A loose soil such as sandy loam is preferred. The crop requires moisture, but water must not be allowed to settle about the tubers. In rotation it may follow dus paddy or jute, but is often grown year after year without an intervening crop, especially in the vicinity of large markets, the fertility being preserved by high manuring. Previous to planting the land is prepared by numerous ploughings and is thoroughly pulverised. Manure, preferably cow-dung at the rate of 240 maunds per acre, or castor-cake

1028
at the rate of 20 maunds per acre, should be spread on the ground after
the first few ploughings and thoroughly mixed with the soil. The field
is then divided into sections by water-channels and laid out in ridges and
furrows. Sets consisting of entire tubers or portions with two or three
"eyes" are planted along the ridges, 9 to 12 inches apart in a single or
double row. Experiments at the Sibpur Farm showed that the average
outturn per acre from double rows was about 9,500 lb., and from single
rows about 7,300 lb. Planting the sets should not ordinarily take place
in the plains before October. Between planting and harvesting, the crop
should be watered if necessary, but not in excess, the earth stirred and
weeded and heaped up several times round the base of the growing plants.
Harvest takes place from 15th January to 15th March. Mukerji estimates
the cost of cultivation at Rs. 170 per acre and the outturn at 150 maunds
valued at Rs. 225, giving a net profit of about Rs. 50.

Agri., 1901, 336-43; Roy, Crops of Bengal., 1906, 113-9; Ann. Repts. Dept. Land
Rec. and Agri.; Agri. Dept. Bengal., 1906, No. 8; Exper. Farm Repts. Bardwan,
1900-7, 33-40.]

Assam.—Potatoes are extensively grown on the higher slopes chiefly
in the Khasia hills, and in lower land which has been well drained. In the
Gazetteer of Assam (1906, x., 73-4), which deals with the Khasia, Jaintia,
Garo and Lushai hills, it is stated that the crop was first introduced in
1830 by Mr. David Scott and in 1881-2 the export of potatoes from the
province reached 127,000 maunds. Five years later, however, the tuber
was attacked by disease and in 1887-8 the export fell to 42,000 maunds,
and in 1899-1900 had decreased to 5,000 maunds. A change then came,
due to the introduction in 1897 of the Naini Tal potato, and in 1903-4
the exports reached 51,000 maunds. Two crops are raised: "The first
is sown in January and February, and is gathered in June and July; the
second is sown in July and August and is harvested in November and
December." [Cf. Ind. Gard., Sept. 29, 1898, 429-30; Repts. Dept. Land
Rec. and Agri.; Agri. Dept. Assam Bull., 1904, No. 10, 5-7.]

United Provinces of Agra and Oudh.—The potato is said to flourish
well in the hills at Naini Tal, Almora, Paorri Lohiygat, and beyond Mussourie
and also in the plains. Dutchie and Fuller (Field and Garden Crops., pt. iii.,
15-6) state that cultivation is conducted on the European method, and
differs in no material respect from that described above for Bengal. Two
hundred maunds is stated to be no extraordinary outturn, but the cultiva-
tion is very expensive. "The eyes are planted in November and the
potatoes are ready for digging up in February. They are sold in the
bazar at the rate of 12 annas to one rupee and four annas per maund." On
the authority of the late Mr. Gollan, it is also stated that "the best
time to sow the acclimatised varieties is from the middle of September
to the middle of October, and that the hill kinds and those imported from
Europe must be sown later. Water is freely given during growth, but the
quantity is reduced when the leaves begin to turn yellow. If the soil is
naturally rich, manure is not essential, but in the plains manure is always
given."

In recent years three varieties have been experimented with at the
Cawapore Farm, viz. the Madrasie white, country red, and hill variety.
In the report for 1903-4 it is stated that the average outturn for six years

1029
THE POTATO

SOLANUM TUBEROSUM
Bombay

Yield.

of Madrasi and hill varieties amounted to 13,527 lb. and 8,546 lb. respec-
tively, while the average for five years for country red amounted to 13,119 lb. [Cf. Nevill, Dist. Gaz., 1904, iv., 46; 1904, xxxiv., 56, 63, 150, etc.; Cavenpore Exper. Farm Repts. (several years).]

Bombay.—The potato is grown to a small extent on garden lands in all parts of the Presidency. The chief cultivation, however, is in the Poona district, which, according to Mollison, claims 75 per cent. of the total area. The following is the method of cultivation which he says is there pursued:—The soil is mixed black, and the field usually fallowed during the rains. The land is ploughed two or three times between June and September and farm-yard manure, 15 to 20 tons per acre, applied before the third ploughing. The crop is planted in October. Tubers of medium size are selected for sets, and 900 lb. to 1,100 lb. of potatoes furnish sets sufficient to plant an acre. The tubers are each cut into three or four pieces and are planted 7 to 8 inches apart, in furrows 9 to 10 inches distant. The crop must be weeded and irrigation given every eight days. In March the haulms begin to wither and turn brown, and water is now withheld for a fortnight or three weeks. When gathering the crop, the potatoes are exposed by ploughing, first along the rows, then across. According to Mollison, an average crop in Poona tested by himself gave an outturn of 10,230 lb. per acre, worth Rs. 201. The cost of cultivation, estimated for the Surat district, is stated to be Rs. 130–8 per acre, and an average outturn of about 12,000 lb. to be worth Rs. 200 (at wholesale rate of 60 lb. per rupee). [Cf. Crop Exper. Repts.; Repts. Dept. Land Rec. and Agrt.; Exper. Farm Repts. Poona; Mollison, Textbook Ind. Agrt., 1901, iii., 200–6.]

Uses.—It is much to be regretted that no sort of statistical information can be furnished regarding the extent of cultivation of potatoes nor the magnitude of the traffic in these tubers throughout India. As already mentioned, within access of the great markets of the plains it is customary to find large plots of suitable land thrown under the crop, during the season of the year that may be suitable. And on the hills the cultivation is even more extensive, such as on the Khasia and Garo hills, and the Himalaya at Darjeeling, Nepal, Garhwal, Kumaon, Simla, Kangra, Kullu and Kashmir. So also on the tableland and lower hills of the central tracts of India, such as the Nilgiri hills, Bangalore, etc., extensive potato cultivation exists, the produce being largely exported to the plains.

As an article of food, potatoes are now valued by all classes, especially the Hindus on days when forbidden the use of grain. At first potatoes were eaten by the Muhammadans and Europeans only, but for some years past they have got into universal usage, and it is now no uncommon circum-
stance to find cooked potatoes offered for sale at refreshment stalls, in various cold preparations, to be eaten along with so-called sweetmeats that form the midday meal of the city communities. The dried small tubers are also a common adulterant for the more expensive salép. Po-
tatoes are also fairly extensively employed both in the manufacture of starch and in the distillation of alcohol. Ligon (Hist. Barbados, 1657, 31) speaks of the beverage called mobjie being made from potatoes. The knowledge of their possible employment in distillation is thus by no means a recent discovery.

The following are the returns of the wholesale prices per maund (82 lb.) of potatoes in Calcutta during January of the years 1900–6:—1900, Rs. 2;
SORGHUM, *Pers.*; **GRAMINEAE.** A genus of grasses which embraces several useful species, as, for example, the important millet *judr*—a cereal, which, after rice, is perhaps the most valuable single article of food in India. The present brief review of information may therefore commence with a botanical statement of *Sorghum halepense*, the plant from which the cultivated *S. vulgare* (*judr*) is believed to have originated. [Cf. Watt, *Agri. Ledg.*, 1905, No. 6.]

1. **Var. genuina** (*Andropogon millicus*, *Roxb.*). Lisboa mentions *narces* and *bhonda* as vernacular names for this plant.

2. **Var. efusa** (*A. laxus*, *Roxb.* (non Linn.)). According to Roxburgh, this is the plant denoted by the names *kâla-mucha*, *gadi-janu*. He says it grows in hedges, on banks of watercourses and on land lately cultivated.

It is considered a good fodder grass both for grazing and for hay, but is held to have frequently poisonous after-effects, especially if eaten when too young or when stunted by drought. In many parts of India it is believed to be injurious till after the rains. The name *bikkonda*, given to *S. halepense* in certain mountainous countries, may be intended to denote its evil reputation. The grain is often collected and eaten, though the plant seems nowhere to be specially cultivated. Hamilton, for example, speaks of a kind of bread being made from it in Rajmahal, and Tod (*Rajasthan*, ii., 170) mentions the seed being collected, mixed with *bâjra* and eaten by the poorer classes in Bikanir. [Cf. Sly, *Exotic Drought Resisting Plants*, in *Agri. Journ. Ind.*, 1907, ii., pt. ii., 163.]

*S. vulgare*, *Pers.*; *Holcus Sorghum*, *Linn.*, *Sp. Pl.*, 1753, 1047; *Andropogon Sorghum*, *Brot.*; *Holcus Sorghum*, *Roxb.*, *Fl. Ind.*, i., 269; *A. Sorghum*, *Prain, Beng. Plants*, 1204, ii.; *A. Sorghum*, subsp. *sativus*, *Hackel*, in DC., *Monog. Phaner.*, vi., 505; *Fl. Br. Ind.*, vii., 183. The Indian or Great Millet, Guinea Corn, Turkish Millet, etc., *judr* (*jowar*), *jondhala*, *kurbî*, *charî* (stalks), *phag*, *kangra*, *shâlu*, *sundiya*, *cholam*, *talla*, *jonna*, *yengara*, *pâyûng*, etc. A tall, handsome grass, cultivated throughout India since very remote times. Though botanists are agreed that the *judr* is derived from *S. halepense* it has been dispersed by cultivation to latitudes considerably to the north and south of its indigenous habitat. In most countries it is cultivated between latitudes 45° N. and 35° S.—the area of cotton. In India and

1031
Africa it is of greatest value in the upland tracts between latitudes 15° and 30°. In warmer, moister regions, as in Bengal, in large portions of Madras, in Lower Burma, and in Ceylon it hardly ranks as an important cereal, since in these regions the grain ripens but indifferently.

**Names.**

History.—According to Crooke (*Rural and Agri. Gloss.,* 1888, 139; also his edition of Hobson-Jobson, 1903, 468), the word *judr* has been derived from the Sanskrit *yava-parkâra* or *akâra*, which means "of the nature of barley." Dutt (*Mat. Med. Hind.,* 324) mentions *yâvânâla* and *rakta-khurana* as its special Sanskrit names. From *yâvânâla* it would become *javanâla*, *javânâra*, and finally *judr*. The Arabic *dûra* (or, as it is variously written, dhurma, dhaur, douro, etc.) readily becomes *zûra* and has been Sanskritised as *zûrana*, and is thus but a variant of *judr*. It would seem probable that the earliest mention of the name *dura* (*or dorah*) occurs (9th century A.D.) in Avicenna's reference to the people of Zanzibar living very largely on the grain of that name. The Javanese name for it is *djagomutri*. The *cholam* is probably also the *tsojolam* of the Malabar (Rheed, *Hort. Mal.*, xii., 113, t. 60). It certainly is the *battari* of the Malays (Rumphius, *Herb. Amb.*, v., 194, t. 75).

The origin of the name *sorghum* or *Sorgho* might be expected to throw much light on the history of the crop. Rees (*Cyclopædia*, 1819), followed by Paxton, Johnson, and most botanical lexicographers, says it is an Oriental word and stems from the Indian *sorghi*. This is undoubtedly a mistake, since no such name for it exists in any Indian language. Körmiker and Werner (*Handbuch Getreidebaues*, 1885, i., 294–315) seem to think that it came direct from the Arabic *dorah*. The initial letter, on its passing westward, became softened into "th" and ultimately into "s." Sadebeck (*Kulturgew. der Deut. Kolon.*, 1899, 48–52) and many other authors speak of it as the *sirch* of the Southern Tyrol.

John Arduin in his notes on Pliny (ii., 105, n. 23), published 1723, observes that Scalinger (*Excerpt*, 1557, 292, 869) is responsible for the statement that his countrymen, the Italians, called it *surgyum*. Schweinfurt (*Heart of Africa*, 1873, i., 246) says that Petrus de Crescentius, about the year 1290 A.D., is the first author who definitely alludes to *sorgo*. However, in the editions of the *Agricultura*, dated 1471, 1519, and 1553, *melica* (*melica*) and in Italian versions *sagina* occur, but not *sorgo*. Porta (*Vilke, etc.*, 1592, 865), accepting Pliny's statement that this millet came from India to Italy in the time of Nero, observes that it was called by the Italians *saginia, melica, or surga*. He then gives a derivation of the last name from "*surgo*, to rise," in allusion to its towering above all other crops. It would seem that the word *Sorghum*, as it now exists, originated in Europe, and is strictly speaking the name for the warm temperate grain-yielding races of the plant, the forms that correspond with the *rabî jûr* of India presently to be described.

Few, if any, of the European travellers in India, whose writings, as a rule, are so fruitful of historic evidence, make any reference to this grain. Yet we can have little doubt that it was extensively cultivated in India during at least the period of the explorations indicated. In the *Ain-i-Akbari*—the Administration Report of the Emperor Akbar for the year 1590—its price is quoted in a list of autumn grains, and in a further passage (Gladwin, transl., ii., 62) it is remarked that—"Jewary and Bajera are the grains chiefly cultivated in the Subah of Guzerat." So again, speaking of Khandesh (Jarrett, transl., ii., 223), we read—"Jowari is chiefly cultivated, of which, in some places, there are three crops in a year, and its stalk is so delicate and pleasant to the taste that it is regarded in the light of a fruit." It is, however, comparatively little grown on the Malabar coast even to the present day, and was hardly likely, therefore, to have been seen by the traders and travellers who for the most part visited the coast towns. Koernicke, who maintains with De Candolle, that as a cultivated plant it originated in Africa, not India, observes that it probably reached Asia by sea and not by land routes, as was often the case. But that if were so, we might expect to find it most extensively cultivated near the coast, whereas when we first learn definitely about it in India, it is the staple food of the people who occupy the interior and drier tablelands, not the warm, moist regions near the sea. It is, in fact, met with approximately in regions where its presumed wild stock *sorghum halepense* is most plentiful.

We may, therefore, conclude that in all probability the Sanskrit people first learned of this grain in India, but gave themselves very little concern regarding it. Everything, however, points to its having been cultivated in the peninsula
VARIETIES AND RACES

FOOD SUPPLY.

Varieties and Races.—Speaking in a very general sense, there are two great crops of *jüdr*. Of these one is the *kharîf*, which ripens in autumn. The majority of the *kharîf* forms would fall under the botanical varieties *bicolor*, *cornutus*, and *vulgâris* proper. They have usually compact heads, the grains are more or less rounded, and the floral envelopes almost completely glabrous. The second crop is the *râbi*, or that which ripens in spring. It seems likely that most of the races placed in this position would be found to fall under the varieties *hians*, *Rozburgii* and *saccharatus*, and to approximate nearer to *S. hulepense* than do those of the *kharîf* series. They have lax feathery panicles with the grains elongated and the floral envelopes often more or less hairy. As a rule the best kinds are creamy white (the extremity only being darker coloured) and of a pearly lustre. It is customary for the grain to be slightly flattened near the apex, a peculiarity often much increased until in some forms it becomes almost hooked or even indented. The curved grains are generally the most highly prized, for the purpose of being parched. The glumes or envelopes are usually darker than the grains themselves, and may be awned or awnless. In some forms the envelopes (chaff) are coloured and the grain-husk (or seed-coat) white; in others the seed-coat also is uniformly or parti-coloured. Lastly, the floral envelopes may firmly embrace and almost adhere to the seed, while in other conditions the attachment may be so slight that (as in certain barley) the grain may deserve the description of being naked.

Mollison (Textbook Ind. Agri., iii., 10–11) says: “The most noticeable differences between varieties are that *kharîf*, i.e. rain crops or early varieties are much more numerous than *râbi* or late varieties. Early or late varieties do best if sown at their approximate seasons. A *râbi* variety may or may not thrive if sown as a rain crop. None of the rain crop varieties are likely to succeed if sown in the *râbi* season.” In the experiments conducted at the farms in the Bombay Presidency it was established that forms of *jüdr* procured from *gorâdu* (light) soils—for example, those of Kaira and Baroda—could not be cultivated on the black cotton soils of the Deccan. Thus there would seem no doubt centuries of selection and special cultivation have directly adapted this plant into the numerous recognisable races that exist in India.

*Area and Yield.*—From the *Agricultural Statistics*, 1900–1 to 1905–6, this crop is shown as occupying in British India approximately 22 million acres. To these figures we have to add 24 million acres for the Native States, making the total of some 24 million acres for all India and Burma. The chief provinces in order of importance are Bombay, Madras, Berar, the United Provinces, Central Provinces and Panjab. An almost identical
distribution exists in the Native States: *juádr* becomes important on land not inundated. Out of the total mentioned, Gwalior takes usually close on half, that is, a little over one million acres. This is followed by Mysore with about half a million acres, by Kotah State with 350,000, and by Tonk and Jaipur, having about the same acreage between them.

It has been estimated that a yield of 6 maunds (or, say, 500 lb.) an acre might be a safe though probably a low average for the crop. To be rather under than over the mark, therefore, this would come to an annual production of, say, 5 million tons of grain. Mukerji (*Handbook Ind. Agric.*, 1901, 254) says of *juádr*, “It yields a nourishing grain about the same quantity per acre as wheat or rice (900 lbs.) and ten times as much in fuel and fodder as ordinary cereal crops.” Mollison (i.e. 8–9), speaking of the Deccan *kharij juádr*, remarks: “An average crop in the Deccan will vary, according to the quality of soil, from 500 to 900 lb. per acre of *jowár* and 100 to 200 lb. subordinate pulses with 350 to 450 bundles of *kadbi*” (fodder). Referring to the Gujarati *rabí juádr*, Mollison continues: “An acre produces 800 lb. to 1,000 lb. grain and 300 to 400 bundles of *kadbi*; each bundle weighs 4 to 6 lb. The fodder is usually of excellent quality, because the crop stands fairly thick upon the ground and the stalks are neither very tall nor very coarse. A *rabí* crop in other black soil districts yields generally in a fair season 550 to 700 lb. per acre.”

In the *Report of the Experimental Farm at Surat for 1903*, the yield is given as 1,213 lb. grain, by-products 3,974 lb., the value of the outturn Rs. 34–3–1, and the cost of cultivation Rs. 30–14–0 an acre. These returns, as also Mollison’s figures, may be accepted as in accord with the numerous crop experiments that have been performed in Bombay.

### Diseases

#### DISEASES AND PESTS.—The Sorghum crop is exposed to four chief adverse circumstances:—(1) fungal blights; (2) parasitic flowering plants; (3) insects and other animal pests; and (4) climatic disturbances. Massee (*Textbook Plant Diseases*, 216) gives particulars regarding smut. Much advantage might be anticipated from the systematic washing of the seed in hot water (at a temperature of 135° to 150° F.), or in sulphate of copper (½ per cent. solution), before being sown. By this process the crop would be protected against smut and bunt. Of the parasitic flowering plants found on this crop the most curious is the small *Striga* (known in the vernacular as *tastrí* or *talúk*), which sometimes affects frightful havoc. One or two parasitic insects do much damage (such as the sugar-borer and an aphis), but birds and squirrels are by far the most destructive. To safeguard the crop, the owner watches it from sunrise to sunset for some twenty days before the harvest. For this purpose he and his assistants sit on elevated platforms, placed at intervals all over the field, and make discordant noises by beating on old tins, or cast by slings small stones or hardened pellets of mud at the flocks of birds which every now and then again settle on the field. The climatic disturbances may be briefly stated as want of rain at the proper season, excessive humidity and cloudy weather, or unnaturally high temperatures. In a further paragraph, while dealing with the production of this plant as a source of fodder, reference will be made to the evil reputation of the stems for becoming poisonous. This peculiarity is not constant, though it often occurs in an epidemic form such as to justify belief that the germ concerned in the production of the poisonous property is dependent upon accidental climatic or disease conditions. The plant stunted because of deficiency of rain is always a dangerous fodder for cattle. A study of the races of the plant, more critical than hitherto attempted, might therefore be looked to as likely to result in the discovery of forms better suited to certain tracts of country than those at present grown. On this aspect Mollison’s pertinent observation may be given here:—“Some varieties mature much more quickly than others. It is important to know which varieties reach maturity earliest; because after a period of scarcity or famine, varieties which produce grain and fodder in the least time would be most in demand.”
ROTATION AND MIXED CULTIVATION

It may be added that since the above was published in The Agricultural Ledger, Maxwell-Lefroy has given many useful particulars regarding the mothborers found in the Sugar-cane, Maize and Sorghum (Agri. Journ. Ind., i, pt. ii., 97-113; also Mem. Dept. Agri. Ind., 1907, i, No. 2). No one has as yet, however, written a complete account of the diseases and pests of this crop for the whole of India, but Barber (Dept. Land Rec. and Agri. Med. Bull., 1904, ii, No. 49) gives a review of the available information so far as the Southern Presidency is concerned. He there deals with the subjects of Shoot Rotting of the Leaves, West Weather Mould, Reddening of the Leaves, Rust, Mites, Red-spot Disease, Insect and Other Animal Pests, Borers, Plant Lice, Plant Bugs, Weevils in the stored grain, Striga, etc. An interesting account of the fungal disease caused by *Sclerotium graminicola* (also described by Barber, *loc. cit.* 278) is given by Butler (*Mem. Dept. Agri. Ind.*, 1907, ii., No. 1, 13-4). ([Cf. Watt, *Agri. Ledg.*, 1895, No. 20, 285; and Barclay, 375, 379.)

**Rotation.**—The advantage of sowing mixed with the hulless pulse *tur* (*Vigna lenticularis*) turns very largely on the protection afforded from severe droughts and destructive winds. The action of leguminous crops on the soil is, however, valuable, and a mixed crop may on that account serve part of the purpose of a rotation. The rotations most frequently seen are cotton, and *juār* with *tur* mixed; cotton, *juār*, *til*; cotton, *juār*, *anne* hemp (the last often ploughed in as a green manure); or cotton, *juār*, fallow. *Juār* is supposed to participate in the manure and cultivation bestowed on the cotton. Farm experiments have proved the three rotations distinctly preferable. The special value of the use of *til* (*Setaria*) lies in the fact that being a late crop it allows of the land being thoroughly ploughed every third year. Besides the plants mentioned many others are used, but as these may now and again be referred to in the observations below, nothing further need be added to the scheme of rotation just indicated.

**CULTIVATION.**—**Bombay and Sind.**—There are usually 5½ to 8 million acres under this crop in Bombay, and about half to three-quarters of a million in Sind. But this may be more fully exemplified thus:—In 1905-6 the total area in Bombay was 6,570,339 acres, and the chief districts within the area were—Bijāpur, 1,209,066 acres; Sholapur, 1,313,422 acres; Ahmadnagar, 662,918 acres; Poona, 681,413 acres; Satara, 600,097 acres; Belgaum, 583,184 acres; Dharwar, 567,091 acres; Khandesh, 432,638 acres; Nāsil, 74,541 acres; Ahmedabad, 249,881 acres, etc. In the *Season and Crop Report*, published by the Department of Agriculture, the area in 1906-7 is stated to have been 5,643,000 acres in Bombay, and 630,000 acres in Sind. Mention has already been made of the large number of recognisable forms of the plant in this Presidency. Discussing the merits of those grown at the Surat Experimental Farm, the Superintendent, in his Report for 1902-3, speaks of 23 having been found superior grain varieties, and then adds that 269 forms have been under experiment.

Stress may be laid on the relatively greater importance of the *rabi* *juār* crop in Bombay than in the other provinces of India. It follows accordingly that a larger percentage of the Bombay forms of the plant might be looked for as belonging to the group with open feathery pappules and succarine stems. Many valuable reports and special publications have appeared, such as those in connection with the Experimental Farms and the Crop Experiments. Mollison tells us that *juār* is the staple grain crop where black and mixed black soils predominate, provided the rainfall is moderate and well distributed. Where rainfall is excessive, it gives place to rice, and on sandy loams and shallow soils to *bajra*. Mollison then refers his account of this cereal to the sections shown in the following abstract:

(a) The Kharif *Juār* of the Deccan.—The land should be ready for sowing by the end of June. Subsequent sowing are not so satisfactory. The amount of seed to be used depends on a large extent on the kind cultivated. Large-headed forms require more space. But the ordinary rate of seed is 6 to 8 lb. an acre along with
Sorghum Vulgare

Madras

14 to \(2\frac{1}{2}\) subordinate pulses. The seeds are mixed and drill sown, the rows being 14 inches apart. In successful cultivation the crop is hand-weeded as well as hoed once or twice. "The crop will come into flower in August and September and be ready for cutting in October and November." (b) The Kharif Juár of Gujarat.—Usually alternates on black soil with cotton: after removal of the latter, the land is repeatedly harrowed and scarified in April and May, but no ploughing is, as a rule, given since juár likes a firm seed-bed. In June or July the seed is drilled in rows 20 inches apart. When the crop stands 9 inches high, it is again hoed and the plough passed between the rows of seedlings. The principal crop is ready five months after sowing.

(c) The Rabi Juár of Gujarat.—In Broach this form of juár is called skialu. It is drill-sown in September or October, after one ploughing and several harrowings of the soil. The seed is sown at the rate of 7 to 8 lb. an acre. The rows are 20 inches apart, and the seedlings appear in the furrows. The crop is twice intercultured with the bullock hoe. "As the ears begin to fill, the stalks are tied up to each other so that they may not be lodged."

Mysore. Mysore has usually a little over half a million acres, chiefly in Mysore and Chitradurg districts. Of Mysore, the published averages of yield have shown from 453 to 800 lb.

An exhaustive account of Sorghum in Madras has been written by C. Benson, Deputy Director of Agriculture, and C. K. Subba Rao, Sub-Assistant Director of Agriculture (Dept. Agri. Mad. Bull., 1906, No. 55, 58 et seq.). These authors state that the outturn varies within wide limits. "The punasa or early crops of Sorghum give a larger outturn of comparatively poor fodder, but less grain, than the hingári or late crop. The outturn of unirrigated Sorghum varies from 200 to 600 lb. per acre. Under irrigation, the yield on the average is double that amount. The outturn of dry straw from an unirrigated crop on fairly good land is two full cartloads per acre" (l.c. 117–8).

"The chief characteristic of the climate of the principal areas in the Madras Presidency where sorghum is an important field crop, is the lightness of the rainfall. The only exception is that part of Nellore and Guntur adjoining, where the annual rainfall is 30–40 inches. Elsewhere the usual fall is less than 25 inches and in some places as little as 20 only." There are two main seasons for sowing, an early at the beginning and a late towards the end of the southwest monsoon. The early-sown crops are raised chiefly on the lighter soils.

"On the mixed and more loamy soils, the middle season varieties are usually found, and the late-sown crops on the heavy soils." The crop is regarded as an exhausting one, and its growth, year after year, on the same land, is considered bad practice, but is not uncommon. It is stated that "speaking generally, on loamy or sandy soils sorghum, following castor or horsegram, is looked upon as the best rotation, while the ryots will not grow sorghum if they can avoid it after a crop of Italian millet or varagu." Again, "The commonest practice is to sow sorghum mixed with other crops, which vary according to the nature of the soil, the season and the local customs."

"In the Deccan districts green gram and other pulses, gogou and goqu (Hibiscus cannabinus) are mixed in small and irregular quantities with the sorghum seed for an early crop and sown through the drill, while red gram, amamulu (Boeckea Labia), cow gram (Vigna Cujang), and castors are sown in lines amongst the crop."
AN IMPORTANT GRAIN

"In the southern districts, somewhat similar mixtures are made and the whole is sown broadcast, while it is a common practice to sow the red grain in lines at intervals of about six feet apart in the furrow made with a plough" (i.e. 94).

The methods of preparatory tillage, of sowing, and treatment during growth are fully described, but cannot be gone into here.

**Berar and Hyderabad.**—The area under the crop in 1905-6 was 2,660,144 acres in Berar. The average for the five years previously was approximately three million acres. Hyderabad furnishes no returns.

The following information is abstracted from an interesting account by S. Harcourt King (Agri. Bull., 1900, No. 3). While written professedly for Amraoti, F. W. Francis comments that the account is applicable to all the Hyderabad Assigned Districts (Berar). Juār is undoubtedly the most important grain crop of the province—more than one-third of the total cultivated area being devoted to it. There are no less than 43 varieties, 12 of which come under the denomination *sāmi,* or forms which are baked in hot ashes and eaten green, when the grain is tender. Of the other forms, four groups are formed according to their value as sources of bread, viz.:—(1) the yellow *juārs*—the bread made from these is considered best; (2) whitish *juārs*—the bread is hard and wanting in taste; (3) reddish *juārs*—bread is of the same colour as the grain; (4) dirty-coloured *juārs*—seldom utilised for bread, but in making *lādh* (parched grain). Unless the soil is very hard or full of weeds, *juār* lands are ploughed once in four or five years only, and then in April or May. Usually the soil is simply harrowed, generally three times. The crop is rotated with cotton, sesameum, gram, wheat, *lādh* (*Lathyrus sativus*) and tobacco, and is generally grown as a mixed crop, along with certain pulses. Weeding is done three or four times at intervals of a fortnight. *Juār* is never specially watered in Berar apparently, nor is it customary to grow the crop on land systematically irrigated. This is the rule for the grain crop, but when required to make up deficiencies of fodder, thickly sown and irrigated crops are taken. *Juār* requires good rain in August and it comes into ear from three to four months after being sown, and ripens in five months (November to December). In a good season the yield would be 833 lb. to the acre, and, after making all allowances, an estimate of 600 lb. would be a fair average production.

In Hyderabad it is stated that there are two crops of *juār* : the one sown from the 6th June to the 17th July and reaped from the 22nd October to the 30th November. The second crop, known as white *juār,* is sown between the 25th September and the 3rd November and reaped between the 17th February and the 15th March.

**United Provinces.**—In 1905-6 the area in Agra was 2,095,995, and 353,161 acres in Oudh. In Agra the largest areas are:—Jhānsi, 235,237 acres; Hamirpur, 169,946 acres; Cawnpore, 160,903 acres; Matta, 122,021 acres; Aligarh, 106,150 acres; Balandshahr, 102,440 acres; Meerut, 102,334 acres; Agra, 95,002 acres; Farukhabad, 92,894 acres; Budaun, 85,283 acres; Etah, 78,822 acres; Mainpuri, 77,777 acres, etc. No district in Oudh, except Rai-Bareli, has usually over 55,000 acres under the crop. The Season and Crop Report states the area in 1906-7 to have been 2,371,154 acres in Agra, 335,839 in Oudh.

Duthie and Fuller (*Field and Garden Crops*, i., 25) mention three well-marked varieties:—(1) the double-seeded form with two grains within a single husk; (2) a dwarf kind, grown at Allahabad; (3) the variety known as *chākha* in Cawnpore, in which the grain is completely covered by the husk. In the report of the Cawnpore Experimental Farm for 1901-2, mention is made of 90 varieties.
THE GREAT MILLET

C. Prov.

Areas.

Districts.

Central Provinces.

Yield.

being under cultivation. The yield is given at 10 maunds grain for irrigated land and 8 maunds for unirrigated. In the reports of crop experiments, returns ranging from 440 to 820 lb. have been ascertained.

Central Provinces.—The area in 1905–6 was 1,860,714 acres. The largest areas in that year were:—Nagpur, 423,121 acres; Wardha, 282,556 acres; Chanda, 223,130 acres; Nimar, 202,926 acres; Chhindwara, 188,982 acres; Bhandara, 87,637 acres, etc.

Juadr constitutes the chief food of the working class, wheat and rice being alike but little used by them. The white variety is the most highly prized. In certain districts, such as the Upper Godavari and the neighbourhood of Sironcha in Chanda district, a rabbi as well as a kharif crop is obtained. Repeated mention is made (in reports on this plant) of a cold-season form known as ringni. Some writers even speak of this as a hot-weather plant that has recently been successfully grown as a cold-season crop. It is commonly produced in the rice-country of Ramtek and Umrer.

Sir J. B. Fuller published in 1894 A Note on the Outturn of Land under the Chief Crops in the Central Provinces, in which he gives most useful particulars regarding juadr. He points out that the loss through its being grown as a mixed crop with a pulse (mostly tur, p. 190) is very little indeed, so that the pulse is a clear gain. The yield per acre averages from 450 to 960 lb.; 500 lb. has been accepted as the average standard. He further remarks that Nagpur, which has the largest district area, is also the chief importing province and that it draws on Berar. This is due very possibly to the place of juadr being taken by linseed and cotton. In the Settlement Report for Senni (1900, 17), it is observed that a few years ago juadr was of very little importance in that district, but since the last three years it has been greatly extended, and outrun the area under wheat. In recent Annual Reports by the Director of Land Records and Agriculture, interesting particulars will be found of valuable experiments made with a view to improve the quality of the juadr and the cotton grown, as also the methods of cultivation pursued in the districts of Bilaspur and Raipur. Trained ploughmen had been sent from the Government farm, furnished with superior seed and improved ploughs, to prepare and sow certain fields. The result would appear to have been so satisfactory that many indents were subsequently made by the cultivators for a supply of improved seed. Demonstration farms have since been organised where local men, specially trained at the Government farm, would continue to exemplify the advantages of the improvements recommended.

Panjâb and North-West Frontier.—The area in 1905–6 was returned as 694,181 acres in the Panjâb, and 32,593 acres in the North-West Frontier. The largest areas in the Panjâb occurred in Dera Ghazi Khan, 83,754 acres; Ferozpur, 77,701 acres; Multan, 60,429 acres; Gujrat, 52,413 acres; Jhang, 48,910 acres; Shahpur, 38,223 acres; Hissar, 35,014 acres; Karnal, 34,501 acres; Delhi, 28,030 acres; Gurgaon, 24,335 acres; Rohtak, 11,719 acres, etc. In the Season and Crop Report for 1906–7 the area of the Panjâb is stated to have been 1,557,813 acres, of which 1,172,362 were unirrigated. In certain crop experiments performed in the Panjâb in 1892, the yield ranged from 276 to 800 lb. per acre. The areas manifest extreme fluctuations, the unirrigated juadr being chiefly grown in Dera Ghazi Khan, Gujrat, Rawalpindi.

There are said to be many races of the grain, and in most districts it would appear as if special fodder (chari) forms had only recently been systematically cultivated. The Gazetteers afford useful particulars, but it would seem that since the date of Baden-Powell’s Panjâb Products (1868, 236) no publication has discussed the juadr cultivation of the province as a whole.

Bengal and Assam.—Although grown by the hill tribes to a limited extent, juadr cannot be regarded as an important crop in these provinces,
FODDER SUPPLY

not in fact in any rice-producing country. The area under it is in Bengal usually about 150,000 acres. In 1906-7, according to the Season and Crop Report, the area was 143,700 acres, chiefly in the Bhagalpur and Patna Divisions. Eastern Bengal usually has about 5,000 acres, and Assam a purely nominal acreage devoted to the crop. In the Annual Report of the Burmese Experimental Farm (1901-2) particulars are given of experiments with black-seeded and also red-seeded forms as fodder crops. Further experiments with other forms are alluded to by the Director of Agriculture in his Annual Report (1902-3).

Burma.—The crop is important in Upper Burma, where in 1905-6 it occupied 856,437 acres, but in Lower Burma, the rice country, it is very unimportant. The chief districts of Upper Burma are Pakokku, 203,345 acres; Myingyan, 190,635 acres; Lower Chindwin, 133,977 acres; Magwe, 93,851 acres; Meiktila, 92,130 acres; Sagaing, 90,594 acres, etc. Results of crop experiments have shown the yield to vary from 328 to 875 lb. an acre.

Recent Settlement Reports have furnished some useful particulars regarding this crop. Speaking of Myingyan, we read that "the seed was said to have been introduced" after the famine of 1855-7. Blanford reported having seen it in Pegu in 1862. There are two forms recognised—(1) kun-pyaung, grown for human food; it has a round white seed with yellow husk; and (2) kun-pyaung, grown for fodder, but not exclusively so; it has both red and brown grains. Both crops are sown in July and August and gathered in December and January. The stalks, which often run up to 18 feet in height, are given to cattle after being chopped up and mixed with water.

Speaking of the Meiktila district, we read in the Settlement Report that judr is one of the chief upland crops. It is in greater request as an article of food in the western than in the eastern portions of the district, owing primarily to the fact that the scope of the cultivation of paddy is somewhat limited in the former. There are three kinds:—(1) kun-pyaung, has a reddish-brown seed, is not deprived of its husk on being threshed, and gives the highest return; (2) sun-pyaung, gives the lowest return in proportion to the seed sown, since in the process of threshing and winnowing it is entirely cleared from the husk, so that nothing but the little pearly yellowish seeds remain. It has a better appearance than the kun-pyaung, and yields after being milled 11 as compared with 8 from the kun-pyaung; (3) pyaung-net-ri—this is not very extensively cultivated. It has a jet black husk and forms (like kauk-hnyin rice) a glutinous mass when cooked, and is used for cakes and other sweet confections. The judr is sown in August and September and reaped in January and February, being a six months' crop. It grows well in paddy fields provided water is not allowed to stand in them, and when scarcity of water prevails it often takes the place of paddy. The ground is prepared by harrowing the surface at least ten times and the seed is then broadcasted.

FODDER SUPPLY.

Ripe and Green Stems.—The judr crop is not alone of value as a food for man. Its stems constitute the chief cattle fodder (chari) of a large portion of India. The first signs of famine directly induced by the loss of the judr crop are the starvation and death of the cattle. It thus follows that in India it is the ripe stems and leaves (the straw, it might be called) which become the Indian judr fodder. Here and there special races of the plant are grown as a supply of green fodder. Mollison, speaking of the Bombay Presidency, mentions some six indigenous forms of fodder judr:—(1) sundhia—perhaps the best fodder variety; (2) dudhia—this is met with on the light-coloured soils of Kaira and Baroda; (3) nilea—this is the best Deccan (Poona) fodder for the monsoons; (4) utdli is another Deccan form with loose upright heads of grain; (5) hundi and (6) kâlbondi are recommended for cultivation as
irrigated crops and should be sown any time between November and February. Mollison then observes (l.c. 16): "No other crops can compare with the Sorghums in yielding a heavy weight of green fodder of good quality. Succulent fodder of this class is specially valuable in the hot weather for all farm animals, and hundi and kalondi are the most suitable varieties yet found for the purpose."

*Ensilage.*—Mukerji (*Handbook Ind. Agric.*, 255) says that sorghum fodder may be sown "in May, and sowing should continue through June and July, that there may be a succession of fodder crops of first, second, and third cuttings from July to March or April, a portion of which can be dried and preserved for use from April to June. The dried stalks should be stacked and thatched." Mollison describes the manner of preserving sorghum fodder followed in the Southern Marathá country. "The bundles are built into neat oblong heaps in the field. Each heap is built with a slope from the ground to the ridge, and when complete is protected along the sides, ends and top with big lumps of black soil, which are built or packed closely together. These heaps when complete look like large boundary marks. Cattle can freely graze over the stubble, but can get no access to the stored fodder." Voelcker has expressed himself as opposed to the introduction into India of the European methods of siloing sorghum fodder, and the reports published by the Experimental Farms of India are as a rule unfavourable.

*Poisonous Property.*—It has been already observed that the name bikhonda given to the wild *S. halepense* may be intended to denote the well-known poisonous property which that grass sometimes manifests. It may perhaps be accepted as a further proof of the descent of at least the fodder-yielding cultivated forms of *Sorghum vulgare* from that wild plant, when it is added that under certain circumstances the cultivated sorghums also become poisonous. In this connection attention may be invited to the fact that the Hemp Drugs Commission in their *Report* (1893, i., 156), and more recently the Excise Commissioner of the Central Provinces, have made known a new use of the root of the *judr* plant that seems to have escaped the observation of previous writers (see p. 756). It would appear that it is employed to increase the potency of Indian hemp (*bhang* and *ganja*) as well as of country liquor, but is viewed as too powerful to be used by itself. A poison residing in the root is certainly remarkable and worthy of the most careful and searching future inquiry, and it may be added that it is said to occur also in the roots of rice, but so far as *judr* is concerned, is reported as found only in the cold-weather or *ringni* (Central Provinces) and *shidlu* (Bombay) varieties.

The occurrence of this poisonous property is, moreover, often simultaneous over a large tract of country, appearing and disappearing within certain fixed limits of time and locality. It would thus seem that the effect of climatic disturbances in modifying the quantity and quality of the crop has not received the degree of consideration which it demands. Pease (*Agri. Ledg.*, 1896, No. 24, 225) has recorded the death of a large number of cattle at the Sirsa fair, due to their having eaten *judr* stems. The young plant has frequently been found to be poisonous to cattle in Egypt, the West Indies, United States and elsewhere. Dunstan and Henry have examined young sorghum plants from Egypt and India and have shown that these when ground up in contact with water yield prussic acid, and that the prussic acid originates from the interaction of a crystalline glucoside *dhurrin* and the unorganised ferment *emulsia*, both of which occur in the plants and are brought into contact in the manner just indicated. In Egypt the amount of dhurrin, and consequently the quantity of prussic acid obtainable, is at a maximum when the plants are about 12 inches
SORGHUM SUGAR AND SPIRIT

high, after which it gradually disappears as the plant matures (Phil. Trans., 1902, excix, a, 380). Apart from the variation in the amount of prussic acid in tangible, which accompanies the ripening of the plants, variation appears also to be caused by climatic and other influences since sorghum plants at the same stage of growth yield different quantities of prussic acid in different countries. Dunstan and Henry's observations have been confirmed elsewhere in India (Agri. Journ. Ind., 1906, i., pt. iii., 220-6), Brunswick in Queensland, Avery in the United States and other investigators, so that there can be no doubt that the toxicity occasionally exhibited by green sorghum is due to this property of producing prussic acid. Stephenson has recorded that a sample of Indian sorghum examined by him contained considerable quantities of potassium nitrate, and suggested that this might be the cause of the poisonous character of the plant; but apart from the fact that potassium nitrate is not poisonous, the facts recorded above leave no doubt that Stephenson's assumption is erroneous. His observation is, however, of special interest since many of the plants which contain cyanogenetic glucosides of the dhurrin type have been found to contain also notable quantities of potassium nitrate, and Trent has shown that in such plants there is reason to believe that the potassium nitrate is utilised as a source of nitrogen for the synthesis of the characteristic glucosides they contain. [Cf. T. A. Williams, Sorghum as a Forage Crop, in U.S. Bureau of Farm. Bull., 1909, No. 50; Lyon and Hitchcock, Forage Crops, U.S. Bureau of Plant Industr. Bull., 1904, No. 59.]

SUGAR SORGHUM OR IMPHEE.—In Bikanir and Ajmir a form of sugar-yielding Sorghum, designated the Alipura, has been known and cultivated from time immemorial and used in the preparation of the sugar-candy for which these towns are famed. This statement was discussed some years ago in The Indian Agriculturist, but seems to have been contradicted and then forgotten. In 1890 an official inquiry in the Panjab resulted in the report that while in Feropur, Simkol, and elsewhere sweet sorghums were known, the saccharine property was lost after a few years' cultivation in other districts to which these plants had been experimentally conveyed. Of the exotic forms, the amber and the collier seem to have attracted most attention. But according to the Farm Report (1895, 9) there was little to choose between them either in percentage of sugar or value as fodder crops. The weight of molasses per acre was found to be—collier, 1.174 lb., and amber, 1.072 lb. [Cf. Wigley, Note on Sorgho, Rev. Dept. Govt. Ind., 1877; Prod. of Sugar from Sorghum, U.S. Dept. Agri. Bull., 1890, No. 26; Wiley, Exper. with Sorghum, Bull., 1890, No. 29; 1891, No. 34; 1892, No. 37; U.S. Yearbook Agri. Dept., 1897, 80; 1899, 242-3; Exper. Stat. Record, 1890, x., 345; 1900, xi., 141, 319, 883; 1901, xii., 236, 547, 942; 1902, xiii., 42-3, 242; 1903, xiv., 757; U.S. Farmer's Bull., 1899, No. 90, 92; Agri. Gaz., 1891, 134; 1894, 579; Journ. Agri. S. Australia, 1902, v., 876; Rev. des Cult. Colon., 1905, xi., 51; Journ. Soc. Chem. Industr., 1902, xxii., 628.]

Sprit.—Many writers allude to the fact that the Africans manufacture a sort of beer from the grain of sorghum. In 1884 M. Heinrich Brothers of Askia, Ganjam, reported that the juice of sorghum was most valuable to distillers. The spirit prepared is said to have tasted much like rum, but after being opened was liable to throw down a gelatinous-looking substance. Nothing further has been heard on the subject in India, and of the United States of America it has generally been said that changes in the fiscal laws would be necessary before it could be utilised.

TRADE IN JUAR.

It is exceedingly difficult to furnish any very definite statement regarding the traffic in the products derived from Sorghum vulgare in India, for the simple reason that as a rule the official statistics treat of the two millets—juar and bajra—conjointly. It would, however, seem fairly safe to assume that two-thirds of the quantities recorded are in reality juar, the balance being bajra. The estimate of total production given above for juar alone comes to 100 million cwt. of grain. The exports of juar and bajra together during the years 1901-2 to 1905-7 have averaged about 1½ million cwt.; assuming that two-thirds are juar, we learn that the total exports do not exceed 1 per cent. of the production. Juar is, therefore, grown primarily to meet the food necessities of the people.
Sorghum
Vulgate
Trade

THE GREAT MILLET

and not (as in the case of rice in Burma) as a rent-paying article of export.

The quantities of juár and bájra conjointly shown as carried by rail and river average about 4 to 5 million cwt. in normal years. In the year 1899-1900 the traffic became 11 million cwt.; in 1900-1 it stood at 9 million cwt.; in 1901-2 at 8 million cwt.; in 1902-3 it fell to its normal condition of 4\(\frac{1}{2}\) million cwt.; in 1903-4 it was close on 44 million cwt.; in 1904-5 it again rose to 8\(\frac{1}{2}\) million cwt.; in 1905-6, to 9\(\frac{1}{2}\) million cwt.; and in 1906-7 was 7\(\frac{1}{2}\) million cwt. During the years of scarcity and famine (1900-3), Bombay Presidency imported in 1899-1900, 4 million cwt.; in 1900-1, 5 million cwt.; in 1901-2, 3 million cwt.; in 1902-3, 1\(\frac{1}{2}\) million cwt.; while the town of Bombay itself took in addition 2, \(\frac{1}{4}\), \(\frac{1}{2}\), and 1 million cwt. These supplementary supplies were drawn from Madras, the United Provinces, Sind, etc. In 1903-4 the imports into Bombay Presidency fell to less than a quarter of a million cwt., while those into Bombay town stood at 2 million cwt.; in 1904-5 they were about 2 million and 2\(\frac{1}{2}\) million cwt. respectively; in 1905-6, 2\(\frac{1}{4}\) and about 1\(\frac{1}{2}\) million cwt; lastly, in 1906-7 they were 1\(\frac{1}{4}\) million and \(\frac{3}{4}\) million cwt. The traffic with the other provinces and chief towns is hardly worthy of special comment.

Turning now to the records of the coastwise traffic, we obtain a similar indication of the interdependence of the provinces of India for this all-important foodstuff, especially during abnormal years or local climatic disturbances. The returns of imports show that Bombay draws on Sind, Madras and Burma, and exports to Kathiawar and Kach.

Prices.—The official returns (Prices and Wages in India) afford some useful particulars. The mean average price of juár for all India during the years 1871-5 is taken as 100, the standard of comparison of relative prices in the districts and provinces of India, also of accidental disturbances. During the quinquennial period 1896-1900 (which includes a term of scarcity and famine) the mean average for the whole of India was 153.6, and in 1903, when the effect of the famine had been effaced, it stood at 109.23; but if three provinces be removed from consideration, namely Berar, the Panjáb and Sind, the mean average for the whole of the rest of India becomes 100.6. In the three provinces named (except some districts of the Panjáb), juár never seems to have been procurable at the price expressed by the standard of 100. As exhibiting the actual average prices of this millet, it may be here stated that, expressed in seers (= 2 lb.) and decimals of seers obtainable for one rupee (or 1s. 4d.), the returns of Burma in 1906 show 20.07; Bengal, 12.51; Agra, 14.36; Oudh, 14.05; Rajputana, 14.53; Central India, 15.26; Panjáb and North-West Frontier, 16.24; Sind and Baluchistan, 16.4; Bombay, 13.52; Central Provinces, 15.45; Berar, 18.3; Nizam's Territory, 13.8; Madras, 14.24; Mysore, 14.6.

It may thus be said that approximately in districts of chief production, the number of seers obtained per rupee is higher than in localities where the millet is not very largely grown. A similar series of quotations for a number of years would show that railway extension has equalised the price in relation to production. The most significant feature of the internal trade returns is perhaps the circumstance that Bengal practically takes no part in the traffic. Millets are, in fact, very little consumed in Bengal. Another feature may be said to be that the great producing areas export to tracts of country inhabited by simple agricultural communities or to
regions where modern civilisation with its concomitant luxury has not penetrated to any material extent.

The deep red bark contains a gum, said to afford a good mucilage; it also yields a strong red fibre, which is made into ropes in Chota Nagpur. The bark is astringent and has been used as a tan. For long it has been employed medicinally as a substitute for quinine. The most important product of the tree is, however, the wood, which is utilised for almost every purpose. It is much prized for house-building, ornamental furniture and carving. It is commonly formed into pestles and pounders for oil and grain mills. [Cf. Pharmacog. Ind., 1890, i., 330-8; Russell, Monog. Dyeing Induat., C. Prov., 1896, 17; Rept. Cent. Indig. Drugs Comm., 1901, i., 12, 140-7; Agri. Ledg., 1902, No. 1, 19.]

SPIRITS, and Indian Distilling.—Many of the intoxicating liquors sold in India perhaps hardly deserve the name of Spirits. They embrace both fermented and distilled liquors, and can be conveniently grouped as Foreign and Country. To a small extent wines and brandy are produced in Kashmir, but the bulk of the vintage beverages are imported. Beers and ales are brewed in India under the most improved European methods (see Malt Liquors, pp. 757-62), but they are also largely imported; Spirits are distilled both after the most primitive Native and the most advanced European methods, so that country spirits (arak), as well as rum, brandy and whisky can be had all over India—both of foreign and Indian brands.

Dutt (Mat. Med. Hind., 272) observes that the fermented and distilled liquors that cause intoxication are by Indian classic authors called maduya or madîrâ (Sansk.). He then enumerates some 20 forms of spirits which appear to have been recognised as different, such as those distilled from the grape, the date, sugar-cane, rice, barley, wheat and from the flowers of the mahua. Ray (Hindu Method of Manuf. Spirit, Journ. As. Soc. Beng., 1906, ii., No. 4, 129-42) gives a highly instructive and interesting sketch of the Indian knowledge in spirits.

Arak is perhaps the most generally accepted vernacular name for spirits. Mooden Sheriff (Pharmacop. Ind., suppl., 56, 275) gives, among others, the following synonyms:—shardb, Hind.; mad, surap, Beng.; dâru, Guz., Duk.; shârâjam, Tam.; sârdîyi, Tel. and Kan.; aye, Burm. Regarding the name arak, or, as it is often rendered by Europeans, arrack or rack, the observations in Hobson-Jobson (ed. Crooke, 36) may be exhibited briefly:—"This word is the Arabic 'arak, properly "perspiration," and then, first the exudation or sap drawn from the date-palm (arak al-tamar); secondly, any strong drink, "distilled spirit," "essence," etc. But it has spread to very remote corners of Asia." Thus arika, arki, Mongol and Manchuria; râki, Turkish, etc. The word pachâwi (see p. 757) denotes a beverage (beer) made from malted grain, but when distilled this becomes phatika or madîra. In Sanskrit, three kinds are distinguished according to the grain used—surd (rice), kohala (barley), and madhulika (wheat). So also fermented sweet liquors, such as palm-juice (tari) or honey and water or cane-juice, would correspond closely with ale, and when
SPIRITS
History

distilled become the spirit more especially designated arak. In Sanskrit
the spirits or grades of arak from sweet liquors would be sidhu (from sugar-
cane = rum), gaudi or gouri (from treacle), kharjura (from date-juice), and
maddhika (from grapes = brandy). It would thus appear that the English
word alcohol came from the Sanskrit through the Arabic al-kohl, namely
from kohala, which is derived from ku (the earth) and hala (poison).

History.—The knowledge possessed by the Natives of India in spirits of various
types is very widespread, and dates back to the classic periods. Rajendralal
Misra has shown (Journ. As. Soc. Beng., 1873, xlii., pt. i., 1, 58) that spirits and
other intoxicating drinks have been extensively used in India at all times and
by all classes. Rice spirit was both drunk and used in sacrifices during the
earliest Vedic times: the leading characters of the Mahabharata were addicted
to strong drinks; in the Ramayana the use of spirits is mentioned with approbation:
in the time of Kalidas, drinking was common not only among men
but even with women of high rank: the Purnas abound in descriptions of
spirits and of drinking; and lastly the Tantras afford abundant proof of the
attachment on the part of a large section of the Hindus to over-indulge
in spirituous drinks. Manu condemns the use of sura; kohala and jagala are
described in Susruta, a medical treatise of the 5th century. In Buddhist
works, on the other hand, the use of spirits is stringently prohibited, and in
Muhammadan writings, more especially the Koran, it is similarly proscribed,
so that with the orthodox followers of the Prophet the use of strong drinks is dis
expected. But during the time of the Mughals in India, interdiction was the
rule rather than the exception. The Emperor Baber (Memoirs, 258, 354)
takes pains to describe, with minute detail, his drinking parties, and his subsequent
renunciation of the use of wine. The Ain-i-Akbari gives full particulars
of an intoxicating liquor made from sugar-cane, and the still employed in its
production is that often seen in use to-day in the rural parts of India. The
author of the Ain also records the fact that excessive spirit-drinking prevailed
among the grandees at the Court of Akbar. [Cf. D.E.P. vi., pt. iii., 331;
also Sir George Birdwood's account of the strong drinks of India (E.I.C. First
Letter Book, intro. and n., xxii.).]

Coming down to the commencement of European influence in India, Barbosa
speaks of the "suras" of Surat in 1516. Linschoten, in the 16th century,
deplored the fact that the Portuguese soldiers were learning from the Natives
of India the pernicious practice of drinking spirits in place of the wine imported
from their own country. So also Pyrrad (Voy. E. Ind. (ed. Hald. Soc.), i.,
358; ii., 73, 383) and Tavernier (Travels (ed. Ball), 1676, i., 243) mention a spirit
distilled from palm wine which was largely drunk by the people of India at certain
festivals. The latter also gives details of the method of its preparation. Thvenon
(Travels in Lortn, Indostan, etc., 1687, pt. iii., 16), speaking of Surat, says that
spirits were made of jagre and babul bark, also that the Natives of India
certainly did not learn from Europeans the art of distilling spirits nor the
habit of alcoholic indulgence. But there would seem little doubt that the
special use of Punch originated with the Europeans resident in India. That
word is accepted as derived from the Persian panj and the Hindustani panjh,
and means five. It thus denotes the ingredients of a special concoction in favour
with the Europeans, viz. arak, sugar, lime-juice, spice and water. It would thus
appear that the Europeans were not prepared to consume the Native arak un
filtered and invented the above concoction much as the Greeks prepared their
pentaploia (wine, honey, cheese, flour and oil). There is no evidence that the
Natives ever used the special beverage indicated nor employed the word panj in
the sense implied. Thus Mandelslo (1638) calls the Indian special mixture
paolpunze. Hedges (1658) speaks of having often remembered the Company
in a bowl of the clearest punch, while Fryer (1675) actually gives paunck the
tymology of denoting the five ingredients of the special beverage.

Restriction and Legislation.—So far as can be learned, the system of super
vision over the traffic in intoxicants, exercised by the Muhammadan rulers of
India, was that of farming out the right of manufacture and sale to the highest
bidder. The British Administration inherited that system, but soon began to
introduce wholesale reforms. For some years past the policy pursued has been
to tax the traffic to the utmost limit possible, short of originating illicit produc
tion. The aim has been to secure the maximum revenue from the minimum

1044
consumption. Thus out of the uncontrolled farming sprang the direct control of the British system. The first step taken was the limitation of the number of shops in the area farmed. Hence came the outstill system, under which the right to manufacture and sell at a specified shop was granted. But by neither of these measures was any limitation fixed on the duty per gallon—hence it became the interest of the producer to extend his transactions by lowering the price and thus to encourage consumption. This led to the Central Distillery system, in which the manufacture and storage are both under Government supervision, and a still-head duty had to be paid before issue from the cellars. But unfortunately it has not been found possible to enforce this system all over India.

**Revenue.**—The revenue derived from intoxicating beverages appears under "Customs" for imported liquors and under "Excise" for locally produced. The excise revenue on liquors would seem to have been steadily increasing for some years past, due, it is presumed, to two chief causes:—

(a) the increasing prosperity of the lower classes and (b) the more complete supervision of the Excise Administration. This result may be exemplified thus—in 1860-1, the Excise revenue on liquors came to 91 lakhs of rupees (≈£2606,700); in 1870-1, to 156 lakhs; in 1880-1, to 212 lakhs; in 1890-1 to 349 lakhs; in 1900-1 to 427 lakhs; and in 1902-3 to 486 lakhs of rupees (≈£3,240,000). Taking the last year, the following analysis exemplifies the relative importance of the chief kinds:—Revenue from country spirits, 325 lakhs of rupees; palm-juice, 111 lakhs; grain beer, 17 lakhs; country rum, etc., 12 lakhs; malt beer, 4 lakhs; and foreign liquors, 18 lakhs. Since then the revenue has continued to increase till in 1905-6 it reached over 625 lakhs or £4,166,767, made up as follows:—foreign liquors, £378,724; country spirits, £2,914,067; toddy, £873,976 (Moral and Mat. Prog. Ind., 1905-6, 81). It is believed the total revenue for 1906-7 came to £6,510,000, but the increase shown by no means necessarily manifests expansion in consumption: to a much larger extent it denotes more complete control.

**Incidence of Taxation.**—"The average incidence of taxation per proof gallon of distillery spirit amounted in 1902-3 to Rs. 4—6—8, of which Rs. 3—4—6 was derived from still-head duty, and Rs. 1—2—2 from vend fees. Among the larger provinces, the average rate was highest in the Panjáb (Rs. 6—1—0) and in Burma (Rs. 6 plus vend fees), and lowest in the Central Provinces (Rs. 3—8—4). The average consumption per thousand of population in distillery areas varied from 14 gallons in the Panjáb and 10 (roughly) in Burma, to 127 gallons in the Bombay Presidency proper" (Imp. Gaz. 1904, iv., 16). In the year 1900—1 the estimated consumption in gallons, per thousand of population, in distillery tracts, was as follows:—in Bengal, 18; in the United Provinces, 30; in the Panjáb, 11; in Madras, 22; in Bombay, 112; in Sind, 46; in Burma, 10; in Coorg, 162; in Hyderabad Assigned Districts, 65; and in Ajmir-Merwara, 59.

**Materials Used.**—Except in the Madras Presidency, country spirits (including the Panjáb country rum) is the main source of the revenue from intoxicating liquors. "It is usually prepared by distillation from the mahua flower, molasses and other forms of unrefined sugar, fermented palm-juice and rice—the last mainly employed in Bengal, Assam and Burma. Country spirit is prepared by Native methods in Bengal, Assam, the United Provinces, the Central Provinces, Sind, the Frontier Province and Baluchistan. The ingredients are generally fermented in pots and then distilled in rudely constructed stills. The system is very crude and the product apt to contain a considerable percentage of fusel oils. In Madras, Bombay, the Panjáb and Burma, manufacture of country spirit
or of Indo-European spirit (local brands of rum, whisky, etc.) is, as a rule, carried on in highly organised private distilleries with European appliances” (Imp. Gaz., Lc. 14).

The following may be given as a fairly complete enumeration of the materials used (or which may be used) in the distillation of various alcohols, chiefly consumed as intoxicants. The pages (when cited) denote positions in this work where details will be discovered:

- Agave.—The Mexican mescal spirit (p. 35).
- Anacardium occidentale.—The Cashew-nut. A spirit is said to be distilled from this fruit in Goa (pp. 65-6).
- Acanthus sativus.—The Pine-apple (p. 69).
- Anthocephalus Cadamba.—Spirit distilled from the flowers.
- Arenga saccharifera.—The Sago-palm, employed in preparation of Batavian arak (p. 92).

- Bassia latifolia.—The Mahua flowers, perhaps after grain and sugar the most important alcohol-yielding material in India. The spirit distilled from these is called madhu (p. 119). It is discussed by Baber (Memoirs, 1518, 325).
- Borassus flabellifer.—The Palmyra or Toddy Palm (p. 170).
- Caryota urens.—The Indian Sago-palm (pp. 286-7).
- Cocos nucifera.—The Coconuts (p. 361).
- Coffea arabica.—Ripe pulp of coffee-berries (p. 366).
- Colix.—Beer (p. 396).
- Cymbopogon.—Rice and other perfumes (pp. 450-63).
- Eleusine coracana.—The maruva or ragi (pp. 619-21).
- Eugenia Jambolana.—The ripe fruits are distilled in Goa (p. 526); also largely used for vinegar (p. 1109).

- Hordeum vulgare.—Beer. See Malt Liquors (pp. 643, 757). In Spiti a liquor is distilled from the grain called chang (p. 783).
- Malt Liquors (pp. 757-62).
- Mella Azadirachta.—The nim. A fermented liquor is obtained from the sap that is sometimes distilled (p. 780).
- Morus alba.—The Mulberry fruit affords a beverage sometimes distilled in Kashmir (p. 785).

- Oryza sativa.—Rice. This is the chief grain used in the production of pachuaî, and a spirit is often also distilled from specially prepared rice cakes (pp. 826, 840). The spirit from rice and barley cakes, J. C. Ray tells us, is called paihs. The reader desirous of particulars regarding the method of distillation pursued in Bengal, should consult Ray’s instructive paper (Lc. 130-42). The revenue from rice and millet beer amounted, in 1902-3, to about 6 lakhs in Bengal and 11 lakhs in Burma—elsewhere it is inconsiderable.

- Phoenix.—The sap of the Date-palm is largely employed in Bengal in the manufacture of crude sugar, and the fermented toddy is distilled or alcohol is made from the sugar (see p. 886). The sap of the date, palmyra and cocoanut palms (called tari in the north, and toddy, a corruption of tari, in the south) is used as a drink fresh or after fermentation. The total excise revenue derived from these sources in 1902-3 amounted to over one crore of rupees, of which about 72 per cent. was collected in Madras, 12 in Bombay, 10 in Bengal and 5 in Burma. Thavenot (Travels in Levant, Indostan, etc., 1687, pt. iii., 17, 97) makes interesting mention of “tary” vine.

- Saccharum officinarum.—Sugar-cane. Rum is obtained chiefly by the distillation of the uncrystallised portion of the expressed juice (p. 956). Country brands of rum and the so-called brandies and whiskies are distilled from cane-juice, etc., and are coloured and flavoured as desired. Recently, however, some of the European breweries have started to distil whisky (proper) from barley, and this promises to be a profitable new industry. The cane-sugar liquors are produced at private distilleries situated in different part of the country. In the United Provinces and the Panjâb such liquors pay duty at the rate of Rs. 4 per proof gallon, in the Central Provinces at Rs. 5, and elsewhere at the Customs tariff rate of Rs. 6. The most important factory is the Rosa Distillery at Shahjânpur, in the United Provinces, which, in addition to supplying these provinces, exports considerable quantities to the Panjâb, the Central Provinces, Bengal and other parts of India (see p. 956).

- Sorghum.—A spirit is distilled from the grain (p. 1041).

- Vitis vinifera.—The Grape. Brandy is distilled in Kashmir (p. 1114).

1046
Materials Used to Aid the Formation of Alcohol or to Flavour or Strengthen the Beverages.

Acacia leucophloea.—Distillers’ Bark (p. 15).
Cannabis sativa.—Indian Hemp (pp. 258-63).

"Cerevisiae Fermentum."—Yeast. D.E.P., ii., 257-60; see Malt Liquors (p. 758). The special preparation used in Bengal known by the name of bakhar (Ray, i.e. 130, 133) contains a diastase enzyme that possesses the power of converting starch into dextrine and maltose, but Ray adds the caking of the rice is as essential as the addition of bakhar but no caking takes place without bakhar.

Datura.—(p. 488).
Humulus Lupulus.—See Malt Liquors—Hops (p. 759).
Ligustrum Roxburghii.—The bark put into the toddy of curcota in Madras.
Phyllanthus Emblica.—The fruit put into Native spirits (p. 887).
Sorghum vulgare.—Root added to increase the poisonous property of the liquor (see p. 1040).
Strychnos Nux-vomica.—The seeds added to beverages to make them intoxicating (p. 1052).
Terminalia belerica and Chebula.—The fruits used to increase the potency of spirits (p. 1073).
Vateria indica, Linn. (see pp. 1105-6).

TRADE.—Production.—No sort of tabular statement can be furnished that could make any pretensions to completeness in the exemplification of the production and consumption of intoxicating liquors in India. We know that there were 14 registered distilleries in all India during 1901 and that these employed 520 persons, each having at least 25 employees. But there were many smaller distilleries, each employing on an average fewer than the number of persons that justify registration. In 1902 and 1903 the registered distilleries were only 9, and in 1904 only 8, so that there would appear to have been some curtailment.

The quantities of spirits issued from the regularly constituted and registered distilleries is of course ascertainable, but not the amount of other intoxicating liquors issued by the smaller concerns, nor the production that is either authorised or not but which, nevertheless, takes place domestically. In 1903-4 the spirits issued from the distilleries came to 8,439,167 gallons; in 1904-5 to 8,744,302 gallons; and in 1905-6 to 9,288,013 gallons (Rev. Trade Ind., 1905-6, 8).

Foreign Imports.—To contrast with these figures of regular production of spirits, the following particulars regarding the imports from foreign countries of supply may be given:—The returns of foreign trade show that the imports of spirits into India have been steadily increasing. The following are the quantities of imported Spirits of all sorts during the six years 1901 to 1907 :—1901-2, 1,275,525 gallons, valued at Rs. 88,69,374; 1902-3, 1,380,953 gallons, valued at Rs. 95,18,881; 1903-4, 1,409,831 gallons, valued at Rs. 99,15,068; 1904-5, 1,444,207 gallons, valued at Rs. 1,00,59,285; 1905-6, 1,620,492 gallons, valued at Rs. 1,08,78,491; and in 1906-7, 1,489,361 gallons, valued at Rs. 98,69,497. Taking the figure for 1906-7, we find the total was made up thus:—Brandy, 333,957 gallons, valued at Rs. 27,49,931; Gin, 68,575 gallons, valued at Rs. 2,63,877; Likqueur, 12,262 gallons, valued at Rs. 1,53,953; Rum, 66,579 gallons, valued at Rs. 1,09,245; Whisky, 592,514 gallons, valued at Rs. 37,78,813; Spirit used in Drugs, etc., 86,891 gallons, valued at Rs. 15,73,906; Spirit Perfumed, 16,351 gallons, valued at Rs. 6,23,266; Methylated Spirit, 181,369 gallons, valued at Rs. 2,72,998; Other Sorts, 130,863 gallons, valued at Rs. 3,43,508. The shares of the chief countries in the total for 1906-7 were:—United Kingdom, 766,686 gallons; France, 256,472 gallons; Germany, 193,575
SQUILLs
Medicinal Bulbs

INDIAN DISTILLING

gallons; Straits Settlements, 56,218 gallons; Ceylon, 56,665 gallons, etc. The quantities received by the different provinces were:—Bengal, 477,043 gallons; Bombay, 426,343 gallons; Burma, 250,879 gallons; Madras, 199,815 gallons; Sind, 133,832 gallons. A feature of the imports of some interest may be here mentioned, namely arak from Ceylon and the Straits, in direct competition with Indian production. It may also be added that the Indian Amendment Act of 1906, which came into operation on the 26th February, 1906, raised the rates of import duty on ordinary spirits from Rs. 6 to Rs. 7 per imperial gallon, and on liqueurs and perfumed spirits to a rate corresponding with that on ordinary spirits. The Amendment Act was thus intended to place imported spirits on a par with Native spirits in the matter of taxation.

Exports. — The exports of spirits are small and unimportant, and during the five years under review have dwindled almost to nothing. The total exported in 1901–2 was 78,084 gallons, valued at Rs. 1,20,547; in 1902–3, 11,986 gallons, valued at Rs. 12,146; and in 1906–7 only 134 gallons, valued at Rs. 939. In addition, small quantities are also re-exported, amounting to 3,768 gallons, valued at Rs. 32,573 in 1906–7.

Internal Trade.—Unfortunately no comparison can be made with the returns either of production or of imports, since the returns by rail and river are made in cwt. (not gallons), and moreover the spirits are classed along with wines (see p. 1119). But the total transactions in 1906–7 amounted to 189,045 cwt., and the distribution of that quantity can be exemplified. CALCUTTA exported 36,362 cwt. (Eastern Bengal and Assam 10,669 cwt., and Bengal 10,252 cwt.; to United Provinces, 9,636 cwt.). BOMBAY PORT exported 41,528 cwt. (to Bombay Province 18,299 cwt. and to Central Provinces 5,611 cwt.). MADRAS PORTS exported 32,701 cwt. (to Madras Province 23,454 cwt. and to Mysore 7,584 cwt.). MADRAS PRESIDENCY exported 34,617 cwt. (to Madras Ports 16,323 cwt. and to Central Provinces 12,207 cwt.). KARACHI exported 20,467 cwt. (to the Panjáb, 12,582 cwt.). UNITED PROVINCES, 10,567 cwt. (to the Panjáb, 4,740 cwt.).

A further conception of the internal traffic may be learned from a study of the transactions along the coast of India. The total exports of spirits coastwise in 1905–6 amounted to 1,875,882 gallons, valued at Rs. 58,58,808. Almost the whole of this quantity came from Bombay, viz. 1,744,683 gallons in 1905–6, and was consigned chiefly to British ports within the province.

SQUILLS.—Two bulbs are sold as Squills in Indian drug-shops, and more or less used indiscriminately, viz. Scilla and Urginea. The former is frequently regarded as the preferable quality, and is accordingly the one most largely traded in. The bulbs of Scilla are imbricated, those of Urginea are tunicated like the onion.

Scilla indica, Baker; Fl. Br. Ind., vi, 348; Frain, Beng. Plants, 1903, ii, 1974; Cooke, Fl. Pres. Bomb., 1907, ii, 767–8; Liliaceae. The suphadie-khus, bhui-kandá, shiru-nari-vengayam, etc. A small bulbous herb, frequent in sandy places near the sea, in the Deccan peninsula from the Konkan and Nagpur southwards. This fact is mentioned by Fryer (New Acc. E. Ind. and Pers., 1675, 178), who speaks of the squill or sea onions that grow near the sea on the Kârnâtak coast. The bulbs are used in India as a substitute for the true Squill, i.e. Urginea Scilla, which is imported into India from the Mediterranean, and Urginea indica, Kauth—the Indian Squill. It grows wild on the sandy shores near Bombay, but can also be cultivated on light sandy soil. Parker (Rept. Proc. Cent. Indig. Drugs Comm., 1901, i, 39, 152–3) says, "The young small bulbs should
be planted in ridges about 1 or 1½ inches below the surface just before the monsoon, much in the same way as onions are cultivated. The bulbs selected for medical use should be of medium size, neither too young nor too old. In the wild state, other bulbs are found growing with the Scilla indica, and have to be differentiated. Also bulbs collected on the hills are apt to be offered for sale as Scilla indica. The bulbs growing with the Scilla indica are oblong, not so spherical as the latter, and are yellowish in section. The hill bulbs are generally of larger size. The process of preparing the bulb, called killing, consists in cutting it up into fragments and drying; this should be carried out in the cold season. The cutting should be done in the early morning so that the segments may be at once exposed to the sun for some hours, otherwise they blacken." [Cf. Rept. Proc. Gent. Indig. Drugs Comm., i., 152-3, 233-42, 289-91, etc.]

Urginea indica, &c. (Scilla indica, Rouxb.): Pl. Br. Ind., vi., 347; Prain, Beng. Plants, 1903, ii., 1075; Cooke, l.c. 700; Liliaceae. Indian Squill. kaolú, jangli-piyāz, takīl, phaphar, kochinda nari-vengāvase, nakko vull-gadda, adavi-irulli, kāttulli, to-kásu, etc. A bulbous herb found in the drier hills of the Lower Himalaya and on the Salt Range, ascending to about 6,000 feet in altitude. It is a larger plant than the preceding. It is considered an efficient substitute for the genuine squill (Urginea Scilla). But there are several other species of Urginea met with in India, and these are doubtless used in some cases as inferior grades. The most important substitutes or adulterants for the above are Trimmul allotetrum and tattollum; Dipeuict uniclor; Panerium triformum. [Cf. Pharmacog. Ind., iii., 1893, 476-9; Rept. Proc. Cent. Indig. Drugs Comm., i., 1901, 125, 233, etc.]

STEATITE OR TALC.—Ball, Man. Econ. Geol. Ind., iii., 439-45; Mallet, Note on Ind. Steatite, in Rec. Geol. Surv. Ind., 1889, xxii., pt. 2, 59-67; Royle, Further Note on Indian Steatite, 1890, xxiii., pt. 3, 124-30; Hayden, Steatite Mines, Mindu Dist., Burma, 1896, xxix., pt. 4, 71-6; Holland, 1905, xxxii., 115-6. A soft magnesian or talcose mineral commonly called Soapstone from its smooth, soapy feeling. A coarse variety is known as Potstone, on account of its being generally used in making pots, dishes, etc. In the Indian vernaculars it has the following names:—abrik, silkhari, appractum, sang-i-palun, bulpum, etc.

According to Holland, "there is a trade" in this substance "of undetermined value in nearly every province, but it is impossible to form even a rough estimate of its value." Again, he states that "the returns, which are confessedly incomplete, give an average annual production in India of about 35,000 tons, valued at £1,900."

OCCURRENCE.—Steatite is said to be one of the most widely distributed minerals in India, occurring very commonly in metamorphic rocks. The provinces in which good qualities chiefly occur are Madras, the Central Provinces, Rajputana and Burma. The following gives a brief summary of the supplies:

Madras.—The best forms are met with in Betumcherla and near Maddawaram village in the Kurnul district. After that, the soapstones of Anantapur, North Arcot, Bellary, Cuddapah, Salem, Malabar, Vellore, South Kanara districts and Puddukotai State may be mentioned. In 1896 a request was made that a consignment of some 10 tons from Maddawaram village should be furnished for trial as tops for gas-burners. The mineral was collected by local officers, under the superintendence of the Geological Department, and shipped to England. It was found, however, that nearly the whole of the consignment was useless for the purpose contemplated. In 1899 the quantity produced in Madras is stated to have amounted to 103 tons, valued at Rs. 4,900. [Cf. Poole, Rec. Geol. Surv., 1895, xxv., pt. i., 39-5; Mem. Geol. Surv., 1895, xxv., pt. 3, 203; Francis, Dist. Gaz. Mad., Bellary, 1904, 20, 265, 294; Anantapur, 1905, 11, 196.]

Central Provinces.—The marble rocks in the Jabalpur district and Kanheri in the Bhandara district are said to yield excellent stone. According to a report by the Deputy Commissioner of Bhandara, the quarry at Kanheri was leased in 1898 by Government for Rs. 118, the output being approximately 2,000 maunds of stone. "This stone is used for making cups and other vessels, and there are about 10 factories called 'jantar' all in the above village at work for making Cups.

Uses.—There is a large demand for steatite in India, chiefly for the manufacture of bowls, plates, cups, fancy boxes, etc. Many ornamental articles, such as paper-weights, pen-holders, etc., are also made of it. It is largely used in the manufacture of idols, and a special form found at Mysore has, owing to its suitability for this purpose, received the name of pratima kaller, or image stone. Many temples and palaces also contain ornaments of sculptured steatite. Ground to powder it is commonly employed as a white ink, or is added to plaster (e.g. the chunam or lime-plaster of Hyderabad) to make it shine (see p. 714). In Burma, pencils are made of it and used for writing on black-paper slates. In Madras Presidency, Cuddapah soapstone is largely used for polishing chunam walls. Out of India it has come into prominence through the property it possesses as a pigment of protecting steel against corrosion. Mixed with a quick-drying varnish, it produced a paint of great covering capacity and firmness. Owing to its refractory nature, it is largely employed in the manufacture of gas-burners and crucibles. It is reputed to be almost unaffected by atmospheric agencies, and in China is commonly used to preserve structures built of sandstone or other substance liable to disintegrate.

S. foetida, Linn. A large tree known as the fangli-badam, pin, pinârî, burapubadam, letkup, etc. It occurs on the west coast of India, in Martaban and Upper Tenasserim in Burma; often cultivated. It is remarkable for the disagreeable odour of its flowers, which appear in March. It exudes a gum resembling tragacanth, and an oil is extracted from the seeds by boiling in water. Flowers and leaves are used medicinally, and in times of scarcity the seeds are roasted and eaten. [Cf. Andrés, Veg. Fats and Oils, 1897, 169, 218; Woodrow, Gard. in Ind., 1903, 188; Cunningham, Plagues and Pleasures of Life in Beng., 1907, 335.]
ASSAM INDICO

STRECHNOS

S. urens, Roxb. The güńi, kunrai, olla, tabe, sellay güni NgModule, pandruk, etc. A large deciduous tree of the dry forests of Northern India; throughout Central India and the Deccan; common on the west coast in the Konkan and Karnata; as also the dry forests in Burma.

It yields a gum, called katila or katira (see p. 95), which is of the tragacanth or bassora or "insoluble" series, and has been used in the Bombay hospitals as a substitute for tragacanth. Guibourt (Pharm. Journ., 1855, 15, 57) has observed that the gum gives off acetic acid when exposed to moist air, and that consequently it develops an odour of vinegar when kept in closed bottles. The origin of this acetic acid in a similar gum from Australia has been investigated by Robinson (Journ. Chem. Soc., 1906, lxxxiv., 1496). From the bast a good fibre is procured and made by the Natives into ropes and coarse cloth.

The bark is obtained when the trees are over ten years old. The trees are cut down, and after lopping off the branches, the trunk is cut into pieces, six feet long, from which the bark is separated by making a perpendicularly incision." (Ind. Text. Journ., Aug. 22, 1894, 205). Gum, leaves and branches are all employed in Native Medicine, and the seeds are roasted and used by the poorer classes. Gannio (Rec. Bot. Surv. Ind., ii., 177) states that the roots are also edible. "They are first cut into little pieces, then boiled into new vessels, and mixed with either spices or sugar."

The twigs and smaller branches are used as cattle fodder, especially in times of scarcity (Indrajit, in Ind. For., 1900, xxvi., 167). The Wood is made into guitars and toys. [Cf. Pharmacog. Ind., 1893, iii., app., 129-30; Cameron, For. Trees of Mysore, 1894, 32; Agri. Ledg., 1901, No. 9, 346.]

S. villosa, Roxb. The udal, gul-bodha, poshwa, kanhlyem, baringa, buti, omak, yake nar, siset, savaya, lakhwasa, etc. A moderate-sized tree of the Sub-Himalayan tract from the Indus eastwards; common in forests throughout India and Burma. It is valuable on account of its fibre, which is coarse and strong but made into ropes and bags. In Southern India and Burma it is said to be much esteemed for making elephant-ropes, and in Northern India for cattle-halters. [Cf. Agri. Ledg., 1894, No. 12, 202; Cameron, i.e. 32-3; Dodge, Useful Fibre Plants of the World, 1897, 302; Kenz Bull., 1897, 8; Nabet, Burma under Brit. Rule and Before, 1901, i., 371, 384; Hooper, Rept. Labor. Ind. Mus., 1905-6, 35-6.]

STROBLANLTHES FLACCIDIFOLIUS, Nees; Fl. Br. Ind., iv., 468; Bot. Mag., 1887, 6947; Gamble, Man. Ind. Timbs., 519; Acanthaceae. The Rüm or Assam Indigo Plant, rämpdt, bar-rum, khuma, sapro, chimohu, tonham, mai-yee, etc. A shrub of North and East Bengal, Assam, Manipur, and distributed to North Burma and Southern China.

This plant yields the rüm Dye of Assam and is probably the source of much of the so-called indigo of Burma (see Indigofera, p. 663). It is fairly generally cultivated, for the purpose of obtaining the dye, by the hill tribes throughout the region of its distribution. The plant is propagated freely by root cuttings made in May or June or earlier if the rains set in. It yields prunings twice or three times a year, and is perennial. The two chief crops are in April or May and again in September or October. Mr. Srijut Lakhi Nath Kakoti, a sub-Deputy Collector in Assam, has recently contributed an interesting paper on the cultivation of bar-rum. He speaks of one cotta of land yielding 8 to 10 seers of the dye. The Native methods of utilising the dye are fully described in the Dictionary. [Cf. Duncan, Monog. Dyes and Dyeing in Assam, 1896, 48-50; Rec. Bot. Surv. Ind., i., 221, 257; Hosie, Rept. on Prov. Ssu'ch'wan, China, 1904, No. 5, 43-4.]

THE BENZOIN TREE

forests in the Bombay Presidency; deciduous forests all over Burma; dry regions of Ceylon” (Gamble).

The tree is important as being the source of the alkaloids, STYRCHNINE and BRUCINE, which are obtained from the SEEDS. The fruits are collected and the seeds washed out and dried in the sun, or the seeds are simply gathered from the ground, but in the latter case have little market value. They are roundish, flat or concavo-convex and silvery in colour. "Cochin nux-vomica is collected in the dry deciduous forests at the foot of the Travancore hills and is sold to small Native dealers at a low rate, who send it to the merchants. Coconada nux-vomica is obtained from the Ganjam district and the Godaveri. The Madras seeds come from Nellore and several other parts of the Presidency,” (Phar-
macog. Ind., ii., 500). "The London market quotation is usually about 7 to 10 shillings per cwt. The exports are chiefly from Madras, Bombay and Cochin, and are of considerable amount” (Gamble). In addition to the alkaloids just mentioned, they yield a DYE, which produces light brown shades on cotton cloth, and an OIL employed medicinally by Native practitioners. By the hill tribes of the Nilgiris they are used as a fish poison and are employed by Native distillers, who add small quantities to arak to render it more pot (p. 1047). The bark and wood also contain brucine and are employed medicinally in India. The Wood is said to be used in Burma for making girts, agricultural implements and for fancy cabinet work. [Cf. Paulus Agineta (Adams, transl. and Comment.), 1847, iii., 368–60, 461–2; Fryer, New. Acc. E. Ind. and Pers., 1675, 178; Faber, Strychnomania, 1677; Milburn, Or. Benzoin.

STYRAX BENZOIN, Dryand; Fl. Br. Ind., iii., 589; Gamble, Man. Man. Ind. Timbs., 1902, 466; Brandis, Ind. Trees, 1906, 442; STYRACEÆ. The Benzoin Tree. The Resin = luban (Ind. bazâr), hussi, shambirdin, kaminian, etc. A small tree of the Malay Archipelago, important as yielding the true Benzoin or Gum Benjamin of commerce.

This substance appears to have been first mentioned by Ibn Batuta (Voy., etc., Fr. ed. 1858, iv., 228, 240), who visited Sumatra (A.D. 1325–49). He calls it Luban-Javi (= incense of Java), the name Java being used among the Arabs and Persians of that time for the Eastern Archipelago. According to the Pharmacographia Indica (iii., app., 169) there are four kinds of the resin met with in the London market, viz.:—Siam, Sumatra, Penang and Palembang. It is well known that the present species is the source of the Sumatra resin, but there is considerable doubt regarding the plants which yield the other three sorts. The Siam resin is the costliest and most esteemed, and is imported by India in cubic blocks which take their shape from the cases in which packed while still soft. The resin is largely used both in India and Europe in Medicine, as an INCENSE and as a source of benzole acid. The import trade is considerable, amounting in 1905–6 to 16,090 cwt., valued at Rs. 4,14,643. Almost the whole comes from the Straits Settlements, viz., in 1905–6, 16,074 cwt., and goes chiefly to Bombay, 9,177 cwt. in the year named. Exports of the resin in 1905–6 amounted to 52 cwt., and re-exports to 1,394 cwt. [Cf. Varthéna, Travels, 1510 (ed. Hakl. Soc.), 1863, 224; Garcia de Orta, 1563, Coll., ix.; also in Ball, Proc. Roy. Ir. Acad., 1889–91, i., ser. 3, 394; Ain-i-Akbari (Blochmann, transl.), 82; Foster, E.J.C. Letters, 1602–17 (numerous passages); Milburn, Or. Comm., 1813, ii., 305–6; Pharmacog. Ind., ii., 369–73; iii., 169–73, app.; Kew Bull., 1895, 154–5; 1896, 158–5; Greshoff, Nutt. Ind. Plant., in Extr. Bull., Kolon. Mus. Amsterdam, 1894, 115–9; Thorpe, Dict. Appl. Chem., 1898, i., 278–9; Hobson-Jobson (ed. Cooke), 1903, 86–7; Tschirch, Die Harze und die Harzbehälter, 1906, i., 195–212.]

1052
SWERTIA CHIRATA, Han.; Fl. Br. Ind., iv., 124; Gentianaceae. The Chireta, charayutak, chir réta, nila-véppa, shirat-kush-chi, nila vén, nelabevu, sekhági, etc. A small erect herb of the temperate Himalaya from Kashmir to Bhotan at 4,000 to 10,000 feet; also the Khasia mountains between 4,000 and 5,000 feet.

The dried plant (stems, leaves, flowers, roots, etc.) has long been held in esteem by the Natives of India. It is possessed of tonic, febrifuge and laxative properties and is official in the British Pharmacopoeia. It is collected when the capsules are fully formed. The plants, pulled up by the root, are tied into flat bundles with a slip of bamboo. Most of the commercial article is said to be collected in the Morung district of Nepal, and seems to find its way largely to Dacca. The bundles are packed in bales, each containing about 1 cwt., and exported to Calcutta, thence distributed all over India and to the rest of the world. In India the true drug is said to be sometimes confused with the Creat (Autographis paniculata, Nees), and in some localities another species, S. augustifolia, very inferior to the genuine article in its bitter tonic properties, is used as a substitute. [Cf. Pharmacop. Ind., ii., 511-5; Waring, Bz. Med. Ind., 1897, 45-6; Dutt, Mat. Med. Hind., 1900, 200-1; White and Humphrey, Pharmacop., 1904, 127; Burkill, in Journ. As. Soc. Beng., 1906, ii., No. 8, 363-81.]

SYMPLOCOS RACEMOSA, Roxb.; Fl. Br., Ind., iii., 576; Gamble, Man. Ind. Timbs., 465-6; Prain, Beng. Plants, 1903, i., 655; Styraceae. The Lode or Lodh Tree, lodh, khoidai, singen, kavting, bhom reti, lapóngdong, chamlani, palyok, kura, luddiga, māryana, etc. A small tree of the "Sub-Himalayan tract from Kumaon to Assam, up to 2,500 feet or even higher; open and dry forests of Burma up to 3,000 feet, including the Shan hills; Andaman Islands; Chota Nagpur, common" (Gamble).

The bark and leaves are used in DYEING. By itself the bark yields a yellow dye obtained by simple steeping in hot water. It is, however, rarely employed in that way, but more generally as a mordant with other dyes, such as al (Morinda tinctoria, p. 783), hac or bakam (Cassia fistula or Sappan, p. 195), and para (Butea frondosa, p. 189). The bark is also largely utilised in Hindu Medicine. The Wood is durable if properly seasoned, though apt to warp and split. [Cf. The Bower Manuscript (Hoernle, transl.), 1893-7, 23, 117; Monographs, Dyes and Dyeing.—Duncan, Assam, 1896, 50; Hadi, U. Prov., 1896, 82; Russell, C. Prov., 1896, 18; Dutt, Mat. Med. Hind., 1900, 189; Walton, Tanning and Working in Leather, U. Prov., 1903, 25.]

TACHARDIA (CERTERIA) LACCA, Kerr.—an insect belonging to the Coccidæ. Green, Coccidea of Ceylon, 3; also Ind. Mus. Notes, 1903, v., 99; O'Conor, Lac Prod., Manuf. and Trade, 1876; Watt, Agr. Ledg., 1901, No. 9, 181-347; Pharm. Journ., Nov. 1905; Tschirsch, Die Harze und die Harzbehölter, 1906, ii., 812-30. Lac (Dye and Resin, lák̄h̆, lák̄, gála, arakkou, ambalu, khejijk, etc. Lákshá or rákhshā and alaktā (= washed lac), the Sanskrit names, are apparently the source of most of the vernacular names for both the insect and its products. Thus stick-lac is khām-lák̄h̆; seed-lac, dāndá-lák̄h̆; shell-lac (or shellac), chapra-lák̄h̆, and lac-dye, kirnmāi.

History. There can be no doubt as to the lac insect and its name being endemic in India. The insect is even to-day practically confined to India. But the word lákshā in the Atharvaveda seems to denote Butea frondosa (p. 189), a tree upon which it is not uncommon to find the lac insect, and which by the more recent Sanskrit writers has come to be described as the lákshā-taru or lac-tree. The
TACHARDIA

LACCA

History

Close Connection with India.

Vedic description—the golden, the odorous, the hairy one, sister of the waters, etc.—might easily be viewed as appellations of *lākṣaḥ* (*Butea frondosa*) and indicative of its appearance, structure and habitat—frequenting as it does the margins of water-channels and creeks. But a vast antiquity being thus established for the Indian knowledge of *lākṣ*, it is surprising that it finds no definite place in the ancient classic literature of Greece, Rome, Egypt, Persia and Africa. All the passages which, according to some dictionaries, are taken to denote a knowledge in lac, refer to a red-dye-yielding wood, or to *kermes* or to a resin at present unknown, but do not denote Indian lac. That substance was made known to Europe through the Arab traders, hence its being often called "Arabian" or "Ethiopian Resin." If it was known to the ancient Greeks, their knowledge of it could not have much preceded the date of their discovery of India itself.

Dye and Resin.

Lac yields two distinct products—a DYE and a RESIN. At first these were confused, but ultimately clearly and separately recognised. In the *Periplus* (written somewhere about 80 A.D.) "lakkos chronatinos" or lac-dye is mentioned as conveyed from India to Adulis on the African coast of the Red Sea. *Aelian* (*Nat. Hist. Anim.*, 250 A.D., iv., 46) describes lac as made in India from insects and employed as a red dye. Pegolotti (*Della Decima*, 1343, iii., 365) speaks of "laccia" as Indian, produced on branches of trees. Nicolo Conti and also Nikitin (in the 15th century) mention, as if an important commercial product, the "laca" of Cambay. Varthémna (*Travels*, 1510 (ed. Hakl. Soc.), 222, 238) discusses the "laccia" of Pegu, also the "lacca" wood of the Malay. The former is the true lac, the latter a red-coloured wood exported from Sumatra (Crawford, *Dict. Ind. Islands*, 1856, 204). Garcia de Orta was perhaps the first European, however, who critically examined and described lac in India, and he gives the properties and uses of both the dye and the resin in such detail that the passage might be quoted as from the pen of a 20th instead of 16th century writer. As physician to the Portuguese Governor of India, he visited that country in 1534. His volume of *Colloques* was published at Goa in 1563 and was the second book printed in India.

European Travellers.

He there (Coll., xxix ; also in Ball, *Proc. Roy. Ir. Acad.*, 3rd ser., i., 414) criticises the accounts given by Isaac (a physician of Bagdad, who was crucified in 799 A.D.), by Serapion (who lived about 850), and by Avicenna (whose works are assigned to 980-1036). These early Arab writers, Garcia tells us, called it "laca," "lacu," etc., but confused it with the *cancamum* (the resin known to the Greeks to which reference is made below) and ultimately with the dye *kermes* of the Greeks. They were in error, he observes, in regarding it as an Arabian or Armenian product—a circumstance which Garcia very rightly accounts for by the Indian supply on reaching the Red Sea and Persian Gulf ports being subsequently designated by the name of the port from which procured. Many writers confused a red-dye wood, such as logwood or sappan-wood, with lac, and one of these red-dye woods, as just mentioned, actually bears the Malay name of *laka*. Gaspard (*Purchas* *Pilgrimes*, iii., 177) alludes apparently to the same wood under the name *cayolagne* (1 kes [lac] and *lak*). If this be so it is possible it was so named because employed as a substitute for the true lac-dye. "Lac" and "lacquer" wood and dye are words frequently mentioned, when there is nothing to show that they denoted Indian lac—resin or dye—as understood to-day. Every passage that contains the word "lac" cannot therefore be accepted as of necessity denoting the *lak* of modern Indian commerce.

Linschoten and most European travellers in India, subsequent to Varthémna and Garcia, content themselves with compiling from the latter, without adding anything of value as the result of personal observation. Some few years previous to the appearance of Garcia’s *Colloques*, however, an interesting passage on lac had been published by Amatus Lusitanus (1553) in his *Commentary on Dioscorides* (book i., ch. 23, 44), the passage regarding *cancamum*. Amatus there repudiates all idea of lac being the classic gum of the Greeks, whatever that may have been. He then adds that lac was being brought from India by the Spaniards to be used as a dye and also in the fabrication of the Arabian medicinal preparation known as *ditacca*. We next hear of lac through Masilius (1565), who in his commentary on the *cancamum* of Dioscorides, tells us that lac was being largely used by the Italians as a silk dye called *laccas* or *lachetta*, the best quality of which was in the trade designated *laccas sumetri*. By Clusius (1567-1605, compiling largely from Acosta (*Tract. de las Drogas*, 1578, 113) and other subsequent writers, we are told that it had become customary for lac to be consigned from Pegu to Sumatra in exchange for pepper, hence its being designated Sumatran Lac.

1054
LAC MIXED WITH RESIN

To this circumstance is due also the fact of its being often mentioned in lists of spices in place of among dyes or resins. Acosta supplemented, however, Garcia de Orta’s account by the interesting particular that the resin lac was mixed with, or, as he calls it, adulterated with, common resin and wax. Thus then the adulteration in recent years, often much complained of by the trade, is not a product of the greed of modern commerce. Mandelslo (Travels, in Olearius, Hist. Muscova, etc., 1639, 27), speaking of the lacquer work of Gujrat, says, “They give them such a lustre as none yet could ever imitate in Europe.” Tavernier (Travels Ind., 1676 (ed. Bell), ii., 281–2) observes that—“The country also produces an abundance of shell-lac. There are two kinds of it. That which is formed on trees is of a red colour and is what they dye their calicoes and other stuffs with, and when they have extracted this red colour they use the lac to lacquer cabinets and other objects of that kind, and to make Spanish wax. A large quantity of it is exported to China and Japan.” Thvenot (Travels in Levant, Indostan, etc., 1687, pt. iii., 112) repeats the statement that lac was exported from Pegu. Lastly, Salmasius (Plinius Exercitationes, 1689, 810) asserted that the very name “lao” had been derived from the Greek and originally denoted a red wood. He arrived at that conclusion chiefly through his own supposition that the Indian name for the substance was trec, not laih. Trec is doubtless a variant of the Pegu name chekkt, and, as already abundantly indicated, was carried to Europe through the Spanish trade between Burma and Sumatra.

While knowledge of lac was thus being gradually disseminated over Europe, there are not wanting indications that within India itself the subject was not being neglected. Thus in the Ain-i-Akbari (Blochmann, trans., 220), a work often spoken of as the administration report of the Emperor Akbar for the year 1590, we read of the proportions of lac resin and certain pigments to be employed in varnishing chikes or screens on the doors of public buildings. It would from that circumstance seem highly probable that a coloured spirit varnish may have been known and used in India long before Europe possessed any knowledge of that valuable substance. Fryer (New Acc. E. Ind. and Pers., 1672–81, 83) also alludes to elegantly coloured chikes, but it may be added the modern chikes are crudely stained with mineral dyes, never with lac varnish.

The period of the struggle for European supremacy in the East was practically that of the birth of all definite knowledge in lac. But the scenes and the persons change rapidly and the interest shifts from the dye to the resin, back again to the dye, and finally once more to the resin. From the Portuguese on the west coast of India the trade passed to the Spanish and Burma via Sumatra, while a little later on (and in the hands of the British) it returned once more to Bombay. In the Records of the East India Company (First Letter Book, 1600–19, 338, etc.) we are given certain glimpses of the Company’s instructions to their servants. “Gum lac” was to be obtained from Cambay. “Gum lack” of first and second sort was to be procured at Surat, “but none of the worst of any hande.” Private trade in gum-lac was prohibited. So again, of date 1616, “much gum-lac, both of the sort used for dyeing and also that of which wax is made” was to be purchased in Surat. The following year the “lack” of Baroda is said to be in “grains like mastic pure as amber.” Of Agra it is observed there are two kinds: “The one is in small sticks usually carried hence to Mocha: the other is in great cakes. They both cost one price, viz., 8 rupees per maund.” The amber-cooured grains of Baroda were doubtless “washed seed lac,” and the great cakes of Agra would imply manufacture. Is the canna (kana = grain) lacce mentioned in 1623 as purchased at Baroda simply washed lac? But in these early records of the East India Company there is apparently no mention of shell-lac nor of some of the chief centres of the present manufacture, but as Mirzapore and Calcutta—but of course the town of Calcutta was not in existence at the time indicated. The fact remains the same that the early records manifest localities of production that are quite unimportant compared with other more recent centres.

The demand for cochineal served the useful purpose of pointedly directing attention to the lac-dye. This, though inferior, was found quite good enough for most of the purposes to which cochineal was put, and had the additional advantage of being considerably cheaper. A large trade in lac-dye accordingly sprang into existence that gave the impetus for numerous lac factories owned directly or indirectly by the East India Company. At this time was invented (and by Europeans doubtless) the method of manufacturing lac-dye into special cakes ready for use. Such importance did this new industry assume that it crowded
the gum-lac of the earlier commerce until it might almost be said that the resin (lac) became a by-product of the lac-dye factory. To this circumstance is due the fact that the methods of cultivation, of collection and of manufacture, that exist to the present day, were invented and perfected with a view to produce the dye, one might almost say, at the expense of the resin. The dye gave the profits of the industry. But Sir W. H. Perkin's discovery of aniline struck at once the death-blow of both the Mexican cochineal and the Indian lac-dye industries.

By this time, however, new methods and directions of using the resin lac had been discovered in Europe, and the interest of the factory shifted until the dye became first the by-product and ultimately the useless or waste material of the factory. Here then we are presented with a demonstration of the startling fact that a by-product that can be produced at an almost nominal cost cannot of necessity contest the market against the products of the chemical laboratory. Attention was thus concentrated on the resin, and it soon became the chief feature of interest. James Kerr (Phil. Trans., 1781, lxxi., 374) was one of the first to mention and describe the manufacture of shell-lac. From about that date, therefore, the modern factory industry may be assumed to have originated. In the story of lac we have once more a demonstration of the indebtedness of India to England for her modern commerce.

**ORIGIN OF LAC.**

Life-history of the Insect.—The minute Hemipterous insect *Tachardia lacca* lives upon the plant juices sucked up by a proboscis. In the adult state the females have no power of locomotion, but the males on attaining maturity emerge from their pupal cases, become possessed of a pair of long transparent wings, and fly away to visit the females and shortly after die. At two (in some cases three) seasons the swarming of the larve takes place, viz. July and December or also January. The larve are seen to emerge from the dead bodies of the females and to crawl away in quest of fresh feeding grounds. They are then minute creatures of an orange-red colour, have no recognisable separation of body into head, thorax and abdomen, have fully formed feelers and powerful legs, but are devoid of any characteristics by which they can be separated into male and female. They measure about one-fortieth of an inch in size. For some days the swarming continues until the twigs become distinctly reddish in colour and literally alive. The vast majority, however, perish; the more fortunate are wafted on the breezes or are carried by the bees, birds, squirrels, etc., or by their own exertions, to new situations. The larve thus becomes fixed, and their legs, being useless, drop off. Lastly, a resinous excretion begins to form around their bodies, which by the aggregation of many in time assumes the condition of a more or less complete encrustation of the twigs. If at this stage the encrustation be cut open lengthwise, it will be seen to be of a cellular structure and to comprise two kinds of cells—large circular caverns and smaller oval cells. The former will, moreover, be noted to be much more numerous than the latter. The circular cells are the females and the oval ones the males.

About two and a half months after the swarming, the males escape from their cells, become (as already stated) winged, and fly or flutter away to visit the females. Shortly after this the bodies of the females become greatly enlarged, assume a bright red colour, and in due course develop viviparous larve. The mother then dies, her body becomes the resting chamber of her offspring (about 1,000 in number), which at their appointed time make their escape by swarming, and thus twice (or it may be thrice) a year this strange cycle of life is repeated.

**PRODUCTION OF LAC.**—The system of propagation that at present prevails consists in lopping off a few twigs of well-formed lac, a little before the expected date of swarming. These are carried to fresh trees or fresh
FOOD PLANTS

boughs of the same tree and tied in convenient and suitable positions. The larvae on swarming crawl to new wood and become fixed. If the object in the collection of lac be to procure the red dye, the stick-lac (that is, the lac-encrusted twigs) should be gathered before the larvae have swarmed. But if the resin-lac be sought, there would seem every reason to delay collection until the swarming has taken place. The industry assumed its present form while lac-dye (if not equally valuable with the resin) was a profitable by-product. It is now valueless; its presence admittedly depreciates the shell-lac very greatly; it necessitates expensive and possibly to the resin injurious methods of removal; and the decomposition of the larvae gives the offensive smell to the factory, which well-nigh becomes a public nuisance. It would therefore seem that the time has more than come when this state of affairs might be mitigated by some change in the season of collection, that would allow of the colour being very largely removed before the stick-lac comes to the factory. The collecting seasons at present adopted are May to June for the one brood and October to November for the other; a delay of a month or six weeks in each case would see the swarming accomplished. [Cf. with opinion of Hooper, Rept. Labor. Ind. Mus., 1906-7, 7.]

Improvement in Quality.—There would seem to be little or no doubt that in India there is not one species of Tachardia, but several. The well-known different qualities of lac are due, it has been said, to the plants on which the insects feed. This is, however, likely to receive an even more rational explanation, viz. that the grades of lac are due to being the resins of different species of insect. It is also well known that the forms of lac found on leguminous plants (or on soft-wooded plants), such as Butea frondosa and Cajanus indicus, can with difficulty be induced to live upon hard-wooded trees, such as Schleichera trijuga and Shorea robusta, upon which lac is nevertheless found. But there is still a further consideration of importance. It has been observed that there are special cultivated races, such as those found on Acacia arabica. In Sind and adjacent tracts that plant is used as a food-stock, but hardly anywhere else is lac to be seen on that tree. We have here either a special race or a remarkable climatic adaptation. Further, all over India albino-broods have been recorded as occasionally seen. It would thus appear that were the selection of stock placed on a rational and scientific basis vast improvements in quality might be effected, if it were not possible actually to evolve a white insect or at all events one to a large extent devoid of the objectionable colour, the removal of which so seriously enhances the cost of the present-day resin.

Food of the Lac Insect.—The insect lives upon a large number of widely different plants. In The Agricultural Ledger (i.e., 210-3) I have given a list of some 56 trees. Those best known are Butea frondosa, Ficus religiosa, Schleichera trijuga, Shorea robusta and Zizyphus Jujuba. These are all indigenous Indian trees, so that the lac obtained from them may be called wild lac (the insect being at most semi-domesticated); but two plants are specially grown for it, and where this is the case, the lac may be regarded as a plantation product and accordingly spoken of as existing under a greater degree of cultivation than the wild insect. The plants specially grown are Acacia arabica in Sind, Rajputana and Gujarat; and Cajanus indicus in Assam. But lac does not, in many localities at least, pay as a special plantation product. The
crop is most capricious both in yield and price. One year it may be highly profitable, the very next sold on so narrow a margin that no inducement exists for extension. In support of this statement, witness the fact that in 1902–3 the exports of shell-lac were 195,000 cwt., valued at 15\(\frac{1}{2}\) million rupees (£1,048,991), while next year, 1903–4, they were only 178,000 cwt. but were valued at over 21 million rupees (£1,456,067). That is to say, while there were 17,290 cwt. less exported, the sum realised was nearly half a million pounds sterling more in 1903–4 than in 1902–3. And the fluctuation might just as likely have been toward a loss as a gain of half a million in the sum realised. No other item of Indian trade manifests anything like such extreme fluctuations in price as lac, and it can, therefore, be no matter for surprise that the supply should correspondingly fluctuate.

**LOCALITIES OF SUPPLY AND COST OF PRODUCTION.**—Lac is met with practically throughout the warm tropical areas of the whole of India, but most abundantly in the Central Provinces, Bengal, Assam and Burma. In Sind and Gujarat, as already stated, the *babul* tree (*Acacia arabica*) may be said to be that on which it is met with most abundantly. In Bengal, where both the *babul* tree and the lac insect are plentiful, it is extremely rare to find lac on that tree. But, as already suggested, the question naturally arises, is the *babul*-feeding insect of Sind the same species as the *palas*-feeding one of Bengal and the Central Provinces? The climates and soils of Sind and Bengal are about as different as it is possible to imagine, although both are tropical. The one is extremely dry, the other extremely moist, and that alone may account for the behaviour of the insect.

**Cost of Production.**—Mukerji (*Handbook Ind. Agri.*, 1901, 496) gives the following calculation of expenditure based on an actual experiment conducted by an Assam planter:

<table>
<thead>
<tr>
<th>Item</th>
<th>Cost</th>
</tr>
</thead>
<tbody>
<tr>
<td>Rent at Rs. 3 per acre for 80 acres</td>
<td>Rs. 240</td>
</tr>
<tr>
<td>Hoeing or cutting jungle between trees</td>
<td>Rs. 320</td>
</tr>
<tr>
<td>Upkeep of necessary buildings</td>
<td>Rs. 100</td>
</tr>
<tr>
<td>Cutting branches and putting in seed</td>
<td>Rs. 340</td>
</tr>
</tbody>
</table>

**Total**

Rs. 1,000

Manufacturing charges at 5 per cent.

Rs. 3,500

Packing and dispatching at 2\(\frac{1}{2}\) per cent.

Rs. 1,750

Calcutta charges for forwarding and river freight, at 2\(\frac{1}{2}\) per cent.

Rs. 1,750

London charges for sea freight, Dock and Broker’s charges

Rs. 3,000

**Total**

Rs. 11,000

Proceeds of Sales, £1,750 at 14d.

£26,250

Deduct discount to buyers

£656

**Total**

£25,594

Deduct Expenditure

£11,000

Balance of profit

£14,594

"Lac worked in connection with tea, etc., the amounts for European and Native supervision and upkeep of coolie lines, etc., may be added proportionately according to circumstances. The planter referred to, however, lost nearly his whole crop next year from the attacks of a night moth."
Bengal.—According to the Administration Report (1901-2, 31), “it is found over the large tract of hilly country covering the Chota Nagpur Division and overlapping the west of the Bardwan and the north of the Orissa Divisions. The principal lac factories are in the districts of Ranchi and Manbhum in the Chota Nagpur Division, and in the Bankura and Birbhum districts in the Bardwan Division. Stick and shell-lac are largely exported from Ranchi, Manbhum and Bankura.” It is also stated that “the manufacture of shell-lac is an important industry in the Bankura district, and is chiefly carried on in the town of Sonamuki. The main supply of this article for all the factories in Bankura is obtained from the districts of the Chota Nagpur Division. The industry is carried on to a large extent at Elambazar, in Birbhum. Shell-lac and lac-dye are also manufactured at Mankur and Degnuggur in Bardwan; but the industry is on the decline here also. There is a lac factory at Cossipore in the suburbs of Calcutta.”

Assam.—In 1900, Basu (Agri. Dept. Indus. Bull. (ser. 1), 1900, No. 6) wrote an account of the lac industry of Assam, from which the following may be abstracted. “Kamrup and the northern part of the Khasia and the Garo hills bordering on the Brahmaputra valley are at present the chief seats of its cultivation. In Kamrup lac-rearing is chiefly confined to the south bank of the Brahmaputra, the annual outturn of stick-lac in two mauzas (Rani and Chhayani) being estimated at about 2,000 maunds. A small quantity is reared by a few Kachari families in mauza Jhargaon on the north bank. The bulk of lac exported from the district is, however, obtained from Garos inhabiting the northern slopes of the Khasia hills, who are said annually to bring in about 2,000 maunds of lac to the weekly markets at Palasbari and Chhaygaon and about 300 maunds to the markets at Boko. A small quantity of lac, averaging about 400 maunds a year, is brought in by Bhtias to the annual cold-weather fairs at Darranga and Subankhata in the north of the district.”

“In the Garo hills lac-rearing is chiefly confined to the north and north-eastern parts of the district, comprised in the northern range of the Garo hills Forest Division. The people of the south and south-western parts are said to have a superstition against lac cultivation. The annual exports of crude lac from the northern range is estimated at 1,300 to 1,400 maunds. In 1894 the Assistant Conservator of Forests, Garo hills Division, estimated the annual production and export at 2,000 maunds, and reported a serious decline in the cultivation of lac, which he attributed partly to the low prices and partly to the depopulation of the district through kala-ázár and migration. Considering that the bulk of lac exported from the Brahmaputra valley is the produce of the Kamrup and the Khasia and Jaintia hills and the Garo hills districts and that the exports have during the past five years averaged over 16,000 maunds a year, the foregoing estimates of outturn of lac in those districts would seem to be much below the truth.”

Central Provinces.—The lac insect is found throughout the Central Provinces, but the main centres of collection are the Jhabalpur, Saugor, Damoh, Nagpur, Raipur, Bilaspur, Sambalpuri, Chanda and Mandla districts. A Note on the Lac Industry of the Central Provinces (Bull., 1902, No. 8) gives useful particulars regarding production. The lac-collectors and sellers in these provinces were given in the census as 2,592 persons. Of the amount collected by far the greater part is exported, only a small
quantity being retained for local use. During the five years ending 1900–1
the exports fluctuated very greatly; in 1899–1900 they came to 99,961
maunds, valued at Rs. 11,96,394—the highest return in point of quantity—
and in 1898–9, 39,713 maunds, valued at Rs. 5,42,391, the lowest record
for the period mentioned. These exports, moreover, were almost entirely
from Jabalpur and Chhattisgarh; and were consigned to the United
Provinces almost entirely, thus feeding the Mirzapore factories.

**Burma.**—The large forests of Burma are said to be capable of producing
an almost unlimited quantity of lac. The chief sources of commercial
Burmesen lac are the Shan States and Upper Burma, stick-lac from these
places being imported into Calcutta, where it is manufactured into shell-
lac for export. For some years the supplies received by the Calcutta
factories from Burma have begun to be appreciated as important.
According to Sir J. G. Scott (Gaz. Upper Burma and Shan States, 1900,
ii., pt. 1, 393), though lac is found all over these States, it seems to be
only in Karen-ni that its production is stimulated artificially. "Elsewhere
if a tree happens to be attacked, or settled on by the insect, the deposit
is collected when it is found."

**Manufacture of Lac.**

**Lac Factories.**—In the Imperial Gazetteer (1905, iii., 173–4) it is
stated that though steam power has been successfully applied to the
industry, the hand-labour factories still hold their own and for some grades
produce qualities hardly, if at all, attainable by machinery. Lac factories
are almost confined to Bengal and the United Provinces. In 1904, according
to the Financial and Commercial Statistics, there were 128 lac factories
giving employment to 7,851 persons. Of these 92 were in Bengal and
employed 4,116 persons; 36 in the United Provinces, employing 3,715
persons. The number in Bengal is said to be not fully recorded.
With the exception of the factory at Cossipore they are, however, in
most cases small. Those in the United Provinces are all situated at
Mirzapore. The value of the manufactures turned out has been stated at
about two-thirds the total foreign exports, while the very large Indian
consumption has to be met, and thus mainly by small factories possibly
not included in the above returns.

**Stick-lac.**—*Stick-lac* is the name given to the twigs encrusted with lac
that are collected from the trees in May to June and the second crop,
October to November. These are dried in the shade, by which the wood
shrinks, thus often leaving the lac as hollow tubes, but much of the wood
still adheres. It is packed in sacks and conveyed to the marts, and sold
through various brokers or middlemen to the manufacturers. There is
a quaint practice usually followed in most sales of lac. The buyers and
sellers join hands and sit facing each other, a cloth being thrown over the
hands. The buyer presses certain fingers of the seller's hand, thus making
an offer. This is usually rejected by a motion of the head, and further
finger-pressing ensues. Finally the bargain is struck without a word having
been uttered.

**Seed-lac** is stick-lac crushed, and reduced to roundish pieces that more
or less correspond to the female cells. The dust produced, when sifting
the seed-lac, is known as *khud*. The pure seed-lac is then washed in large
stone troughs and left covered over with water for 24 hours. The wood
floats to the top and is removed, dried, and used as fuel. A man or woman

1060
now enters the trough and, while holding on to a transverse bar placed at a convenient position, treads with the bare feet on the granular lac and presses it against the sides of the trough. As a result the lac is broken into still finer particles and the water becomes of a deep claret colour. The coloured water is run off, a fresh washing given, and repeated till the washings pass off colourless. The washings, if it be so desired, are evaporated down to a thick consistency and compressed into cakes. This is lac-dye. The resin is now called washed-seed-lac, but it is sifted into two qualities—granular and dust; the latter is called gaud. When steam machinery is used, the washing is done with revolving cylinders and beaters.

In some parts of India the seed-lac is now either washed or even boiled in a solution of crude carbonate of soda or of soda and borax, or of crude carbonate of potash, or of borax alone or of alum. After several such washings it is said to become almost white. But in most of the larger factories, especially those concerned in the production of shell-lac, the washing or boiling in alkaline preparations is dispensed with; the seed-lac is simply repeatedly washed in pure water but not bleached. Indeed, according to some authorities, it is even maintained that bleaching weakens the lac. After being washed, or bleached and washed, to the desired extent, the seed-lac is spread out on special floors and exposed to light and air, by which it is thoroughly dried and still further bleached.

According to the purpose for which intended, the dried washed lac is now mixed with either or both of the following substances—yellow arsenic (orpiment) and resin. The mixture is then fused either before an open fire or by steam-heating. Steam is practically confined to the European factories. The arsenic is said to make the lac opaque and to impart a rich straw colour to the shell-lac, but its action would appear to be mainly if not entirely mechanical. It is responsible for the opacity and rich straw colour of all the finer qualities of hand-made shell-lac. But the inquiry for a substitute for arsenic has often been made, though not as yet supplied. A yellow colouring material that will fuse into the lac when subjected to the temperature that corresponds to 35 lb. steam power is required. Arsenic is not, however, employed in the preparation of garnet or button lacs, nor other grades where fulness of colour is no disadvantage.

The object of the resin is to lower the melting-point, a condition essential for many industries and one known from fairly ancient times (witness Acosta’s allusion to it in 1578). Its value, therefore, is fully recognised and a certain amount is not only admissible by the rules of the trade (2 to 5 per cent.) but few of the shell-lacs that are regularly exported can be said to be entirely free from resin. During seasons of high prices the proportion is often, however, raised until it passes from the condition of permissible admixture to what might be called criminal adulteration.

**Lac Fusing.**—The specially washed and bleached lac, mixed with its required proportions of arsenic and resin, is now (by the hand manufacture) placed within long narrow bags (20 feet by 2 inches). For one quality of lac American drill is necessary; for another a cloth specially made at the Cawnpore cotton mills is preferred, and for a third two bags are required, one within the other. After being charged the bag is arranged in front of a long open fire and so fixed up that it may be twisted the while it is being moved slowly along. The foreman operator sits on a little raised mud platform, on the immediate left of the fire and slightly behind it. With
his left hand he holds the end of the bag and resists the twisting action produced by his assistant. The fused lac, in the portion most exposed to the dry heat, is thus squeezed through the bag. Every now and then the foreman gives his end of the bag a reverse twist, and this causes the portion from which the lac has been removed to coil up like a rope. Steadily the bag is drawn forward as portion after portion is exhausted. With his right hand the foreman wields at intervals three weapons—one a long iron hooked poker with which he stirs the fire: a wooden spoon with which he every now and again sprinkles with water the tiled floor in front of the fire: and an iron scraper with which he removes the molten lac as it oozes on to the surface of the bag and allows it to drop on the dam floor. If not sufficiently cooked, the fused lac is picked up from the floor and placed once more on the top of the bag and fused again, and even two or three times. There seems to be great skill in knowing when the lac has been cooked to the proper extent. It is freely admitted that the hand-made lac possesses certain properties never attained by the steam-machinery factories. Shell-lac.—The next stage is the production of shell-lac. For this purpose a mass of molten lac is handed to an assistant and placed by him on an earthen or zinc tube filled with hot water (or on a green banana stem) fixed in the ground at an angle of about 45° to the floor. By means of a ribbon of palm-leaf stretched between the hands, the assistant spreads the lump of molten lac into a thin skin perhaps one-eighth of an inch in thickness. But in this operation, which looks so simple, great skill is required in exercising just the right pressure to cause the lac to spread out in a compact sheet of uniform thickness. The sheet or skin is now clipped off the tube, trimmed into a rectangular form, and handed to still another assistant, who, carrying it in front of the fire, seizes it between his toes, teeth and hands, and widening his legs as he expands his arms and straightens his body and neck, stretches the sheet into three or four times its original size and reduces it to the thinness of tissue paper. It is then laid on a mat and allowed to cool gradually.

When quite cold the sheets are given to persons who assort them according to colour and break out all impurities and darker coloured portions. The rejections either constitute lower grades or are mixed with dark-coloured seed-lac and used up in the manufacture of shell-lac where colour is no objection. In the production of garnet-lac, the sheets are taken at the hot-tube stage, no further stretching being necessary. Garnet-lac is very largely, however, the special product of the steam-power factories. As its name implies, it is of a deep rich red colour, and is in demand for industries where colour is not a disadvantage. In the preparation of button-lac, the molten material is not stretched at all but is simply allowed to drop on to a smooth substance, such as a green leaf-sheath taken from the banana stem. Garnet and button lacs contain as a rule no arsenic, though they may possess a high percentage of resin.

The refuse that remains in the melting-bags is removed and the bags cleaned by being boiled in alkali. The refuse is then made into large circular cakes 6 inches in diameter and 1 inch or more thick. These are very possibly the "great cakes" alluded to by the East India Company as procured in 1816 from Agra, as also the lump-lac of the early commercial returns. They are sold, like the khud and gaud, to the manufacturers of sealing-wax, bangles, toys, etc., and by the cabinet-makers such crude lacs are largely employed to cover up cracks in wood.
INDIAN LAC WARE

THE USES OF LAC.

Lac enters into the agricultural, commercial, artistic, manufacturing, domestic and sacred feelings and enterprises of the people of India to an extent hardly appreciated by the ordinary observer. The existence of the poorer communities, in the agricultural and forest tracts, is made more tolerable through the income derived from the collection of the crude article. Every village has its carpenter, cartwright, turner and shoemaker, and all these craftsmen use lac in some form or other every day of their lives. The blemishes and defects are plugged up and concealed by crude lac, and the surfaces are uniformly varnished or coloured with lac where colour is desired. Coloured lac, in fact, takes the place of the oil paint of Europe. The silver and coppersmiths employ it as a resist bed upon which to hammer out or punch certain of their wares. By means of lac, coloured ornamentations are made on copper and brass wares, as also on ivory. Lapidaries construct grindstones of the same material fused with sand and with it cement blade to haft in knives and swords (p. 495). Potters, bookbinders, and makers of smoking-pipes all need lac as a varnish or a stiffening material. Jewellers load hollow gold and silver ornaments with it, or fix the stones in these by its means. The makers of the humbler personal ornaments prepare most of their wares almost entirely of lac. Indeed it is highly possible that one of the very earliest utilizations of lac was the very preparation of peasant jewellery. Lastly, in the hands of the lac-turner and toy-maker lac is supreme. But let it be here observed it is desirable to call this lac-work and to reserve lacquer for the art practised in Burma and Japan, where a vegetable oleo-resin is the chief material, not the animal resin-lac.

The turner (kharidi) with his lathe is met with in every village of India, and has an assured position in the community. He prepares toys, nests of boxes, bed-posts, gándâna, hukka mouthpieces, and decorates agricultural and other implements, etc., etc. The pigments employed are ombint, sulphur, white lead, red mercury, Prussian blue, lamp-black and indigo. Recently, however, aniline dyes have been much used, with the result that the delicate artistic colours have almost disappeared and the articles made at the present day fade and tarnish to such an extent as to render them no more desirable ornaments. Metallic results are produced by mixing the lac with powdered mica, with powdered tinfoil, with imitation gold leaf, or with an amalgam of mercury, lead and tin. These metallo materials, if used in large particles, give a quaint mottled appearance and simulate the grain of stone, thus often producing a rich effect.

In the preparation of coloured lac, shell-lac is melted over the fire until it becomes plastic. It is then placed on a stone and a small quantity of pigment (previously dissolved in water or absorbed by oil) is deposited within a hollow formed on the surface of the lac. This is closed in and the lac hammered, then pulled out with the hands, doubled up, hammered, and pulled out again and again, until the colour becomes uniformly intermixed. The hammering communicates heat so that the mixture gradually assumes the consistence of india-rubber. The coloured lac is then formed into sticks the length and thickness of lead pencils, or thicker as may be desired. These sticks of sealing-wax, as they may be called, are known as battîs and are the form in which both the lac and pigment are applied to woodwork. After the article has been prepared and smoothed, a battî is pressed against it as it revolves on the lathe. The heat generated melts the lac and thus colours the wood irregularly. The colour is then diffused by a small piece of hard wood pressed firmly on the revolving article. Lastly, a cotton rag, dipped in sweet oil (preferably Sesamum), is next applied to the revolving article, and this imparts a lasting polish to the lac surface. Obviously, therefore, the first conception in lac ornamentation must be a direct adaptation to a revolving object, hence the articles are either uniformly coloured in one shade or are ornamented by rings and bands of different colours. In the higher flights of lac-turnery and in the metal and ivory ornamentation with lac, however, a diversity and richness in effect are produced that have to be seen to be fully appreciated. The chief types of this work are designated as:

1. Plain ornamentation.
2. Abru or Cloud Work.
3. Atišî or Fire Work.
4. Nakshi or Pattern Work.
5. Painted Ornamentation.
6. Tinfoil Ornamentation.
7. Lac Ornamentation to Metal Ware.
8. Lac Ornamentation to Ivory.

For timbers suitable for turnery and lac-work see Buxus (Boxwood Substitutes), Timber. p. 190.
The reader who desires particulars regarding these various art utilizations should consult the special Agricultural Ledger mentioned above, as also Indian Art at Delhi, 1903. I have gone into the above details of Indian methods and experience from the belief that they throw some sidelight on the nature of lac. The systems of work mentioned are mostly very ancient. Barbosa, Garcin de Orta, Terry and other European travellers give such details regarding lac turnery, for example, that there can be little doubt the art was as fully known three or four hundred years ago as it is to-day. But it is singular that no mention is made by any traveller of having seen lac factories in India, or even of the manufacture of shell-lac, till the early decades of the nineteenth century. It is not clear when and how that name came, in fact, into use. Pomet (Hist. Drugs (Engl. transl.), 1712, 202-4) describes the molton lac being (in Burma) spread out on marble surfaces, but does not call the article thus produced shell-lac. That name was, however, used by James Kerr in 1881 and by Vincent in his Appendix to the translation of the Periplus (ed. 1806, 25), so that it had by then come into general use. The production of lac in former times thus appears to have been a village craft practised all over India, which was most likely not concentrated into factories till the European demand arose.

**TRADE IN LAC.**

The first recorded exports of lac to Europe, as already stated, took place about 1607, but for nearly two centuries the traffic was entirely a Native commodity, as it had been still earlier (while in the hands of the Arab traders). Milburn (I.c. 217) tells us that the exports from India in shell-lac were in 1805, 2,377 cwt., valued at £12,978, and that in 1808 they stood at 239 cwt., valued at £1,243. The trade was thus not well established, and the expansion had been slow, for even in 1839 the total exports in “lac-resin” were only 7,226 cwt., and in 1840, 6,043 cwt., and, correspondingly, in 1839 the “lac-dye” stood at 4,756 cwt., and in 1840, 5,440 cwt. But in 1868-9 the shell-lac sent to Europe had reached a valuation of just under 12 lakhs (£80,000), and that of the lac-dye of 8 lakhs of rupees (£53,300). Since then the trade in lac-dye has gradually disappeared, while the exports of shell-lac have expanded to over two crores of rupees (£1,400,000 at present rate of exchange). This state of affairs is, perhaps, best exemplified by the following table:

**Exports of Lac-dye and of Shell-lac from India.**

(= £1,831,703)
I have not dealt with the button-lac nor with the unmanufactured forms of lac, since the exports of these are comparatively unimportant. The figures as they stand exhibit strikingly the way in which the traffic in the resin-lac has compensated for the loss of the trade in lac-dye.

**Production and Local Traffic.**—In the return of railborne traffic, lac is not treated under its separate headings, viz. of stick, seed, shell-lac, etc., but collectively. In 1906-7 the total quantity shown as exchanged came to 446,574 cwt. Of that amount, Bengal is exhibited as having exported 172,614 cwt., chiefly as follows:—122,155 cwt. to Calcutta, and 50,076 cwt. to the United Provinces. On the other hand, the United Provinces exported 134,356 cwt., almost entirely to Calcutta. Next come the Central Provinces with an export of 45,430 cwt., chiefly to the United Provinces. Lastly, Assam exported 35,159 cwt. entirely to Calcutta. It has already been shown that the lac factories of India are almost confined to Mirzapore in the United Provinces and to Calcutta in Bengal. This accounts for the traffic being toward these centres. But all over India small quantities are worked, so that the statistics of lac factories by no means convey a full conception of the Indian production and consumption. For example, the Indian dyers, when they use lac-dye, prefer to obtain it direct from the stick-lac, so that they are continually producing a certain amount of seed-lac, which they dispose of to the local dealers and lac manufacturers. It is, however, probably correct that the railborne traffic gives us the only satisfactory indication obtainable of the chief items of production. A total supply of 446,674 cwt. of stick-lac should be more than sufficient to furnish the raw material for the export of 205,473 cwt. of shell-lac. The production of the registered lac-factories is commonly believed to represent two-thirds of the actual production, so that one-third (or thereabouts) of the annual supply escapes all trade registration.

**Receiving Countries.**—Another feature of importance may be here stated, namely the direct dealings of India with Europe and America instead of through the United Kingdom. The following classification of the returns for the past twenty-one years will exemplify this feature:—

**Analysis of the Exports of Shell-lac from India.**

It will thus be seen that, while the exports from India have steadily expanded, the share drawn by the United Kingdom has not maintained its supremacy. America has become by far the most important single consuming country for lac, and what is still more remarkable, all the finer grade laes go to the States and are purchased direct from the factories and not through Indian or British merchants. The traffic is, in fact, controlled by the United States dealing with the manufacturers direct. The possibilities of expansion are also extremely problematic.
THE TAMARIND TREE

The following statement classifies the foreign exports from India during the past three years:

<table>

It will thus be seen that during the years 1903–6 the exports of shell-lac have increased by 12·56 per cent. in quantity and by 21·63 per cent. in value, while button-lac has correspondingly expanded by 22·1 per cent. in quantity and 14·75 per cent. in value. On the other hand, the traffic in the raw material has, if anything, declined. Everything points to a continued expansion of the traffic in connection with the necessities of electric appliances.

**TAMARINDUS INDICA, Linn. ; Fl. Br. Ind., ii., 273 ; Gamble, Man. Ind. Timbs., 1902, 278–9 ; Prain, Beng. Plants, 1903, i., 444 ; Brandis, Ind. Trees, 1906, 252–3 ; Hooper, Agri. Ledg., 1907, No. 2 ; LEGUMINOSÆ.**

The Tamarind Tree, *amī, tintīrī, tintūdī, koya, pūṭī, chinta, jojo, chinch, neddi, shenta, sitta, karangi, hunase, magyi*, etc. A large evergreen tree, cultivated in India and Burma as far north as the Jhelum, in the Central Provinces, Central India, and many parts of Southern India ; it is also found self-sown in waste and forest lands. Is said to be indigenous in Africa. According to Dutt, it was known to the Arabs as *Tamare-Hindi*, from which is derived Tamarind.

**Properties and Uses.**—It yields a dirty Gum of no value, and according to Prebble, old trees are sometimes seen to have a liquid exudation consisting of calcium oxalate (*Pharmacog. Ind.*, i., 533 ; Kanny Lall Dey, *Indig. Drugs, Ind.*, 1896, 310). An infusion of the leaves is believed to yield a red Dye and to impart a yellow shade to cloth previously dyed with indigo (Atkinson). Leaves, flowers and fruits are also employed as auxiliaries in dyeing, especially with safflower. An Oil of an

Chaulmugra

amber colour is prepared from the seeds by expression. From a very remote period the tree has been valued in Sanskrit Medicine as an antiscorbutic in place of lime-juice, and accordingly the fruit is official in modern Pharmacopoeias. The fruit is a large swollen pod, 4 to 6 inches long, filled with an acid pulp. It matures in February and is largely used as Food, being a favourite ingredient in curries and chutneys, and for pickling fish (see Fish, p. 547). It is also employed in making a cooling drink or sherbet. According to Lakshman Dhargel, Ker (Therap. of Indig. Veg. Drugs, Bombay, 1899, 16, 30, 58), the sherbet is a useful laxative for children. Marco Polo (ed. Yule, ii., 328) mentions tamarindi and seawater being used as an emetic preparation.

According to a recent writer (Philippine Bureau of Agric., Press Bull., No. 6: Trop. Agrist., Nov. 1905, xxv., 687-8), "In British India the average annual yield from an adult tree is 350 pounds of pods, and this shrinks to about 200 pounds of the prepared fruit pulp." The same writer states that a new market has recently sprung up for the tamarind in Genoa, where the pulp is employed in the manufacture of syrups and sweetmeats. The East Indian tamarinds, he says, are packed in salt, but the best market now seems to be for the unsalted article, of the preservation of which in Jamiaca he gives the following account:—"After gathering, the ripe pods are first stripped of their outer shells and the pulpy contents are laid down in the bottom of wooden casks or barrels, and there sprinkled over with a layer of cheap, low-grade sugar. These follow alternate layers of fruit and sugar, until the receptacle is filled to within 8 to 10 centimetres. The whole is now covered with boiling-hot sugar headed up, and is then ready for export. So packed, tamarinds may be preserved for years without deterioration." He also adds, "The current price of salted tamarind in the Bombay market is at this time only about $30 per long ton of Madras fruit and $40 for Calcutta fruit, while the prevailing average price for the sweetened Jamaica fruit in the Genoa market for nearly a year past has been about 40 liras per 100 miles (220 pounds) or, in our values, about $80 gold per long ton."

The seeds, boiled or fried after removal of the outer skin, are also eaten by Natives, especially in times of scarcity, while the seedlings, leaves and even flowers, are utilised as food in various preparations. Cameron mentions a cement or paste as made from the seeds which is used in dressing country-made blankets. The Wood is regarded as very durable, and is highly prized, though difficult to work. It is used chiefly for wheels, mallets, planes, furniture, rice-pounders, oil and sugar mills, and is excellent for turnery. It is also valued for fuel when great heat is necessary. [Cf. Baber, Memoirs, 1519 (Leyden and Erskine, trans.), 1826, 341; Mesua, Opera (ed. Marinus), 1502, 52; Garcia de Orta, 1503, Coll., iii.; also in Ball, Proc. Roy. Ir. The Chaulmugra Oil, chaulmugra, kalavbin (the tree), kalaunbee (the seeds), toung pung, etc. A large tree, 40 to 50 feet high, of the forests of Sylhet, Chittagong and Burmah. The seeds yield the true chaulmugra oil, long supposed to be the product of Cinna-
cardia odorata.

The identification of the true source of the chaulmugra seed originated with a
French pharmacist, G. Desprez, in 1899 discovered that the seeds received in Europe did not belong to *Gynocaridia odorata* and the fact was communicated to Lieut.-Col. D. Prain, who had found about the same time that the seeds sold in the Calcutta bazaars were not those of *Gynocaridia*, and subsequently that the tree which yields the *chaumugra* seed was *Tectoglossus Kurzii*, a plant described by Sir George King in 1890. The two seeds can be easily distinguished. *Gynocaridia* is about one-half shorter than that of *Tectoglossus*. The shell of *Gynocaridia* is thicker and harder, marked on one side by a few radiating ridges or furrows, and the kernel is pale yellow. The shell of *Tectoglossus* is plain and the kernel dark-coloured.

*Chaulmugra* Oil has long been known and used in India as a remedy for cutaneous diseases, and has become a drug of some importance in European practice (p. 204). A full account of the history and composition of the oil is given by Hooper. The seeds are brought to Calcutta, chiefly from Chittagong, and are of two kinds—(1) mature seeds with brown kernels, rich in oil; (2) immature seeds with black kernels, poorer in oil. The seeds arrive in the market at the end of the rainy season in November and December. At present the price of the seed is stated to be Rs. 3 to Rs. 4 per maund at Chittagong and Sylhet, and the Calcutta price Rs. 6-9 per maund. To extract the oil the kernels are separated from the shells and dried in the sun. They are then pounded with a pestle and mortar, and the broken kernels put into canvas bags and the oil expressed with the aid of fire in a castor-oil mill. The oil is of two kinds—(1) clear, bright, straw-coloured; (2) muddy and precipitating a sediment of earthy colour. One maund of oil is obtained from 4 to 5 maunds of seed. The price of the oil is Rs. 60 per maund. [Cf. Mason, *Burma and Its People* (ed. Theobald), 1883, ii., 646; *Gynocaridin* Pharmacog. Ind., i., 142-6; Borsodi and Desprez, C. **TECTONA GRANDIS, Linn.**; *Fl. Br. Ind.*, iv., 570; *Stat. Atlas Ind.*, 1895, 29-31 and map; *Gamble, Man. Ind. Timbs.*, 1902, 526-34; Prain, *Beng. Plants*, ii., 828; Cooke, *Fl. Pres. Bomb.*, 1905, ii., 424; Brandis, *Ind. Trees*, 1906, 505-6; VERBENAEC. The Teak Tree, *ságün, sákhū, chingagú, ság, siguwan, khaka, teka, loherú, ságwán, tégu, térku, pedda térku, tigada mara, jădi, kyán, etc.* A large deciduous tree, indigenous in both peninsulas of India. The wood is that chiefly exported from India, more particularly Burma, and is the most important building timber of the country.

Gamble discusses the teak areas under two divisions, the western or Indian and the eastern or Burmese. The Indian region has for its northern limit the rivers Nerbudda and Mahanadi, but here and there it may occasionally be found north of this line, as in Jhansi and Banda, while south of it, it scarcely occurs in Orissa or the Circars. It is found in deciduous forest, but is not gregarious; and the localities where the most important forests are found are (1) Chanda district, Central Provinces; (2) North Kanara; (3) Wynad, especially the tracts known as Bendi and Mudumali; (4) the Anamalai hills; (5) Travancore. There are also considerable extents of teak forest in other parts of the Central Provinces; in Berar and Bombay; on both sides of the Godavari in Khadacakalam, Rumpa and Yermagam; in the Nallamalai hills of Kurnool and Cuddapah; in South Arcot and in Mysores. But teak may be found sporadically in places in forests throughout the Indian region, and even in such very dry apparently barren rocky hills as those of Western Karnatı and Bellary, patches of stunted more or less gregarious teak are not uncommon. In the Burmese region, teak is chiefly found in what are called by Kurz the "upper mixed forests," which occupy the parallel ranges of (1) the Arrakan Yoma, eastern slope; (2) the Pegu Yoma; and (3) the Martaban hills and the hills which continue these ranges northwards. The northern limit, according to J. W. Oliver, is about Myitkyina and Kamaing, in lat. 25° 30', though there it is mostly of stunted growth. Teak has been largely planted about stations all over India, even so far north as Saharanpur, Dehra Dun and Lahore, in avenues and gardens; and forest plantations have been made
in many provinces, the chief of which is that at Nilambur in Malabar, commenced by Mr. Conolly, who was Collector in 1844. In Bengal it has been grown about Kaptai in Chittagong and Bamumpolki in the Darjeeling Tera; and in the Assam Valley there is a plantation as far up as Makum near Dibrugarh."

**Cultivation and Management.**—The above paragraph gives a general idea of the distribution of teak throughout India and Burma. For further details regarding the distribution and general management of teak plantations the reader might consult the Dictionary (l.c. 5–10), where particulars will be found of climate, soil, cultivation, seed, nurseries, growth, felling, and diseases. The voluminous *Forest Administration Reports and Working Plans* issued by the Imperial and Provincial Departments of India and Burma, as also the pages of the *Indian Forester*, are full of much important and practical information. [Cf. Brandis, *Teak Forests of Pegu*, 1856.] But the following are a few of the more important facts relative to the growth of the tree. It is said to thrive best with a mean average temperature of between 72° and 81°. Regarding the large plantation at Nilambur in Malabar, Percy Lushington (Rept. and Working Scheme of Nilambur Teak Plant., 1898, 41) states that "the distinguishing characteristic of the Nilambur climate is its damp heat so favourable to rapid growth. The temperature in the shade ranges from 75° to 95°. The average rainfall for the past ten years is 94.5 inches." He then explains that the soil of the plantation is very varied, alluvium overlying gneiss rock or laterite derived from the hills. Gamble states that teak thrives best on sandstones and metamorphic rocks, but may also be found on trap, laterite and even limestone. At the Nilambur plantation it has been recorded that the teak growing on alluvial soils was of first class; that on laterite second class. Damp alluvial soils are, however, unfavourable, and there must be good drainage if straight timber is to be obtained. The tree also requires full light for its head and free circulation of air. It seeds freely even when young, and the seed germinates well if it gets sufficient warmth and moisture. According to Gamble, "germination is best if the seeds are simply mixed with sand and dead leaves after being thoroughly soaked." J. W. Oliver says that in Burmese *taungyas* the practice is to spread the seed in a corner of the area chosen for the plantation, and then pick out and transplant to their proper places those which germinate. Gamble then continues, "as teak has an enormous tap-root, which resents being cut, the seedlings cannot be kept long in nursery, but must be planted out when quite small, and succeed best when planted out straight into the forest after germination," as has been mentioned above; "but when this is not feasible, basket or pot plants will give good results." McIntosh (*Ind. For.*, 1905, xxxi., 129) observes that at Nilambur the seed is collected in February and sown early in April, after having been soaked for forty-eight hours in water. With copious waterings the seeds germinate in fifteen to twenty days. Regarding the management of natural teak forests, Oliver says that reproduction of teak is hardly satisfactory unless the forest is burnt, because, being usually mixed with bamboo, shade is too dense until the bamboo flowers, and then, unless the forest is burnt over, the bamboo seedlings choke such teak plants as may germinate. Gamble, summarising the *Working Plans*, says: "It has been ascertained by experience that great improvement takes place if certain well-defined operations are carried out, and these are usually prescribed. They are—(1) not to girdle isolated trees unless with the object of relieving existing seedlings; (2) to leave sound trees, likely to improve, in localities whence

Rules to be Observed.
The Teak-Wood Tree

Large timber can be extracted; (3) to fell and not girdle trees attacked by epiphytic Ficus; (4) to continue taungya plantations with energy, and to weed such plantations regularly; (5) to sow or plant up areas of flowered bamboo; (6) to pay much attention to creeper-cutting.” According to P. Lushington (l.c. 67-8), the method adopted in the Nilmābūr plantation is “a system of high forest with a clean felling of the final crop and artificial regeneration. The felling to be accompanied by thinnings with a view to the improvement of the final crop. The felling to commence not earlier than the year in which the average girth at breast-height will be 6 feet 6 inches. The measurements taken show that the centre girth will not be less than 4 feet 6 inches. On first-class soil the final crop should consist of not less than forty trees, and on second-class of not less than fifty per acre.” Lushington further states “the age of exploitability has been found out to be 95 years on first-class, and 140 years on second-class soils.”

“The total yield per acre on first-class soils is 3,000 cubic feet per acre, and on second-class 2,000 cubic feet per acre. The annual yield, if spread over 50 years, will be 147,910 cubic feet of first-class and 73,780 cubic feet of second-class timber. According to the present market this will fetch not less than Rs. 3 per cubic foot standing for first class, and Rs. 2 per cubic foot for second class. The total revenue to be derived will, therefore, be Rs. 4,43,730 and 1,47,910 — Rs. 5,91,290, or with the net profit derived from miscellaneous sources such as third-class bamboos, etc., may safely be fixed at 5 lakhs per annum.”

Minor Products.—A somewhat liquid, black tar may be prepared by destructive distillation of the wood; this is used for medicinal purposes in South India and Burma. The leaves yield a dye, of which little is known, and are employed as food for the tasar silkworm (p. 1005). An oil is also extracted from the wood, used in Burma as a medicine and as a substitute for linseed-oil in painting.

Wood.—Teak owes its value chiefly to its great durability, ascribed to the fact that it contains a large quantity of fluid resinous matter, which fills up the pores and resists the action of water. As manifesting its durability, mention may be made of the fact that the great umbrella over the Htee in the Karli cave is still in existence, though it is most probably at least two thousand years old. Gamble observes that the weight may be taken at approximately 45 lb. per cubic foot and the value of P (the coefficient of transverse strength) at 600. When quite fresh teak hardly floats, but when seasoned it floats easily. The oil in the wood prevents its getting waterlogged, and seems also to safeguard it against weevi and other timber-boring insects. It is specially valued because it does not rust the iron with which worked up. It is exported chiefly for shipbuilding, especially for the decks of vessels, for the construction of railway carriages, and for the best class of house-carpentry, being admirably suited for staircases, balustrades, door and window frames and furniture. In India it is used for all purposes of house- and ship-building, for bridges, railway-sleepers, furniture, shingles, etc. It is used for carving, the Burmese carved teak-wood being especially noted; in Burma itself carved “kyuang,” or monasteries, are prominent in almost every village of any importance (Gamble, l.c. 532). The ease with which teak-wood lends itself to carving has, in fact, originated special art conceptions; these may be learned by perusal of the observations on this subject recorded in Indian Art at Delhi in 1903 (100, 124, 129, 135-40).

Trade.—Grave apprehensions have on more than one occasion been expressed that the diminished supply and high prices of late years favour
the substitution of other woods to the permanent injury of the teak-wood trade (Hauxwell, in Ind. For., 1905, xxxi., 618–35). No statistics are available of the Indian internal trade by rail and river, but the transactions by coast show that a large demand exists in India for teak-wood. This demand in former years was almost entirely supplied by Burma, but in recent years, as will be seen, one of the chief features of the present-day Indian trade in teak has been the gradual displacement of the Burmese timber, especially in the Bombay market, by wood imported from Siam and Java. Turning to the coastal trade, we find that for the five years 1900–1 to 1905–6, the registered imports averaged annually 116,639 cubic tons, valued at Rs. 93,38,559, and the registered exports 134,142 cubic tons, valued at Rs. 86,70,414. In the last year, 1905–6, the exports were 131,458 cubic tons, valued at Rs. 88,25,140. Of this Burma exported 85,749 cubic tons (to Bengal, 47,578; to Madras, 24,253; to Bombay, 11,870); Bombay 44,084 cubic tons (to British ports within the province, 26,410; to Kathiawar, 9,599; Madras, 1,469 cubic tons (to Kathiawar, 654; to Bombay, 265; to British ports within the province, 195); Bengal, 153 cubic tons (to British ports within the province, 113; to Madras, 39). Perhaps it may be said that an important feature of the Indian traffic in teak-wood is the imports brought across the land frontier. In 1899–1900 these were 73,912 tons, valued at Rs. 44,16,143, which came from Karen-ni (43,434 tons) and Zimme (19,067 tons). Five years later the imports were valued at Rs. 54,34,063—imported by the Salween. [Cf. Dipl. and Cons. Repts., 1902, 6–11; 1903, 4–5.]

With regard to the foreign trade, as already pointed out, the chief feature has been the rapid rise, within recent years, of a large import trade in teak from Siam, Java and the Straits. The figures of Imports for the years 1901–2 to 1906–7 have been—1901–2, 17,842 cubic tons, valued at Rs. 13,03,968; 1902–3, 32,081 cubic tons, valued at Rs. 24,96,317; 1903–4, 34,588 cubic tons, valued at Rs. 30,55,695; 1904–5, 46,915 cubic tons, valued at Rs. 42,46,190; 1905–6, 71,676 cubic tons, valued at Rs. 62,17,331; and 1906–7, 61,696 cubic tons, valued at Rs. 60,71,557. Almost the whole quantity comes from Siam, whose exports to India during the years in question increased from 17,572 cubic tons in 1901–2 to 61,657 cubic tons in 1905–6, and in value from 12 to 53 lakhs of rupees. Three-fourths of these imports go to Bombay and the remainder chiefly to Bengal. Turning, by way of comparison, to the latest figures of the coastal trade, we learn that in 1905–6 Burma consigned to Bombay 11,870 cubic tons, while the supply of foreign teak, almost entirely Siamese, in that year amounted to 53,253 cubic tons. Noël-Paton points out (Rev. Trade Ind., 1905–6, 44) that “practically the whole of the teak trade in the north of Siam is controlled by British Companies.” [Cf. Siam Trade, Ind. For., 1905, xxxi., 464–71.]

The Exports from India during a similar period have been—1901–2, 60,671 cubic tons, valued at Rs. 71,53,855; 1902–3, 57,500 cubic tons, valued at Rs. 68,67,879; 1903–4, 73,913 cubic tons, valued at Rs. 91,45,605; 1904–5, 46,912 cubic tons, valued at Rs. 60,05,383; 1905–6, 52,768 cubic tons, valued at Rs. 70,41,660; and in 1906–7, 44,202 cubic tons, valued at Rs. 61,48,291. Four-fifths of the total go from Burma, amounting to 41,469 cubic tons in 1906–7, the surplus from Madras, Bombay and Bengal. The great bulk of the exports is consigned to the United Kingdom, which in the last year took 30,318 cubic tons, 

1071
while the other chief markets are ordinarily Germany, Ceylon and Australia.

Commenting on the price of teak, Noel-Paton states: "A great expansion in shipbuilding and in some other branches of construction in the United Kingdom, Germany, and the United States, has synchronised with a contraction in the available supplies of teak, and has induced a rise of price—in some cases prohibitive. The average price in 1904-5 at Calcutta was Rs. 111 to Rs. 116 per ton of 50 cubic feet. In 1905-6 it was Rs. 120 to Rs. 125. Exports of teak have increased in quantity by 12-5 per cent. to 53,000 cubic tons, and in value by 17-29 per cent. to Rs. 70'4 lakhs. But the difference between these two percentage rates of increase does not gauge the enhancement in average value of a uniform quality of timber, for it is understood that a good deal of inferior wood has gone forward in the twelve months under report. Exports from Burma to India proper decreased by a further 5'9 per cent. and reached a value of only Rs. 71,30,683, while imports into India from Siam and Java increased by some 34'7 per cent. to a total of Rs. 57 lakhs."

**Myrobalans.**

**TERMINALIA, Linn.; Fl. Br. Ind.; ii., 443-9; Gamble, Man. Ind. Timbs., 337-45; Prain, Beng. Plants, 1903, i., 481; Cooke, Fl. Pres. Bomb., 1903, i., 477-81; Duthie, Fl. Upper Gung. Plain, 1903, i., 337-7; Brandis, Ind. Trees, 1906, 307-12; Comberetaceae.** A genus containing many species distributed over the tropics of the world. There are some 16 representatives in India, many being large trees, valued for their timber and as producers of the tanning fruits—Myrobalans. An interesting historic sketch of the knowledge of myrobalans will be found in Hobson-Jobson (ed. Cooke, 1903, 607-10).

**Arjan.**

T. Arjuna, Besd. The arjan, kathu, gara-hatana, kanha, mangi, sând-matat, vellai-marud, tanda, tella-maddi, toukkyan, etc. A large deciduous tree on banks of rivers and streams throughout Central and South India, extending as far north as Oudh. Beyond that, towards the north-west and in the Panjab, it is found only as a cultivated tree; Burma; low country of Ceylon. (Gamble).

It yields a clear transparent Gum met with in the bazars of Northern India as a drug. The astringent bark is sometimes used as a Dye and Tann, and also in Native Medicine. The Wood is apt to split in seasoning and is not easy to work, but is used for cars, agricultural implements, boats and for building. At the Mysore gold mines it is used for supports and is called "White Matti." The ash from burning the wood contains a very high percentage of lime (Trop. Agrist., 1906, xxv., 870-1). [Cf. Pharmacog. Ind., ii., 11-2; Cameron, For. Trees of Mysore and Coorg, 1894, 135-6; Duncan, Monog. Dyes and Dyeing in Assam, 1896, 52; Dutt, Mat. Med. Hind., 1900, 163-4; Hooper, in Agr. The Chebulic or Black Myrobalan, *harrí or hár, hilikha, silim, kaređha, halra, rola, mahoka, kadakai, karaka, hirada, alalé, panga, etc.* A very variable deciduous tree, found throughout India and Burma. The *Flora of British India* enumerates six varieties. "In high-level rocky and dry places on the outer Himalaya, the hills of the Deccan and South India, it is only quite a small tree, but in valleys and forests of big trees it also grows big and gives a hard, dark-coloured timber" (Gamble).

History.—The tree yields a Gum, said to be largely collected in Berar and mixed with various other gums (*Acacia arabica, Anogeissus latifolia, Anogeissus leiocarpus*).
**THE INDIAN MYROBALANS**

*Chebulic*

_Bassia longifolia_, etc.). The mixed gums are taken to the local markets by the Gonds, who collect them, and are sold for medicinal purposes or to dyers to mix with their colours. The chebulic myrobalan was highly extolled by the ancient Hindus as a powerful alterative and tonic. Indian writers describe seven varieties, which, however, are mostly the same fruit in different stages of maturity. The classic citrine myrobalan, of which Rhases, Serapion, Avicenna, Mesua, etc., all speak favourably, was at one time much in demand in Europe. Even so late as 1813, Milburn (I.e. 218) gives directions for selecting the drug, which, he adds, the Natives frequently candy. Fleming _As. Res_, 1810, xi., 182) ascertained the _zengi har_ (black myrobalan) to be the unripe fruit of this species (Sprengel, _Hist. rei. Herb_, 1808, i., 262; _Paulus Egineta_ (Adams, Comment.), iii., 440–3). The Woon takes a good polish, is fairly durable and used for furniture, carts, agricultural implements and house-building.

**DYE AND TAN.**—The dried fruit of this species constitutes the “Chebulic” and “Black” myrobalan of commerce, one of the most valuable of Indian tanning materials. In India it is also used as a dye occasionally by itself, the rind of the fruit being powdered and steeped in water. With alum it is said to give a good permanent yellow. But the most extensive use to which _harra_ is put as a dye is in the production of various shades of black, in combination with some salt of iron. The chief commercial value, however, of chebulic myrobalan is as a tanning material; it forms the greater part of the ground myrobalans of commerce, though beleric myrobalans are occasionally mixed with it. The liquor prepared from _harra_ is not only a powerful tan, but imparts a bright colour to the leather, and hence is highly esteemed for mixing with other tanning agents.

The tannins in myrobalans appear to consist almost entirely of pyrogallol tannins, gallotannic acid being present; consequently the material blooms well. It gives a greenish-yellow colour to the leather and a porous tannage, so that it is not used alone but may be advantageously employed with materials such as hemlock, which yield a dark colour; it is much used with oak bark and valonia” (Blount and Bloxam, _Chem. for Engin. and Manuf._, ii., 377). Considerable difference exists in the proportion of tannin contained in the fruits. Specimens supplied from Madras, Bombay, Bengal and the United Provinces furnished percentages of tannin ranging from 13 to 38. It has also been shown that the fruit exhibits two well-recognised forms. The best qualities are known in trade to be oval and pointed, and of a pale greenish-yellow colour in section, solid in structure. The less valuable qualities are round and spongy. It has been ascertained that the oval form is simply a less mature condition. Some interesting facts regarding the commercial value of various samples of myrobalans are given by a writer in _Capital_ (Jan. 7, 1904). [Cf. _Ind. For._, xxx., 188–91.] “In English,” it is stated, “are five chief varieties of myrobalans, called after the districts in India from which they are obtained. These are (1) ‘Bhimlies’, from Bimlipatam in Madras; (2) ‘Rajpores’; (3) ‘Jubbelpores,’ from Jubbelpur in the Central Provinces; (4) ‘Vingorlas’ from the Bombay forests; and (5) ‘Madras Coast.’ The price and quality of these nuts vary exceedingly, whilst the opinion as to their actual value in the tanning trade is widely conflicting. Some tanners maintain that Jubbelpore myrobalans, or J’s, as they are technically called, are worth more than Bhimlies or B’s; while others are equally strong in their preference for B’s in comparison with J’s. Some tanners prefer the
light-green coloured nuts, which are higher priced than the others, while some like the dark or browner kind. One remarkable instance is recorded of a tanner who rejected a delivery as being darker in colour than the sample, and on arbitration secured an allowance of £1 per ton. It was afterwards found that the myrobalans were 3 per cent. stronger in tannin than the original sample, which in the opinion of the arbitrators was worth £1 a ton more than the delivered bulk. Some tanners buy myrobalans for their strength and cheapness, when compared with the price of oak bark and valonia, others use them on account of their brightening colour, while others use them because of the light-coloured bloom they deposit on leather."

In the Journal of the Society of Chemical Industry (1903, xxii., 1181–4, 1338) will be found an interesting paper by Dr. J. Gordon Parker and Mr. F. A. Blockley on the relative tanning values of different species and growths of myrobalans. The authors discuss (1) the content of tannic acid in various samples, (2) extent of bloom, (3) acidity, and (4) price of unit of tan in the samples examined. The tannic content was found to vary from 27.3 per cent. in a sample of Jabbalpur, to 38.4 in a sample of Bhimley. With regard to bloom, it was found that Jabbalpur and Vingorla myrobalans were much superior to other sorts, both in the amount yielded and the readiness with which their solutions deposited the same, while with regard to acidity, the Bhimley variety developed most and the Jabbalpur least. The value of the unit of tan per ton was found to be 4s. 3½d. in the most expensive variety (picked Bhimley), and 2s. 2½d. in the cheapest (Bhimley 2).

Trade.—Internal.—The Report of Forest Administration issued annually by the Inspector-General gives the exports from the forests under his control. The average for the five years ending 1902-3 came to 1,022,540 cwt., and for 1903-4 they were 1,299,600 cwt., valued at Rs. 42,10,288, or an increase of 4⅔ lakhs on the value of the preceding year. The internal transactions in myrobalans as registered by rail and riverborne traffic amounted in 1905-6 to 1,080,094 cwt., and in 1906-7 to 869,427 cwt. The chief exporting centres are the Central Provinces and Berar, Bombay, Rajputana and Central India, Bengal and Madras; the chief importing towns are Bombay, Calcutta, the Madras ports, and the importing provinces the United Provinces, and Bengal. Similarly the exports by coast in 1905-6 amounted to 218,146 cwt., valued at Rs. 4,62,454. Practically the whole of this export trade goes from Bombay to British ports within the province.

External.—The foreign trade is large and important. During the period 1900-7 the following quantities have been exported:—1900-1, 945,648 cwt., valued at Rs. 31,68,173; 1901-2, 1,085,174 cwt., valued at Rs. 35,63,652; 1902-3, 1,157,650 cwt., valued at Rs. 37,72,255; 1903-4, 1,229,609 cwt., valued at Rs. 42,10,288; 1904-5, 1,187,583 cwt., valued at Rs. 42,50,063; 1905-6, 1,206,398 cwt., valued at Rs. 44,60,676; and in 1906-7, 1,162,219 cwt., valued at Rs. 43,97,591. Analysing the figures of the last year, we find that of the total, Bombay exported 748,279 cwt., Bengal 292,816 cwt., Madras 121,123 cwt., while the chief markets, with the quantities received by each from India, were, in order of importance, the United Kingdom, 581,481 cwt.; Belgium, 200,729 cwt.; Germany, 191,669 cwt.; Austria-Hungary, 67,476 cwt.; and France, 46,304 cwt.

Pegolotti, La Prat. di Merc., 1343, 377; Januensis, Liber Serapionis, 1473, §§ 92, 105; Relaz. di Leonardo Cà Masser, 1505, 27; Mesua (ed. Marinius), 1562, 1075
THE CACAO PLANT

returns of Great Britain have ranged from 50 to 60 million pounds during the five years ending 1906, and these quantities have been returned at approximately 1½ million pounds sterling in value. The traffic in chocolate is much smaller in quantity, but of course relatively much more valuable, namely from 8½ to 10½ million pounds in weight and close on one million pounds sterling in value. In addition to these supplies of chocolate, there is the traffic in confectionery to which reference has already been made. The trade in cocoa butter is still smaller, but, as already mentioned, some proportion of the published returns of that substance must denote coconut “Cocoa Butter” and not “Cacao Butter.” Of the imports of raw Nibs, the British West Indies (especially Trinidad and Granada) head the list of supplying countries (17 million pounds on the average of the five years named); then come Portugal with 14 million (re-exporting, no doubt); Ceylon with 4½; France with 4½; Brazil with 3; and lastly, the British West African (Lagos) supply has expanded from 303,635 lb. in 1902 to 2,112,352 lb. in 1906. [Cf. De Candolle, Orig. Cult. Plants, 313; Agri.-Hort. Soc. Ind. (Trans.), 1839, iii., 39; vii., 127; 1840, viii., 81; (Proc.) 1843, ii., 208, 397, 443, 591; (Journ.) 1845, iv., 140; (Proc.) 1854, viii., 48; (Journ.) 1857, ix., 292; 1869, i., 83; (Corresp. and Select.) 1882, vi., 71; (Proc.) 31; (Journ.) 1886, vii., 20; (Corresp. and Select.) 29-40, etc.; Ceylon Cacao, Rev Bull., 1890, 170; also Honduras Cacao, 1893, 327; and Ecuador Cacao, 1899, 42, etc.; Cacao Indus. in Granada, West Ind. Bull., 1900, i., 416-22; also Art. Drying of Cacao, 1901, ii., 171-4.]

**Tinstone of India and Burma**

_TIN._—Ball, Man. Econ. Geol. Ind., iii., 313; Hughes, Tin Mining in Mergui, in Rec. Geol. Surv. Ind., 1889, xxii., pt. 3, 188-205; Holland, Rev. Min. Prod. Ind., 1898-1903, in Rec. Geol. Surv. Ind., 1905, xxxii., pt. 1, 90-3; 1907, xxxvi., pt. ii., 81. Tin is said rarely to occur native or as the sulphide (stannite). The commercial ore is known as the dent oxide, cassiterite, or “tinstone.” When pure this contains about 78 per cent. of the metal.

**Occurrence.**—Within India proper tinstone may be said to be but rarely found, but in Burma, more especially the southern portion of Tenasserim, it forms extensive and valuable deposits. According to Holland (l.c. 1905, 90-1), however, “tin has a wider distribution than is generally recognised, and its minerals are often overlooked through the difficulty in distinguishing them from other heavy minerals. Isolated crystals of cassiterite have been found recently in pegmatites associated with gadolinite in the Palanpur State, whilst in the Hazaribagh district of Chota Nagpur instances have been recorded of the accidental production of tin from river-sands by the Native iron-smelters, in addition to the recorded occurrences of ores in situ. The principal deposit, which has either been wrongly described or has received less attention than it deserves, occurs in the Palganj estate near the Barakar river.

“The only persistent attempts made to work tin have been in Burma, where cassiterite is obtained by washing river gravels in the Bawlake State, Karen-ni, Southern Shan States, and in the Tavoy and Mergui districts of South Burma. The work done on these deposits hitherto has been, however, on a smaller scale than might be expected from the favourable reports which have been made as to their extent and richness.”

He further states that the average outturn of tin-ore in South Burma, during the period reviewed (1898-1903), was 1,645 cwt., valued at £6,876, and in 1906, 1,919 cwt., valued at £13,574. “The metal is exported mainly, in the form of block tin, almost all of it going to the Straits Settlements. This, during the years 1897-8 to 1902-3, averaged 661 cwt. a year.” During the same period, Holland points out that the average consumption of foreign block tin in India itself was 24,959 cwt.; “the tin exported from
TIN

Indian Uses of Tin

Burma is a small quantity compared to the requirements of the country."
The average daily attendance at the tin mines in the Mergui and Tavoy
districts was 115 persons in 1905 and 141 in 1906.

Uses. — A salt of tin is a highly important material in certain methods of
dyeing, as practised in Europe, but in this respect it is apparently unknown to
the Natives of India. It has, however, been used from a very remote period in
Native medicine. [Cf. Dutt, Mat. Med. Hind, 1900, 69–71.] By certain classes,
especially the Muhammadans, the metal is also extensively employed in tinning-
copper vessels. Copper vessels, to be free from poisonous deposits, must be tinned
or kalai (in a single month, thus affording constant employment to a large number
of workmen, known as galai-gars or kalaigars, who are Muhammadans. In
Northern India, vessels which are tinned for the first time are boiled in a solution
of alum, verdigris, sulphate of copper and sal ammoniac. On subsequent occasions
they are simply coated with tin without any previous preparation save
that of removing the old kalai by scrubbing the vessel with ground kankar
(brick dust). Tin, reduced to powder, is mixed with sal-ammoniac and applied
by means of a piece of cotton, the vessel being heated on a charcoal fire. It is
then polished with sand and ashes.

Artistic Appliances. — Artistic manufactures, in which tinning forms a definite feature, assume
importance in several centres. Of these the most noted are Moradabad, Jaipur,
Peshawar and Kashmir. The art seems to have come from Persia, and is essen-
tially Muhammadan in origin (Ind. Art. at Delhi, 1903, 16). Tin metal is also
beaten into leaf or tinfoil, and, after being coloured with lac, is sold in that condition
and largely employed in the manufacture of cheap jewellery, tinsel decorations,
and as an adjunct in ornamental turnery. Powdered tinfoil may also be mixed
with lac to produce a metallic effect. Still another use to which the metal is
put may be mentioned, namely the preparation of certain alloys, such as that of
Bidri ware (Ind. Art., Lc. 46, 211, 217–8).

Trade. — Although the uses of tin are both varied and widespread,
relative to other items of trade the metal may be spoken of as comparatively
unimportant. And as already indicated, the supply consists chiefly of
that obtained from foreign countries. Imports for the period 1900–7
have been as follows:—1900–1, 22,741 cwt., valued at Rs. 22,03,360; 1901–2, 26,002 cwt., valued at Rs. 23,54,456; 1902–3, 28,000 cwt., valued
at Rs. 25,58,162; 1903–4, 40,486 cwt., valued at Rs. 39,29,787; 1904–5, 39,323 cwt., valued at Rs. 39,36,023; 1905–6, 21,152 cwt., valued at
Rs. 24,17,290; and 1906–7, 20,336 cwt., valued at Rs. 29,44,061. Analysis
of the figures for the last year, we find that 19,967 cwt. consisted of
unwrought (block) tin and 369 cwt. of wrought tin. Of the total imports,
Bengal takes roughly one-half, 10,864 cwt. in 1906–7, the balance being divided between Bombay, Burma and Madras. Of the unwrought
metal, practically the whole quantity comes from the Straits, viz., in 1906–7,
17,486 cwt., and the balance chiefly from the United Kingdom. It should
be noted, however, that a considerable shrinkage occurred in 1905–6, the imports from the Straits having declined by almost a half, and the total imports from 39,323 cwt. (in 1904–5) to 21,152 cwt.

It has already been mentioned that the exports go entirely from
Burma, and consist mainly of block tin. During the period reviewed by
Holland (1897–8 to 1902–3), these averaged 661 cwt. Since then the figures have been:—1903–4, 480 cwt., valued at Rs. 38,829; 1904–5, 457 cwt.,
valued at Rs. 38,268; 1905–6, 426 cwt., valued at Rs. 36,761; and 1906–7,
929 cwt., valued at Rs. 72,312. They have thus been increasing. Practi-
cally the whole of the exports are consigned to the Straits. Small quantities of foreign tin are also re-exported from India, chiefly from Bombay
to Persia and Turkey-in-Asia. The averages during the six years 1900–6
came to 1,500 cwt.; the actual in 1905–6 was 844 cwt., valued at Rs. 90,926.

Commenting on the production, consumption and prices of tin for the

1078
TORTOISE-SHELL

TORTOISE AND TURTLE, and Tortoise-shell Manufacture.—The two animals of chief importance that fall into this place are:—

The Natives eat the flesh but it is unpalatable to Europeans, though the eggs are regarded as equal to those of other turtles. One of the errors of commerce is to speak of “tortoise-shell”; the name should rather be “turtle-shell”; and though other species afford shells sometimes used as substitutes, this animal affords the true tortoise-shell. Its value depends on a warm translucent yellow colour, dashed and spotted with rich brown tints, and on the high polish which it may take. In China, shells with white ground and black spots that touch each other are most admired. The finest shell is obtained from the Western Archipelago, but is exported from the southern coast of the Indian continent, Ceylon, the West India Islands, and Brazil. The scales are detached from the turtle either by actual force after the animal is killed or by immersion in boiling water. If taken from the animal that has died a natural death or after decomposition has set up, the shell becomesclouded and milky. From very earliest times tortoise-shell has been a prized ornamental material. It was brought from the East to ancient Rome by way of Egypt, and was used as a veneer for furniture. Vincent (Periplus, etc., 1800, app., 48) says that in the time of the Periplus the art of shell was largely traded in, being procured from Africa, Socotra, Malabar, Laccadive and Maldives Islands, etc. In modern times it has been employed in Europe for the characteristic inlaying work known as Buit Marquetry. It is used as a veneer for small boxes and frames and moulded into snuff-boxes and cigar-cases, also formed into knife and razor handles or cut into combs. Vizagapatam may be said to be the chief Indian locality where tortoise-shell is utilised in ornamental work. [Cf. Fryer, New Acc. E. Ind. and Pers., 1675, 211; Ovington, Voy. to Suratt, 1689, 517; Milburn, Or. Comm., 1813, i., 03; Bruce, Travels, v., app., 215; Brandt and Rätzsch, Medicin-Zoologie, 1829, i., 181–98, tt. xxii., xxiii.; Journ. Bomb., Nat. Hist. Soc., 1897, x., 153; Watt, Ind. Art at Delhi, 1903, 153–6, 193–4.]

C. mydus: Boulenger, i.c. 48.

The Green or Edible Turtle or the leik-pyen-won or leik-kye of Burma. This is a herbivorous animal found in the tropical and sub-tropical seas, though rare in the Bay of Bengal. Its flesh forms an important article of food, though at certain seasons it is said to become poisonous. The turtle of the Indian seas is believed to rival in size and flavour that of the Atlantic. The eggs are very rich and have a taste somewhat like marrow: they may be kept for weeks even

THE SINGHÁRA NUT

when exposed to the air (Crawford, Journ. to Ava, 1834, ii., 178; Collingwood, Rambles of a Nat., 1868, 426.)

The following are species of less value:

Emyda granosa: Boulenger, l.c. 17. The bungoma is a river turtle found in the Indus and Ganges. Its flesh is eaten.

Testudo elegans: Boulenger, l.c. 21; Rice, Gaz. Mysore, 1877, i., 157. A land tortoise, found all over India except Lower Bengal. Its flesh is eaten by the Natives, and in Burma is especially esteemed as a delicacy. [Cf. Terry, Voy. E. Ind., 1655, 9.]

TRAPA BISPINOSA, Roxb.; Fl. Br. Ind., ii., 590; Duthie and Fuller, Field and Garden Crops, iii., 32-4, t. xcvi; Cooke, Fl. Pres. Bomb., i., 518; Duthie, Fl. Upper Gang. Plain, 1903, 358; Prain, Beng. Plants, 1903, i., 508; ONAGRACEÆ. The Singhára Nut, Water Chestnut, singhára, paníphal, gáiní, shingódá, kúbyakam, karím-polam, etc. A floating herb, found in lakes, tanks and pools throughout India and Ceylon; often specially cultivated for its edible fruit. [Cf. Cyperus esculentus, p. 465.]

This aquatic plant has been grown in India from the most ancient times. Ball suggests that it may be the edible fruit which García de Orta describes under the name das caceres (1563, Coll., xi.; also in Proc. Roy. Ir. Acad., 3rd ser., 1889-91, i., 397), but that I am disposed to regard as a mistake. It is, however, mentioned in the Ain-i-Akbari (1599) as one of the crops on which revenue was levied (Jarrett, transl., 1891, ii., 65). In certain parts of the country the kernels are ground down and employed for making the coloured powder (gudal) used during the Holi festival. The flour, moreover, is considered by the Natives a cooling and useful article of food in bilious affections and diarrhoea, and it is in addition employed in the preparation of poultices. Both the kernels and the flour from them are largely used as food, and in all localities where the plant occurs in any quantity. In fact it may be said to be extensively cultivated, e.g. in Kashmir, the United and Central Provinces, etc. For this purpose the fruits or nuts are scattered over the water at the end of January and pressed into the mud. In a month they begin to throw out shoots, and in June the plants are thinned out and transplanted. The nut forms under water in October, and is gathered in November and December. A highly instructive account of singhára cultivation will be found in Sir Walter Lawrence's Valley of Kashmir (1895, 72. 345, 354-5). He speaks of it as less cultivated now than formerly. Moorcroft (Travels, 1823, ii., 136, 227) estimated the production at 384,000 maunds of nuts a year, but in Lawrence's opinion the production to-day might be more safely returned at 100,000 maunds. He observes, "Of the chief varieties the best is called basmati, in honour of the rice of that name. The basmati is a small nut with a thin skin, and gives one-third of kernel for two-thirds of shell. The dogru is a larger nut with a thicker shell, and the kangar has a very thick shell with long projecting horns and gives the least kernel of all."

A more extended cultivation of the singhára nut in all localities where water abounds has been advocated at various times, and experimental cultivation in the reservoirs and lakes of the Madras Presidency has been specially recommended. The kernel abounds in starch, and is eaten either raw or cooked, especially by Hindus. It may be boiled whole, after soaking a night in water, roughly broken up and made into a sort of porridge, or ground to meal and made into chapattís. [Cf. Paulus Egineta (Adams, Comment.), iii., 378; Jones, As. Res., ii., 350-1; Forster, Travels, 1798, ii., 29; Sloeman, Rambles of an Official, 1844, i., 101; Fortune, Tea Dist. of China, 1853, ii., 11; Journ. Agrí.-Hort. Soc. bitaceous plants, several species of which are cultivated throughout India for use as vegetables.

T. anguina, Linn.; Duthie and Fuller, Field and Garden Crops, ii., 45, t. xlvii. The Snake Gourd, purul, chichinga, jhakhinda, galar tori, pandol, rekhri, padeul, linga potta, etc. An annual creeper, considered by De Candolle to have been originally wild in India and the Indian Archipelago. It is cultivated throughout India as a rainy-season crop. The long cucumber-like fruit is eaten as a vegetable, either boiled or in curries. Gathered when very young and cut into strips, it is extensivelcooked in the same way as French beans. [Cf. Woodrow, Gard. in Ind., 1903, 330; Firnberger, Man. Gard. Ind., 1904, 172.]

T. cucumerina, Linn.; Kirtikar, in Journ. Bomb. Nat. Hist. Soc., 1892, viii. 487–8, t. E. The jangli-chi-chondla, banpatol, guat kaki, ran parul, ranô-chapadvali, kattup-pêpudal, adavi-potta, etc. A climbing annual, found throughout India and Ceylon. It has various medicinal qualities ascribed to it, and the tender shoots, dried capsules, seeds, leaves and roots are all used in native medicine. The ripe fruit is said to be eaten and by the Natives. [Cf. Pharmacog. Ind., 1891, ii., 78–4.]

T. dioica, Roxb.; Duthie and Fuller, l.c. iii., 23. The parwar, potol, kombudpadalai, kommu-potta, patolam, etc. An extensive climber common throughout the plains of Northern India, from the Panjäb to Assam and Eastern Bengal. It is extensively cultivated during the rains. In Bengal, cuttings are planted at the end of the rainy season and fruiting goes on from March to September, after which the crop may be kept for a second year by ploughing and weeding in October and irrigating in February and March. Mukerji estimates the cost of cultivation in Bengal at Rs. 20 per acre and the outturn at 100 mounds, worth about Rs. 60. The leaves, fresh juice, and the fruit and root are all used medicinally, while the unripe fruit is eaten by the Natives and the tender tops are used as a pot-herb. The young or unripe fruit is valued by Europeans, and next to potatoes and brinjals is perhaps the vegetable in greatest favour. [Cf. Banerjei, Agri. Cuttack, 1893, 117; Dutt, Mat. Med. Ind., 1900, 169–71; Mukerji, Handbook Ind. Agri., 1901, 347–8; Firnberger, l.c. 172; Roy, Crops of Beng., 1906, 143–5.]

T. palniata, Roxb.; Kirtikar, l.c. 71–6, t. B. The lâindriyam, máká, parwar, kavaudal, kavandala, korattai, avvaguda-pandu, etc. A very large climber, common in moist thickets from the Himalaya to Ceylon. The fruit and root are medicinal, and the former, though inedible in the wild state owing to its severely drastic properties, may under cultivation become a wholesome vegetable, when well boiled. [Cf. Pharmacog. Ind., l.c. 70–2; Woodrow, l.c. 330–1.]

TRIGONELLA, Linn.; Fl. Br. Ind., ii., 85–9; Prain, Beng. Plants, 1903, i., 413–4; Duthie, Fl. Upper Gang. Plain, i., 208–10; Leguminosae. A genus of annual herbs that comprises some 50 species, two of which only are of economic interest in India.

T. corniculata, Roxb.; Fl. Ind., iii., 359; Hamilton, Stat. Acc. Dinaj., 104. The lunkaika, përing. Cultivated as a pot-herb. Hamilton observes that it is as good as spinach and is cultivated in the same manner.

T. Fênüm-Græceum, Linn.; Duthie and Fuller, Field and Garden Crops, iii., 46, t. xceix. The Fenugreek or Fenugreek, méthi, haenugreek, shamlí, bhají, vendayam, mentulu, ménthyá, ulava, pe-nán-ta-ra, etc. A robust annual herb, wild in Kashmir, the Panjäb and the Upper Gangetic Plain; cultivated in many parts, particularly in the higher regions.

No estimate can be given of the area under the crop, except in Bombay (including Sind) and Berar, where, according to the Season and Crop Reports, it occupied 2,713 acres and 510 acres respectively during 1904–5. Subsequent areas do not appear to have been recorded. It is grown near wells and on salâb lands. On well lands, it is generally sown after cotton or jítulo. The seed (30 lb. per acre) is sown in February and the crop is ready to cut in April. On salâb lands it is sown at the end of October or beginning of November, and the crop ripens about the same time as on well lands. The seeds yield a yellow Dye, and the plant has been known and valued as a Medicine from remote antiquity. It is grown chiefly as a food and fodder crop, and as a perfumr. [Cf. Paulus Egineta (Adams, Comm.), 184., iii., 373–4; Serapion, De Simpl., 1473, § 171; Takef Shereef, 1050 (Playfair, transl.), 1833, 1081.}
WHEAT PLANT

Indian Names.

Wheat (froment, Fr.; weizen, Germ.) has numerous Indian synonyms. The grain would appear to be most widely known in Sanskrit by the name godhuma, and according to Dutt (Mat. Med. Hind., 269), “three varieties of wheat are mentioned in the Bhāvaprakāsā, namely mahāgodhuma or large-grained, madhuli or small-grained, and nihsuki or bearded.” The first, we are told, came from the West, and the second was indigenous to India. The most general vernacular names are often closely connected (like the Persian gandum) with the Sanskrit godhuma, thus—gēhūn or quin, gahu, ghūm, gahum, gavum, gom, gam, gīh, kanak, kank, rozatt, dro, do, zud, gandum, godumai, gōdu-mulū, godhi, kōtānpam, gıyonsaba, etc., etc.

History.

—The cultivation of wheat, says De Candolle, is prehistoric. It is older than the most ancient languages, each of which have independent and definite names for the grain, such as the Chinese mai and the Hebrew chittah, etc., in addition to the Sanskrit names already mentioned. The Chinese grew wheat 2700 B.C. Heer found a small-grained wheat in the deposits identified with the earliest lake-dwellers of West Switzerland—date about the time of the Trojan war or earlier. Unger detected the same grain in a brick of the pyramid of Dashur in Egypt, to which he assigned the date of 3359 B.C. Another form of wheat has been found in the less ancient deposits of the lake-dwellers of Switzerland and Italy (Stone Age), and still a third or intermediate form at Aggtelek in Hungary. According to Hackel, the wheat found in the most ancient of these deposits is T. dicoccum. This is a summer wheat grown occasionally in Southern Germany, Switzerland, Spain, Servia and Italy, and used largely in the manufacture of starch. The more recent forms, that author identifies as belonging to T. monococcum. Hitherto it has been affirmed that the wheats found in association with the lake dwellings were quite distinct from any known modern wheats, but Hackel’s determinations would seem to remove that impression, while confirming the belief that the wheat named preceded the appearance of those which constitute the bread wheats of to-day.

On the authority of Berosus—a Chaldean priest—wild wheat is accepted as having been seen in Mesopotamia. But similarly, the evidence of Strabo (who lived 50 B.C.) is often given as supporting the belief that wild wheat had been discovered in the Indus valley. In another place (p. 823) I have produced evidence, however, in favour of the idea that the wild plant that looked like wheat—which Strabo spoke—may have been Oryza corveta, and not wheat at all. Other early references to wild wheats might still be given, but their value may be questioned when it is added that no modern botanist has recorded the discovery of wild wheat, nor, in fact, given any very satisfactory evidence of feral wheats (that is to say, of wheats that had survived in a self-sown condition from former cultivation). The authentic cases of wild wheat recorded by modern travellers, so far as can be ascertained, are unconnected with the true wheat.
VARIETIES AND RACES

Modern wheat would appear to be a product of cultivation of which little trustworthy evidence exists as to its origin, except perhaps that it is more closely connected with Asia than with Europe.

A remarkable silence may be said to characterise the writings of European authors regarding wheat cultivation in India, until well into the 18th, if not the beginning of the 19th century. Perhaps the earliest references are found in the records of provisioning the ships which in 1667 sailed from England to the East. These were commanded by William Keeling and William Hawkins, the latter, on reaching Surat, having had instructions to proceed on a mission to the court of the Great Mughul. In the list of articles supplied to the Pinnacle, we read of so many "bushels of Steale Wheato" (see p. 250). Sir George Birdwood, in a footnote to the above passage (E.I.C. First Letter-Book, 90), says that it was French wheat that the ships took on board, the word "Steale" being probably derived from the "steelines and hardnes" which was supposed to be the peculiar property of the foreign-grown commodity, and to make it therefore more suitable for the manufacture of biscuits for long voyages. The passage may be accepted as suggestive of the early introduction from Europe of some of the forms of hard wheat presently grown in Western India, as for example the *spelt.*

But if that be so, a very different story is given by Terry (Voy. E. Ind., 1855 (ed. 1777), 87), who speaks of the wheat of Surat as "more full, and more white than ours, of which the inhabitants make such pure, well-baked bread, that I may say of it, as one sometimes spoke of the bread made in the bishoprick of Leige, it is panis pane melior, bread better than bread." So also Fryer (New Acc. E. Ind. and Pers., 1672-81, 110) mentions the Deccan as possessing "wheat as good as the world affords." It is, however, significant that Milburn (Or. Comm., 1813) makes not the slightest reference to Indian or Eastern wheat, though under most commodities he gives important chapters, such as The Present State of the Tea Trade, The Rise and Progress of the Trade in Sugar, etc.

Species, Varieties, and Races of Wheat.—The distinction between Spring wheat (*T. aestivum*) and Autumn wheat (*T. hibernum*) can have no importance, since these names do not denote structural differences, and, moreover, are interchangeable climatic conditions according to the country where grown, and even in the same locality, according to the dates of sowings. If gradually changed, the autumn sowings being year by year made a little later, and the spring a little earlier, autumn wheat may become spring wheat, and vice versa. A wheat sown in the autumn in the plains of India, if carried to the temperate Himalaya or to Europe, would have to be treated as a spring wheat.

In point of actual botanical priority, however, the name *T. aestivum* should be given to both spring and autumn wheats; in other words, to all the wheats that by Lamarck were called *T. saticum,* and by Villars *T. vulgare.*

According to some writers, the assemblage of the so-called true wheats has been evolved from *T. monococcum* (Vilmorin, l.c. 21, t. 156), a plant indigenous to Servia, Asia Minor, the Crimea and the Caucasian area of Mesopotamia. As its botanical name implies, it is characterised by the presence of but a single seed within the little ear, and its other structural characters place it as a form of spelt rather than of wheat proper; indeed it is often called "small spelt." It has a pale green colour and a flat, short ear. It is, however, still cultivated in Spain, and more rarely in France and Germany. The grain is not often used for bread, but rather for mush, and the plant is valued as a cattle fodder. The yield is said to be from 25 to 35 bushels an acre. Vilmorin would appear not to have been successful in his attempts at crossing this with other wheats. Moreover, Hackel and most modern authors regard it as quite unconnected with the true wheats, and entirely infertile with them. Hackel accordingly refers the important grain-yielding forms of *Triticum* (apart from *Ergot,* the following chief forms: *T. monococcum,* *T. saticum* and *T. Polonicum.* Having isolated *T. monococcum* by itself, he then proceeds to speak of *T. saticum,* and observes that under cultivation many races have been produced, of which those with the rachis articulated are most probably nearest related to the original stock, whatever that may have been. The brittle-
THE WHEAT PLANT

TRITICUM
VULGARE

Races:

Sativum

Spelta.

(A) Rachis articulated at maturity and grain firmly enclosed by the glumes:

(a) spikes loose, almost four-sided = *T. sativum*, var. *spelta*, and (b) spikes very dense, laterally compressed = *T. sativum*, var. *dicoccum* (= *T. amyleum*). Seringe, also Vilmorin, loc. 21, tt. 152, 154). Two-grained spelt, is grown in certain parts of Southern Europe and is sown in spring. Its grain is used chiefly in the manufacture of starch.

Both the forms (or groups of forms) thus indicated approximate closely to *T. monococcum*, however, and according to De Candolle and other writers, that species may be but the ancient form of the spelt wheats (*Spelta* and *dicoccum* just mentioned).

Spelt wheat (*T. Spelta*, Linne, Vilmorin, loc. 20, 146, 148, 150) is, in fact, one of the oldest grains, and there are awned and awnless, hairy and glabrous, also white, grey and reddish-coloured forms of it. It was in ancient times the chief grain in Egypt and Greece and was cultivated everywhere throughout the Roman Empire. Its cultivation has been largely discontinued, and, except in Southern Spain, is unimportant in Europe. In India its cultivation is met with from Sind to Mysore, especially in Bombay. Apparently the first definite intimation of the existence of this wheat in India was made by Buchanan-Hamilton, and subsequently by himself in the *Journal Royal Agricultural Society of England* (1859, xxiv., 36-8). A long and interesting account of it was published by the late Mr. E. C. Ozanne in the *Statistical Atlas of Bombay* (an account reprinted by Lisebo, List, Bomb. Grass., etc., 1896, 129-30). It is known in India as *kapla* (or *kaphli*), a name which is said to denote the difficulty experienced in separating the grain from the husk. It is also called by other names, such as *jod*, *hotte godhi*, and *pamban*. Its value lies very largely in the fact that it is grown during the *kharij* season, all the other wheats being *rabi* crops. Hamilton speaks, however, of two seasons of cultivation in Mysore. It can be profitably raised on poor soils, where the other wheats could not be grown. Its demands, says Hackel, are less, its liability to disease lower, and the grain being firmly retained within the glumes, makes it proof against the attacks of birds. According to Hamilton, *T. monococcum* (*race godhi*) and *T. Spelta* are the two wheats of Mysore, and Mallison, in the opening paragraph of his article on wheat (*Textbook Ind. Agri.*, 1901, iii., 24), mentions *T. monococcum* as a wheat "said to be cultivated." (See Mysore below, p. 1059).

This leads now to the consideration of Hackel's group—

Sativum

*tenax*.

(B) Rachis not articulated at maturity, grain visible between the open fruit glumes and thus readily falling out. This he distinguishes as *T. sativum*, var. *tenax*, which he further says is referable to four imperfectly characterised races. These may be indicated thus:

1. *Empty glumes distinctly keeled on the upper half, rounded below*:
   * Spikes long, more or less loose in *T. sativum*, race *vulgare* (Vilmorin, loc. tt. 28-122).
   ** Spikes short, dense, distinctly four-sided in *T. sativum*, race *compactum*.
2. *Empty glumes, sharply keeled at the base*:
   *** Fruit short, thick, not compressed in *T. sativum* race *furcidentum* (Vilmorin, loc. 18, tt. 28, 130, 132, 134).
   **** Fruit oblong, narrow, somewhat laterally compressed and acute in *T. sativum*, race *durum* (Vilmorin, loc. 19, tt. 136, 138, 140, 142).

Races:

Vulgare.

In this place it may be useful also to dispose of *T. Polonicum* (Vilmorin, loc. 20, and t. 144)—Polish wheat. It is a very striking species with large compressed, mostly bluish-green (glaucescent) spikes, readily distinguished by its empty glumes, which may be one inch long and enclose all the flowers of the spikelets. Hackel suspects that it is, perhaps, not a true species, but may have originated by culture. But Poland is, however, by no means its native country. Perhaps Spain, where it is still cultivated on a large scale, has a stronger claim. It is also met with in Italy and Abyssinia, but apparently is not grown in India. It much resembles in its long and slender fruit some of the forms of rye, and is in fact, often sold under the name of Giant Rye.

The race to which Hackel thus restricts the name *vulgare* embraces numerous forms, such as awnless and bearded, naked and hairy, white, bluish and reddish spikes. It is perhaps one of the oldest of the modern wheats and the most valuable in Europe, America, India and Australia. Several hundred forms
of this wheat have been described. They are commonly grouped into red and white. The white, as a rule, requires a good soil and a dry climate. The red can endure much wet weather, but the red and white forms are interchangeable with altered environment. A better classification is perhaps into beardless and bearded forms.

The race compactum—the dwarf or hedgehog wheats (the latter name being given to the awned forms)—is cultivated in the Austrian Alps, Wurttemberg, Alsace, Switzerland, Chili, Turkestan and Abyssinia. They are specially adapted to stony regions, and are at the same time profitable on soils where other wheats could not be grown. They have short stiff awn.

The form to which the name Turgidum of Rivet Wheat has been assigned is generally designated English Wheat on the continent of Europe. It has dense, four-sided spikes, the leaves are broader than in vulgare and usually velvety, and it affords long, rigid, nearly useless awn. The grain is generally red-coloured, short and thick, with a blunt apex. It is rich in starch but poor in gluten, and for bread-making the flour has to be mixed with more glutinous wheats. This class of wheat is largely grown in the Mediterranean countries, more rarely in England and Germany. English wheat gives a good harvest, but the flour is poor in gluten and usually greyish in colour. The so-called Miracle Wheats (Egyptian wheats) constitute a sub-race under compositum and have branched spikes.

Lastly, the race or group of forms designated durum comprehends all the hard spring or flint wheats—the Macaroni Wheats. They are recognizable by their long, bristling awns, almost solid culms, very hard, pointed, usually vitreous, rarely mealy grains, and often black awns. Cultivated in the Mediterranean countries and Asia Minor, and are most important in Spain and Northern Africa. The grain is specially rich in gluten, hence their being largely used in the manufacture of macaroni.

At the third Hybrid Conference held in London during 1906, Philippe de Vilmorin of Paris put the position regarding the origin of the forms of wheat thus: "When my father began, in 1878, cross-fertilisation between the different types of wheats, the object he had in view, and which he fully proved, was that all our wheats—with the exception of Triticum monococcum—came from one and the same common origin. In consequence of his experiments, he was able to base his argument on two well-proved facts, namely:—(1) that the six species (T. sativum, Lam., T. turpium, Desf., T. Poloncum, L., T. spelta, L., and T. amylaceum, Ser.) of cultivated wheats can be crossed amongst themselves and give products indefinitely fertile. (2) That on crossing any two of these six, the other four may appear among the results."

Only the briefest possible abstract has been attempted in the foregoing observations regarding the classification of the varieties and races of wheat usually adopted by writers on this subject. The student who may wish fuller details should consult Körnicke and Werner (Handbuch des Getreide baues, 1885, ii., 209–529), where it will be seen several hundred forms are discussed.

**Practical Aspects.**—From the study of an extensive series of Indian specimens sent to London, some years ago, the late Dr. Forbes Watson propounded the following classification:—(1) white, soft; (2) white, hard; (3) red, soft; and (4) red, hard. The vernacular term pissi usually denotes soft wheats, and these are the wheats chiefly exported from India. To a certain extent these four groups are cultivated side by side in the same district, but on the whole a geographical isolation may be perceived. Northern India, for example, produces mainly soft wheats, while Southern India and Bengal grow mainly hard forms. The cultivation of the finer
qualities of soft wheats would appear to be for the most part comprised within the upper basins of the three great rivers—the Ganges, the Indus, and the Nerbudda. South of the Nerbudda, the true soft wheats may be spoken of as very nearly unknown. The prevalent wheats of the United Provinces and of some parts of Bihar and Tirthut are soft white, and of the Panjab soft red. Some years ago the late Col. Wace estimated that out of the 7 million acres of wheat then in the Panjab, 5 million were under soft red wheats. But the soft red extends farther to the south than the soft white. Hard wheats predominate in the Deccan, Berar and some parts of Bengal, and the less valuable form, hard red, extends farthest to the south, and is the only wheat capable of cultivation in the moist climate of the lower Gangetic delta, in Orissa and in Burma. In many parts of the Bombay Presidency, south to Mysore and Madras Presidency, an extremely hard red wheat becomes prevalent, namely that already mentioned under the name spelt.

Prain (Note on Races of Beng. Wheat, in Dept. Land Rec. and Agri., l.c.) discusses the value of the characters based on the consistence of the grain—the hard and soft; also the distinction according to colour—white and red; and lastly, the condition of bearded and beardless grains. He finally comes to the conclusion that little reliance can be placed on such distinctions taken by themselves. He, however, points out that white or grey wheats, whether soft or hard, have, as a rule, distinctly broader leaf-blades than have the red wheats, and adds that in Bengal the wheats grown are practically all bearded. Summing up his observation of these aspects, Prain comes to the conclusion that Watson's classification, which combines consistence and colour of grain, is of practical value. The soft white wheats of Bengal are called dudhia; the soft red wheats, jámáli; the hard grey wheats, gangájuli, and the hard red, kheri. Mukerji (Handbook Ind. Agri.) mentions fifth and sixth forms, namely píusa and nanbia.

In the United Provinces the dawdi wheat is spoken of as the finest. Mundia denotes a white, soft wheat of good quality, which is beardless. This wheat is met with here and there: thus Russell alludes to it in his Gazetteer of Damoh as grown in embanked fields, since it requires more moisture and is less liable to rust than the bearded wheats. The account given by F. G. Sly of the wheats of Hoshangabad (Rept. Land Rev. Settl., 1891-1905, 26-7) is probably more or less applicable to the whole of the Central Provinces. "The principal kinds of wheat grown are píssi, soft and starchy, white; jalalia, hard and glutinous, white; daodia, soft and starchy, white; saharia, soft and starchy, white; kathia, hard and glutinous, red; and banasi, hard and red. All kinds are bearded, no beardless wheat being grown, which cultivators say is because birds attack it more freely. At present no less than 80 per cent. of the wheat sown is píssi, whereas at last Settlement píssi is described as an inferior kind, little sown, jalalia and kathia being grown in about equal proportions. This remarkable change has been brought about by the export trade, píssi being in the greatest demand. Jalalia is still preferred for home consumption, because it makes better suji." The cultivation of white soft wheats in most provinces of India has greatly expanded with the foreign demand.

G. A. Gammie (Provis. Class. of Ind. Wheats, l.c.) subordinates the characters based on the consistence and colour of grains to the presence...
or absence of a beard. He forms six sections:—two of which are beard-
less and correspond, he says, to *T. hibernum*, Linn. (i.e., tt. i., ii., iii., iv.).
These would appear to be for the most part white wheats both soft and
hard, though one of them, the *jonaria* group, is described as hard red,
and the illustration shows it to be shortly bearded (certainly not
beardless). Gammie's third section he designates as the *kili kushal,
bakshi or kahno* wheats, which he identifies with *T. pilosum* (l.c. t. v.).
In these, the spikelets are velvety, bearded, and the grains described as
hard white, yellow or red. The *bakshi* wheats are almost confined to
Bombay, more especially the Deccan, and are not met with in the Konkan.
Then the fourth and fifth sections are also bearded wheats, which Gammie
regards as being forms of *T. aestivum*, Linn. The former he calls *popatia*
wheat (l.c., t. vi.), a form met with mostly in Bombay and the Central
Provinces, and possessed of hard yellow or hard red grain. The latter he
designates the *dauddkhan* wheats (l.c. t. vii.); these are shortly bearded
and the grains soft white, hard white or hard red. They are met with
in the Panjab and, Gammie says, may be viewed as the transitional
forms between the long bearded and beardless wheats. Lastly, his sixth
section (l.c., t. viii.) embraces the various forms of *kappli* already discussed
(p. 1084). These, he says, are awned and have a covered, hard red grain.
An American correspondent of Gammie's, it would seem, had identified
the Bombay *kappli* to be the same as *Emmer* wheat of Siberia—"a
variety used to transmit rustproof qualities." But in 1903, Gammie tells
us, the *kappli* "became decidedly rusted, so that it has now lost its long-
maintained reputation of immunity."

Hybridised and Pedigree Wheat.—The improvement of the stock
of wheat has for many years been recognised as an essential feature of
rational cultivation. Recent research would seem to show, however, that
not only better but more immediate and more enduring results are likely
to be attained by hybridisation of stock than by the tedious process of
selection that hitherto has resulted in what are known as pedigree wheats.
It is, in fact, not enough to know the species and varieties of *Triticum*; it
has become imperative to be able to recognise the races and to successfully
cross these in directions ascertained to secure the fixation of properties
of value in direct adaptation to environment. For example, the property
of certain flours, known technically as "strength," that is to say the
capacity to afford a large loaf, has been established as a racial character-
istic that may be secured by the adoption of certain stocks, or by their
utilisation in hybridisation. At one time it was assumed that strength
was due to manuring, to methods of cultivation, to soil and climate, or
to season of reaping, but each and every one of these opinions have
been tested and found unconnected with the production of "strength." All
English wheats are admittedly deficient, but Red Fife Wheat (among
others that might be mentioned) has been found not only to possess
that property, but to preserve it when grown in England, and to trans-
mit the same when employed in crossing with standard English wheats,
such as Golden Drop. [Cf. Hall, in *Journ. Board Agri.* , 1904, xi., 321-
33; *Rept. Confer. on Genetics*, Roy. Hort. Soc., 1906, 384.] In a brief note
by Howard (*Agri. Journ. Ind.*, 1906, i., pt. iv., 401–3) it is very properly
urged that the first step toward improvement is to secure uniformity.
He has accordingly pointed out that in India it is not uncommon to
find wheat not only grown mixed with barley, gram and other such

- **Semolina.**
- **Biscuits.**
- **Maida.**
- **Bread Mixtures.**
- **Cement.**

**Properties and Uses.**—The methods of employing wheat for human food in India vary somewhat in the different provinces. From the grain, three chief kinds of flour are made, viz. suji, maida and ata. The first is a granular meal obtained by moistening the grain overnight, then grinding it. The fine flour passes through a sieve, leaving the suji and bran above. The latter is got rid of by winnowing, and the round, granular meal or suji remains. This preparation may be described as a form of semolina, and is most easily produced from the hard wheats rich in gluten. It is employed in confectionery, and in place of oatmeal in making a kind of porridge. The hard white wheats are also valued in the preparation of macaroni. Maida and ata may be prepared from the flour separated in the preparation of suji by regrinding it and passing it through a finer sieve than used formerly, the finer flour that passes through being maida and the coarser ata. They are, however, most largely prepared without going through the process of separation of suji, the dry grain being at once ground and sifted into the two qualities. Maida is the luxury of the rich while ata is the flour of the poor and is generally cooked in the form of coarse cakes—chapattis—toasted by the side of an open fire. These are eaten along with dal and ghi or other relish, and constitute the chief food in the wheat-consuming tracts of India. In many localities, however, the ata is not obtained from pure wheat but from a mixture of wheat, barley or wheat-grain, the two grains being ground in the mixed form—a habit that has led to cultivation of the mixed crops already alluded to and also to the sale of the mixed grains, a condition by some persons incorrectly regarded as deliberate adulteration. In the larger towns of India, bread and biscuits, prepared from flour leavened and baked in the European fashion, have come greatly into use and seem destined to even more general consumption. But the fermenting of wheat flour in the manufacture of bread seems to have been unknown prior to the advent of the Europeans. The uses of wheat in the arts and medicine need hardly be detailed. Wheat starch is, as a rule, too expensive for extended use in India. Like that of rice, the gluten mixed with fine lime is employed as a special cement.

For microscopical results consult Hanousek (Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 37, 334-49).

**Adulteration.**—The opening of the Suez Canal brought India into direct touch with Europe and demonstrated the possibility of Indian wheat and other foodstuffs being conveyed to Europe in thirty days. Prior to 1870, no mention occurs of India's participation in the world's supply of wheat. And when it did appear in the corn markets of Europe, it was viewed by many as introducing an undesirable disturbing element which it became necessary to ward off rather than to encourage. The delusion that rice was the staple food of India, and, therefore, her chief agricultural (food) crop, seems never to have been more rudely dispelled than by the emphatically demonstrated fact that India not only grew wheat, but was prepared to contest certain markets and to land special wheats at a price lower than they could be produced elsewhere. This was first met by the outcry that, for greed, the better classes of the community were exporting the surplus stocks that formerly were stored against times of scarcity and famine. When this failed, the tendency to uncleanly wheat, instead of being removed by emulation, was stereotyped.
ADULTERATION OF INDIAN WHEAT

into "refraction"—in other words, percentages of impurity were standardised as unavoidable and therefore permissible, below which no enhancement of price was paid but above which deductions were authorised. The practical effect of this system was the payment of freight on mud and the charges for cleaning in Europe, both of which told against India's success as a wheat-supplying country for Europe. Viscount Cross, at a meeting held at the India Office in 1889, pointed out that an enormous amount of dirt was in this way imported annually and freight paid on it as if it were wheat. Assuming an average of 5 per cent. adulteration, that would come, on the 1905-6 exports of wheat conveyed to the United Kingdom, to half a million cwt. of mud, on which freight and other charges had to be paid. Voelecker (Improv. Ind. Agri., 277-8) and others have shown that this state of affairs is in no way due to bad cultivation nor to careless threshing on the part of the Indian cultivators, but is entirely a consequence of deliberate adulteration to suit the requirements of the English corn trade. A similar state of affairs characterised the American wheat trade, since the wheats that first came into Europe contained as much as 10 per cent. of prairie oats, rye and other impurities. It was sold on a standard of "fair average quality" (f.a.q.). But the American producers soon saw the necessity for reform and turned out a clean wheat, and were thus able to establish the standards of sale on their own side of the Atlantic. So far, India has failed to attain that position, though more than one effort has been made to remedy the evil of adulteration both by the Government of India and the Indian merchants.

In an official dispatch, dated November 29, 1906, the Government of India sum up the present position and then add that "The replies received have been considered, and the Government of India now feel justified in announcing for general information that, if buyers of Indian wheat desire to obtain regular supplies containing not more than 2 per cent. of impurities (that term covering all foreign matter other than food-grains) the mass of Indian shipments can be made on that basis."

By the opponents to reform, it has been upheld that Indian wheat is of necessity less pure than the wheats of Europe, America and Australia, due to the imperfect methods and appliances of the Natives; that accordingly it has to be washed, and may as well contain 2 per cent. impurity as one. But if the shippers are prepared to do the cleaning in India, a saving in freight would be effected that might go a long way toward covering the cost of cleaning and, moreover, Native methods might easily be improved. The demand for pure wheat to be made by the buyers in Europe would accordingly seem the natural and only solution of the present anomalous state of affairs, if the further position be not upheld as the ultimate result of the controversy, namely the expansion of the milling interests of India and the export of flour in place of grain (see p. 1101).

Seeds found in Wheat.—The seeds obtained during Indian wheat screenings are gram, polygonum, rape and piazi—the last being a species of Asphodelus, which in the Panjáb is often very prevalent in the wheat-fields—especially in the Jhelum districts—and to such an extent as to give much trouble to the cultivators. [Cf. Howard, Agri. Journ. Ind., 1907, i., pt. iv., 403-5; ii., pt. ii., 210.]
TRITICUM VULGARE

Yield

CULTIVATION.

Range of Seasons and Crop Adaptations.—The antiquity of wheat cultivation in India can be at once realised by the evident direct adaptations of the forms of the crop grown to the varied conditions of soil and climate under which produced. As indicative of this wide range of racial adaptations to climatic and other conditions, the following passage from a paper written by me on The Crops and Climatic Conditions of India (Agri. Ledg., 1895, No. 3, 38) may be here given:—“As a result of these considerations we have the startling state of affairs that a journey from one extreme of India to the other may reveal the cultivators engaged in every stage of the operations connected with certain crops, such as preparing the soil, sowing, watering the advanced crop, reaping, threshing and carrying the produce to market. For example, were the journey made in June from the Panjab to South India, the cultivators would in the north be found engaged in the early preparation of the land, for the crop to be sown in September to December; in mid journey they would be seen tending the mature kaple wheat of the Konkan; and in Mysore and some parts of Madras Presidency, they would be found sowing wheat—a crop that will be harvested in September and thus practically at the very time that the great wheat crop of Northern India is being only sown.” In general terms it may be said wheat cultivation increases on passing to the north, in other words, on leaving the humid atmosphere and inundated soils of the south. Indian wheat as a whole might, moreover, be spoken of as comprising a varied assortment of winter wheats, that is to say, the bulk of the Indian crop is sown in autumn and reaped in spring (rabi crop), but except on the hills it has rarely to pass through a winter of frost, so that from the climatic standard the Indian wheats might rather be spoken of as spring wheats. Frosts are, however, not unknown, and often do much harm as the grain ripening. But unlike the spring wheats of Europe, the Indian crop may in general terms be said to ripen with an increasing, not a decreasing temperature. That is to say, from January onwards the approach is rapidly made to the hot season, and by April and May the hottest temperatures of the year are usually recorded. This circumstance, so dissimilar from that of most other wheat-producing countries in the world, may have much to say to the “ricey” character attributed by the trade to the Indian wheats as a whole.

Yield.—The seed is ordinarily sown in October and ripens in three and a half to four months—a good average crop would be about 800 lb. to the acre. But there may be said to be two subordinate groups, namely dry-crop wheats and irrigated wheats. The increased facilities of canal irrigation account largely for the recent expansion of the area and production of irrigation wheats in the Panjab. The possibilities of the future in this direction cannot by any means be regarded as definitely established. Irrigation wheat on land liberally manured may yield from 1,200 to 1,600 lb. an acre.

Associated Crops.—To a large extent wheat is in India interchangeable with other rabi crops, such as linseed or gram, and it is accordingly rotated with these and may be sown alone or mixed with barley or gram or with intervening rows of mustard or safflower. The value of a rotation with leguminous crops is fully understood by the Indian cultivator and universally taken advantage of all over the wheat area. Recently Howard (l.c. ii., pt. ii., 210) has pointed out that in the Eastern Panjab it is
customary to sow *senbi* (*Melilotus parviflora*) among cotton, so as
to raise a *rafu* forage crop. It is commonly seen also among wheat
(*Fodder, in D.E.P., iii., 416*).

**Diseases**.—So much has been written on this subject, even in con-
nection with India alone, that many pages would have to be devoted
to the subject before anything like a satisfactory abstract could be pro-
duced. Rust is by far the most important or serious. It is known to
the Natives as *geru, gernar*, or *jeru*. According to the belief of the cul-
tivators, it attacks the crops only when sown on irrigated land or when
an undue amount of rain falls or heavy clouds prevail, during the early
growing stages. For some years the late Dr. Arthur Barclay devoted much
attention to the study of wheat rust and arrived at many surprising con-
clusions, one of which may be here stated, viz. that while the barberry
bush of the Himalaya bears abundantly acelial cluster-cups, which he
supposed to be those of *Puccinia graminis*, the rust of the wheatfields is
*P. rubigo-vera* (*Journ. Bot.*, 1892, xxx., 46). In the Agricultural
Ledger (1895, No. 20, 287–98) will be found an illustrated description of
the two chief forms of the rust, viz. *P. graminis* and *P. rubigo-vera*,
and their various stages of existence. Massee (Textbook Pl. Diseases,
1903, 247–9) deals very briefly with black rust and crown rust. A few
years ago the Colonies of Australia held a series of conferences on rust in
wheat. As a consequence, voluminous reports of the deliberations of the
Commissioners were published from 1890 to 1896. These were ably
reviewed by Prain (Agri. Ledg., 1897, No. 16). About the same time
Cunningham and Prain published a *Note on Indian Wheat Rust* (*Rec.
Bot. Surv. Ind.*, i., 99–124), in which they point out that perhaps five species
of *Puccinia* attack the wheat of the plains of India. They also describe
an acelial fungus on *Launea*, which they suggested may possibly be the
pt. i., No. 1) carried the subject a step further by throwing doubt on the
acelial fungus of the Himalayan barberries being at all connected
with wheat rust. He then remarks, “I have found that the common
*Ecidium* on the barberry at Mussourie is not allied to the wheat fungus,
but is a distinct and remarkable species, accompanied by a *Uredo*-form
on the barberry itself, and giving rise to witch’s brooms on the attacked
bushes. The barberry may be entirely left out of account in India.” He
then points out that the *P. rubigo-vera* of Indian writers comprehends
several species, more especially *P. glumarum* and *P. triticina*. Under
the former he places the Ferozpur wheat rust and the Mogul Serai
barley rust of Cunningham and Prain. *P. glumarum* appears earlier
than *P. graminis*, and as far as Indian experience goes, is much more
destructive to the grain.

The next paper of importance that appeared in India is that by Butler
and Hayman, to which is appended a note by Moreland (*Mem. Dept.
Agri. Ind.*, 1906, i., No. 2, 1–57, tt. i.–v.). This reviews the main facts
already mentioned, then pointedly exhibits the issues that remain unsolved
regarding the propagation of rust from season to season (i.e. 10), and in
the concluding summary speaks of three distinct rusts met with in India,
viz. *P. graminis* (black rust), *P. glumarum* (yellow rust), and *P.
triticina* (orange rust). All three commonly attack wheat, and the
first two barley also. In conclusion, it may be said that these authors
seem inclined to accept Eriksson’s theory of hereditary infection in

Bombay.

Areas of Production.—The chief wheats exported from India are the Muzaffarnagar soft white (dudhi) and the Bombay and Central Provinces hard white (bakshi) above indicated, but the wheats most popular within India itself are those produced in the Panjáb. With the vast majority of the people of India wheat is not, however, a necessity of life; it is indeed rarely if ever eaten by them. Wheat becomes an important article of food in the Panjáb only. In India as a whole, therefore, its cultivation is governed more by external than internal considerations. When the markets of Europe give indications of profit, its cultivation is immediately increased. But the mere fact of a definite proportion of this foodstuff being produced as an article of export (far from being a source of danger) is of the very greatest value to India, since, when the necessity arises, exports can be stopped by increased local demand and a new source of food thereby rendered available. It is not to be wondered at, therefore, that exceptionally good harvests in Europe and America are immediately followed by lessened cultivation in India. The effect of famine on wheat exports may also be clearly demonstrated:—The exports for the ten years ending 1899–1900 averaged 12\4 million cwt.; in 1900–1, a year which followed a serious famine, the exports were only half a million cwt., and two years later (1903–4) they expanded to 26 million cwt. If wheat displaces any crop it would be cotton, certainly not the food-grains of the people. Few cultivators are likely to be found so ignorant as to grow the millets on the rich lands on which alone wheat and cotton can be successfully produced. The best lands have always been devoted to rent-paying crops, that is to say, to export crops—such as oil-seeds, wheat and cotton—and only during times of famine would these lands be thrown under the millets and other necessitous food crops.

From these and such like considerations it may readily be understood that the area in India (British and Native States) normally under wheat manifests extreme fluctuations. Thus in 1891–2 it was 27,032,772 acres with a production of 6,093,741 tons of wheat; in 1893–4 it stood at 28,716,735 acres with 7,268,982 tons; in 1895–6 it had fallen to 24,071,320 acres with a production of 5,380,342 tons. Then it rose in 1898–9, and in the very next year, 1899–1900, fell to 18,687,782 acres with 5,357,142 tons. For the three succeeding years it fluctuated around 23 million acres, and in 1903–4 suddenly expanded to 28,413,743 acres with 9,641,145 tons; and in 1905–6 stood at 26,226,200 acres with a production of 8,560,340 tons. The Final Memorandum for 1906–7 estimates the area at 29,444,200 acres, but the yield at only 8,508,040 tons.

The provincial distribution of these acres may now be discussed. The Panjáb (including the North-West Frontier Province) heads the list with its lowest area (in recent years), namely 6,223,000 acres in 1891–2, and its highest record, 10,184,200 acres in 1906–7, with a production of 3,588,100 tons. During the past six years it has shown an average of over 8½ million acres under the crop, and has manifested on the whole a steady expansion. Then follow the United Provinces, which normally fluctuate between 6 and 7½ million acres. The Central Provinces stand next in order, with a normal area of from 2 to 3 million acres and Berar adding about half a million more. Then comes Bombay with from 1½ to 2 million acres.
acres, while Sind and its Native States add to the Bombay Presidency about half a million more acres. Lastly Bengal (including Eastern Bengal) normally possesses about 1½ million acres. Except in the Panjáb, therefore, the area in the other provinces cannot be regarded as giving any indication of expansion.

The Native States have collectively about 5 million acres under wheat. The Final Memorandum issued by the Commercial Intelligence Department estimates their area for 1906–7 at 5,176,000 acres, with a production of 1,048,540 tons. The largest proportion is in Hyderabad and Rajputana, which each have on an average 1 million acres, while Central India has approximately 2 million acres. Included under these areas mention may be made of Gwalior, which during the past five years has had from 298,872 to 726,674 acres under the crop; Bhopal in 1905, 419,766 acres; Indore, 287,681; Bandelkhand, 215,468; Bhagalkhand, 289,128 acres; and, lastly, Kotah has annually from 100,000 to 300,000 acres of wheat.

Panjáb and North-West Frontier.—One-third of the total cropped area of the Panjáb is usually under wheat, an area which represents about 29·3 per cent. of the total wheat area of British India. According to the Agricultural Statistics, the actual wheat area in the Panjáb in 1904–5 was 7,681,700 acres and in the North-West Frontier 821,586 acres, the yield having been 3,122,900 tons. In 1905–6 the total area for the two provinces was 9,596,700 acres and the yield 3,790,000 tons, while the Final Memorandum for 1906–7 estimated the area and yield, as already mentioned, at 10,184,200 acres and 3,588,100 tons. As representative of distribution, it may be added that during 1904–5 the following districts in the Panjáb had each over 300,000 acres of wheat:—Lyallpur, 591,818; Ferozpur, 565,433; Lahore, 438,360; Attock, 407,768; Siálkot, 396,837; Gujránwála, 363,367; Amritsar, 350,397; Sháhpur, 342,483; Gurdáspur, 330,586; Jhelam, 325,793; Gujrat, 310,725; and Multan, 305,051. In the North-West Frontier the areas are smaller, the chief being—Peshawar, 299,347 acres; Bannu, 209,136; and Hazara, 122,068.

The crop is sown on what are known as rausli and rohi lands; the former are light, easily pulverised loams, very prevalent in Upper India; the latter, rich well-drained soils approaching what is known as dákár. Dákár proper is as a rule too heavy and not sufficiently drained for wheat. The crop occupies the soil for about six months—the first sowings are made by the middle of October, and the harvest operations are completed by the latter end of May. The systems pursued vary to some extent locally, but mainly in consequence of the nature of the soil and source of water supply. The following particulars derived from Hoshiarpur District Gazetteer (1905, 93–5) is representative of the Panjáb generally. The common wheat grown is a reddish bearded variety called káthi, the kind most commonly used for mixtures with gram and other crops. “The number of ploughings given to wheat varies according to the crop that precedes it. If it follows maize, the time for ploughing is short, and not more than three or four can be given. If the two-year course is followed, continuous ploughings can be given for ten months; but even so, the majority of farmers do not plough more than eight or ten times. The best time for sowing is from the middle to the end of October, but wheat can be sown up to the end of December. In the riverain villages the land is often not dry enough to sow till November, and if the seed is sown too early it is eaten by a small grasshopper called toká. The subsequent
operations are simple. The field should be occasionally weeded in November and December. After December, nothing need be done besides the protection of the crop from stray animals till it is ripe in April. About the middle of April is the proper time to begin reaping the wheat harvest."

"The quantity of seed used is half a maund per acre, but a good deal depends on weather conditions at the time of sowing, and also on the class of soil. The average outturn varies much from tract to tract. Extensive crop experiments were carried out for five years during the First Revised Settlement, and the results seem to show that in the best plains Talsils, the average produce is 8 to 9 maunds an acre; in Dhashy about 7 maunds; and in the hills only 4 maunds." Of course the difference is enormous between the outturn of the best land, highly manured, 12 to 14 maunds, and that of the poorest sandy soils or badly manured land, 6 to 9 maunds. "In the light soils of Kandi the yield falls in bad years to 3 or 4 maunds per acre."

According to the Agricultural Statistics, the average yield per acre in the Panjab for a period of five years ending 1901-2 was 935 lb. irrigated and 642 lb. unirrigated land, and in the North-West Frontier, 883 lb. on irrigated and 563 lb. on unirrigated. In the Panjab the largest yields were obtained in Gurdaspur, Amritsar, Jalandhar, Ferozpur, Delhi, Ludhiana, Lahore, Ambala and Mianwali; and in the North-West Frontier in Dera Ismail Khan, in all of which average yields of over 1,000 lb. (12½ maunds) per acre have been recorded on irrigated lands.

[U. Prov.]

United Provinces.—The crop is very important in these provinces, ordinarily occupying about one-fifth of the net cropped area, an amount which on an average of the five years ending 1904-5, represented 27.9 per cent. of the total wheat area in British India. According to the Agricultural Statistics, the area in Agra in 1904-5 was 5,533,542 acres and in Oudh 2,197,224 acres, giving a total of 7,730,766 acres. The outturn for the same year was estimated at 1,897,000 tons. In the Final Memorandum on the crop for 1906-7, the area is stated to have been in 1905-6, 6,478,900 acres and the yield 2,428,700 tons; and in 1906-7, 7,039,100 acres and 2,164,500 tons. In Agra the largest areas are usually in the Meerut and Rohilkhand Divisions. In the former, Meerut district had 383,916 acres in 1904-5, Saharanpur 355,272 acres, Muzaffarnagar 276,864 acres, Bulandshahr 258,377 acres, and Aligarh 229,100 acres; in the latter (Rohilkhand Division), Moradabad had 383,555 acres, Budaun 344,345 acres, Shahjahánpur 276,703 acres, and Bareli 222,895 acres. In Oudh—Lucknow Division—Hardoi had 320,938 acres, Sitapur 269,636 acres, and Kheri 221,264 acres. In Fyzabad District, Gonda had 277,487 acres, and Bahraich 247,823 acres.

No general statement regarding cultivation has been published since the Field and Garden Crops appeared, but the annual reports of the Cawnpore Experimental Farm and the bulletins issued by the Agricultural Department contain much valuable information, especially regarding the experimental manuring of wheat. The crop is entirely a rabi one, being sown at the end of October or beginning of November, and cut in March and April. According to Duthie and Fuller, it is grown on 1094
almost every soil, except the lightest sands, but a rather heavy loam is considered best. The better class of wheat-fields are manured every second or third year, and the land is sometimes prepared by herding sheep on it. As a rule, wheat is sown only on land that has lain fallow during the preceding kharif (known as chaunás or púral), but in highly manured lands near village sites it occasionally follows maize. No particular rotation is known to be pursued, but in tracts where cotton is widely grown, wheat is generally said to follow. In the Meerut district an elaborate rotation is practised in which wheat is grown only twice in five years. On an average the land is ploughed about eight times before sowing. The seed rate is said to vary from 100 to 140 lb. per acre. After sowing, the field is divided into irrigation beds. If the soil is sufficiently moist in October to allow of the seeds germinating properly, the necessity for irrigation will depend on the occurrence and extent of the winter rains. Should the soil be too dry for germination, a watering (called pala) is given before sowing. As a rule, three or four waterings are said to be ample even in the driest localities. As regards outturn, it has been estimated that 15 maunds per acre for wheat grown alone, as also for wheat-barley, and 13 maunds for wheat-gram, are the lowest averages which could be taken. According to the Agricultural Statistics, the average yield for the whole province for the five years ending 1901-2 was 1,250 lb. (15 maunds) per acre for irrigated wheat, and 800 lb. (9.75 maunds) per acre for unirrigated. The largest average yields during that period were obtained in Bulandshahr and Bahraich, viz., for irrigated wheat, 1,300 lb. per acre, and in Bahraich and Naini Tal, viz., for unirrigated, 1,050 lb. and 1,000 lb. respectively.

Central Provinces and Berar.—In these provinces wheat occupies about one-eighth of the total cropped area, a figure that represents 11.4 per cent. of the total wheat area of British India. The actual area in 1904–5, according to the Agricultural Statistics, was 3,070,421 acres in the Central Provinces, 427,236 acres in Berar, and estimated yields 751,900 tons and 80,000 tons. The Final Memorandum on the crop for 1906–7 states the combined area and yield to have been in 1905–6, 3,443,800 acres and 834,400 tons; and in 1906–7, 3,689,800 acres and 904,700 tons. According to the figures for 1904–5, the districts with largest areas expressed in acres in the Central Provinces were Hoshangabad, 424,588; Jabalpur, 362,354; Saugor, 332,788; Seoni, 261,674; Nagpur, 214,258; Chhindwara, 197,767; Damoh, 191,511, etc. In Berar—Buldana, 145,582; Básim, 98,862; Amraoti, 67,429, etc.

The system of cultivation is practically the same as that pursued in the heavy black soils of Bombay (see below). Unlike the United Provinces and Panjáb, manure and irrigation are here unimportant. For ordinary wheat cultivation, preparatory operations commence in April or May and the field is ready for sowing by October. The seed rate varies from 80 to 120 lb. per acre. The crop is left entirely to itself till
TRITICUM VULGARE

Central Provinces

harvest in the beginning of March. A different system is pursued in a tract of country which includes a considerable portion of the Jabalpur and a small portion of the Narsinghpur and Seoni districts. The fields are surrounded with banks, and rainwater is allowed to accumulate in them. The water is let off at the beginning of October, and the seed is then drilled in without any preliminary preparations. The average outturn for the province for the five years ending 1896–7, according to the Agricultural Statistics, is estimated to have been 925 lb. per acre for irrigated wheat, 570 lb. for unirrigated. Returns for irrigated wheat are given only for Betul, Chhindwara, Nagpur and Nimar.

The method of cultivation pursued in Berar differs but little from that in the Central Provinces. It is sown in October and reaped in February, and is cultivated in rotation with other crops. The Agricultural Statistics give an average yield, for a period of five years ending 1901–2, of 687 lb. per acre.

Rajputana and Central India.—The returns published annually in the volume of Agricultural Statistics would appear to give actual areas for which definite surveys have been made. The figures, on the other hand, published by the Commercial Intelligence Department would appear to be forecasts and estimates. According to the former, the area in 1904–5 in Central India and Rajputana (viz. Gwalior, Jaipur, Bikanir, Marwar, Tonk, Alwar, Kishengarh, Bharatpur, Jhalawar and Kotah) came to 1,277,872 acres, with Ajmir-Merwara adding 17,167 acres. According to the latter (the Commercial Intelligence Department), particulars of other States are afforded, and thus manifest larger areas, viz. — 2,171,019 acres in Central India and 1,023,773 acres in Rajputana, with yields of 472,658 tons and 188,981 tons respectively. Accordingly, if we accept the areas given in the estimates for Central India and Rajputana as approximately correct and add to them the area for Ajmir-Merwara from the Agricultural Statistics, we would obtain a total of 3,211,959 acres under wheat in 1904–5. The Final Memorandum on the crop for 1906–7 states the area to have been in 1905–6, 1,852,100 acres with a yield of 420,600 tons in Central India; 604,000 acres and 145,000 tons in Rajputana; and in 1906–7, 2,895,000 acres and 639,800 tons in Central India; and 810,000 acres and 215,000 tons in Rajputana. In Central India the most important districts are Gwalior, Bhopal, Indore, Bandel-khand, Bhagalkhand and Bhopawar; and in Rajputana—Kotah, Jaipur, Tonk and Bharatpur.

There is little information regarding cultivation available beyond the facts given above. The climate and soil closely approximate to the Panjâb on the one hand and to the Central Provinces on the other, and the wheats are accordingly similar. In Ajmir-Merwara the best land is said to be selected for wheat, generally near a tank or well. To obtain a full crop, the land is fallowed during the rainy season (June to September), and is ploughed two or three times. Sowing begins about the end of October and lasts till the end of November, the crop being reaped in April. The quantity of seed sown is said to be about 2 bushels per acre, and the outturn, if the crop be manured and irrigated, is about 34 bushels.

Bombay and Sind.—The area in the British districts of Bombay and

1096
Sind, represents about one-eleventh of the total net cropped area of the Presidency, or about 7.2 per cent. (Bombay), and 1.9 per cent. (Sind) of the total wheat area in India. The areas in 1904–5, according to the Agricultural Statistics, were 1,749,182 acres in Bombay, 491,413 acres in Sind. The Final Memorandum for the same year, issued by the Department of Land Records and Agriculture, estimates the area in the British districts of Bombay at 1,611,197 acres, and in Sind at 479,629 acres, while in the Native States the area is stated to have been 533,444 acres, giving a total (including Native States) of 2,626,270 acres. The total yield is estimated at 469,134 tons. The Final Memorandum for 1906–7 states the area and yield to have been in 1905–6, 1,975,353 acres and 471,357 tons; and in 1906–7, 2,219,763 acres and 504,827 tons. The largest areas, expressed in acres, in the British districts of Bombay in 1904–5, were Khandesh, 393,815; Nasik, 271,091; Ahmadnagar, 243,630; Dháwrár, 243,262; Bijápur, 144,328; and Ahmadabad, 100,708. In Sind, Thar and Parkar, 122,165; Sukkur, 118,421; and Lárkhána, 114,930. In the Native States, Kathiáwár, with an acreage of 241,932, is the largest area.

Lisboa (Bomb. Grass., 1896, 130–1) makes some interesting remarks regarding the wheat area in Bombay. He states that the wheats grown are not largely in demand in England, and further that there is little prospect of the area being materially increased. He argues, accordingly, that the growth of wheat is not so greatly influenced by the prices ruling in Europe as some suppose. Being a late-sown crop (October) its area rather depends on the amount of suitable land available after cotton and the early cereals have been provided for. Moreover, as there are not extensive areas of land now uncultivated that are fit for wheat, he holds that the extension of railways in the Presidency and the brisk export demand will not have such an effect in encouraging the growth as some writers allege. Nevertheless, since 1896 the wheat area of the British districts of Bombay has, if anything, steadily improved.

The methods of cultivation pursued in the Presidency have been fully discussed by Mollison (Textbook Ind. Agric., 1901, iii., 25–8). "It is extensively grown as a dry crop on deep, black, moisture holding soil. The finest dry crop lands of the Presidency are along the Tápti in Khándesh, in the plains of Kopergaon and along the Godavery in Ahmednagar." As an irrigated crop it does best on lighter soil. "Medium black soil, so common in the Deccan, is very suitable." The dry crop is either grown alone or with subordinate rows of safflower. In Panch Maháls, wheat and gram are grown together. Irrigated wheat is usually unmixed. The dry crop "is grown continuously in some parts of Ahmednagar, Ahmadabad and Nasik. In the cotton districts of Khándesh, Dháwrár, Broach, etc., it is rotated with cotton and julár. In the deep black soil which borders the Tápti in Khándesh, it is rotated with linseed and gram. In the Panch Maháls on land brought under tillage during recent years it follows a kharif crop of maize, the land being double cropped annually."

In the case of dry-crop wheat, preparatory tillage begins usually before the rains, and the soil is worked into a friable condition so that it may readily absorb the monsoon rain which falls in June, July and August. It is not often manured, but if manure be given, it should be applied in August or September and mixed with the soil by a light ploughing.
It should be sown in October, and the seed for dry-crop wheat is always drilled. The rate varies from 40 to 55 lb. per acre. Irrigated wheat, on the other hand, “is sometimes broadcasted, sometimes drilled and occasionally sown by hand in the furrows behind the plough.” The seed rate is higher than for dry wheat; “70 to 80 lb. per acre are ordinarily sown, and in the case of spelt wheat in husk, 100 lb.” After sowing, the crop requires little attention beyond regular irrigation.

“The outturn of grain varies much with the season. A well-managed irrigated crop produces about 2,000 lb.” (24'4 maunds) “grain and over a ton of straw, whilst a good dry crop will not often exceed 1,000 lb. of grain and about the same weight of straw. 600 to 650 lb. grain per acre probably represent a full average crop in an ordinary year from deep, black soil, cultivated in the ordinary manner.”

The cost of cultivating dry wheat in Khandesh, Mollison estimates at Rs. 12-7a. per acre.

Sind may be said to be intermediate between Bombay and the Panjáb as regards wheat cultivation. In parts of the country, the methods of cultivation, the nature of the soil and the character of the wheats are similar to those in the Panjáb, but in other parts an approximation to the wheats of Northern Bombay is seen. The Sind wheats are generally said to be superior to those of Bombay, and possess a larger proportion of soft white forms. Most of the Sind wheats are, as in the Panjáb, repeatedly watered or flooded during their growth. A dry crop is, however, raised on lands that are inundated during the rains. For a period of five years, ending 1901-2, the average outturn in Sind, according to the Agricultural Statistics, was 1,066 lb. per acre.

Bengal.—The area in 1904–5 (including Eastern Bengal), according to the Agricultural Statistics, was 1,455,500 acres, which gave a yield of 444,100 tons. This represents only about 2 per cent. of the net cropped area of the province. The Final Memorandum on the crop for 1906–7 states the area and yield in Bengal (excluding Eastern Bengal) to have been in 1905–6, 1,248,300 acres and 396,600 tons; and in 1906–7, 1,402,600 acres and 388,700 tons. The districts of the Patna Division ordinaril y contain about one-half of the total area, amounting, in 1904–5 to 746,300 acres, and those of Bhagalpur about one-third, or 422,100 acres in 1904–5. The areas in the other divisions were:—The Presidency, 120,900 acres; Rajshahi, 113,600 acres; Chota Nagpur, 36,000 acres; Bardwan, 14,000 acres, etc. According to the Agricultural Statistics, the average yield has been fixed provisionally at 12 maunds or 984 lb. per acre for the Bihar districts, 10½ maunds or 861 lb. per acre for the Bengal districts, and 451 lb. per acre for the districts of Chota Nagpur.

Mukerji states that a “clay-loam, easy of irrigation, situated in a dry locality, is the best soil to choose for wheat”; and again, “The best crops of wheat are grown on land mainly brought under canal irrigation.” The land should be prepared for sowing as soon as possible after the rains are over. Sowing should be made when cold weather has been established, say, in November. In rocky and laterite soils, sowing should be done earlier, about the 20th or 25th October, or even earlier still if the rains cease in October. About 100 lb. of seed are used per acre, but
Mukerji thinks that is too much and that 50 lb. should suffice. After sowing, the field should be laid out in irrigation beds, and one or two floodings given. One hand-weeding should be done within ten days after the first watering, and two hoeings may be subsequently given. The crop is harvested when the grain is quite ripe. Mukerji estimates the cost of cultivation at Rs. 26 per acre and the value of a crop consisting of 12 maunds grain and 16 maunds straw at Rs. 37-8, giving a profit per acre of about Rs. 11.

Eastern Bengal and Assam.—Wheat is a very unimportant crop in Assam. The area returned for 1904-5 was 10,012 acres, practically the whole being in Goalpara. The Final Memorandum on the crop for 1906-7 states the area and yield in the new province of Eastern Bengal and Assam to have been in 1905-6, 159,800 acres and 50,000 tons; and in 1906-7, 168,700 acres and 44,000 tons. Cultivation in Assam as yet is almost entirely of an experimental nature. An account (Rept. Dept. Land Rec. and Agri., 1904, 20-1) of some of the experiments made in 1903-4 in Manipur and certain localities in Cachar and the Assam Valley is given. “In Manipur,” it is stated, “one of the four experiments made gave a very successful result, the yield being no less than 2,140 lb. of grain to the acre,” but in the other localities they generally proved a failure. Summarising the experiments, it is said that “wheat will undoubtedly thrive and give a good yield in Manipur; it promises well in the Naga hills, but the people need to be educated to appreciate and tend the unaccustomed crop. The same remark applies to Nowgong and Kamrup, and there is a fair prospect of success with wheat in these two districts.”

The area in Eastern Bengal does not usually much exceed 150,000 acres. Taking Eastern Bengal and Assam together, they may be said normally to possess a wheat area equivalent to 1 per cent. of the total wheat area of British India.

Madras and Mysore.—Wheat is unimportant in the Madras Presidency, and occupied only 15,276 acres in 1905-6. In Mysore the corresponding area was 1,178 acres, and according to the Final Memorandum there were in 1906-7, 4,600 acres. The largest tracts are in Kurnul, Bellary, Kistna, Guntur, Cuddapah, the Nilgiris, Anantapur and Madura. In Mysore, Chitaldurg and Shimoga are the most important districts. A brief statement of Mysore is given in the local Gazetteer (1897, i., 129-30) by B. L. Rice, compiled largely from Buchanan-Hamilton. Two kinds are said to be cultivated, jave godhi (affirmed to be T. monococcum) and hotte godhi (T. Spatha). Rice tells us that in Kolar jave godhi (whatever species it may be botanically) is sown broadcast in May—June, after frequent ploughing, and the crop ripens in three months. In the black clay of Madgiri, jave godhi is also the most common crop. In Sira, when there is a scarcity of water, both jave and hotte are sown on rice-lands. A small quantity of jave godhi is raised near Periyapatna on fields of a very rich soil, from which alternate crops of kadale (Cicer arietinum) and of wheat are taken. Near Narsipur hotte godhi is grown, and there are two seasons for its cultivation, known as hain and kar. When the rains

set in early, the kar season is preferred, because the wheat is more productive and it may be followed by cotton. When the rains are late, the kain wheat is taken after kadale. The cultivation is the same as for the kar crop, only the season is different. In the kain crop the produce is said to be only about one-half of the kar crop (Mysore Gaz., l.c.).

Burma.—The area in 1905-6 was 35,178 acres, all in Upper Burma. The most important district is Sagaing, which had 24,361 acres in the year in question, while smaller areas are found in Kyaukse, Minbu, Mandalay and Lower Chindwin. The subject of wheat cultivation in the Southern Shan States and in Burma is fully discussed by a writer in Capital (Sept. 20, 1906, 587–8; Oct. 18, 749–50), who affords much useful and practical information which deserves careful consideration. He there states that “experimental cultivation with the object of ascertaining whether wheat could be grown as a staple crop was begun as early as 1888–9, and the results tend to show that this crop can be successfully grown in the Upper Chindwin district, the Pyinmana Sub-division of the Yamethin district, in Magwe, Maymyo and in the Chin hills. Wheat also succeeded on the river silts in the Toungoo district in Lower Burma, but the outturn was in every case poor.”

The efforts made by A. H. Hildebrand to establish wheat cultivation in the Southern Shan States have been repeatedly told in official publications (Repts. Dept. Land Rec. and Agri. Burma).

The Agricultural Statistics give the average outturn of wheat in Burma, for a period of five years ending 1901–2, as 635 lb. for the province as a whole. Separate returns are shown for Mandalay, Sagaing, Minbu and Kyaukse, and these range from 320 lb. in Mandalay to 800 lb. in Minbu. It has sometimes been affirmed that Burma was to India a great granary. It certainly produces an immense amount of rice, which is mainly exported but of course is available should India require it. That it could similarly afford a large supply of wheat may very possibly be found to turn more largely on the deficiency of labour supply than on defective climate and soil.

MANUFACTURES.—For the minor uses of wheat straw see p. 116. Very little can be recorded regarding the indigenous industries of milling wheat and producing flour. Loaf-bread (p. 1109) is now produced in the larger villages and towns, and in some few localities (such as around Delhi) the baking of biscuits, specially designed to meet the growing demand for imported goods of that nature, seems to be fairly successful and to give promise of a great future. In other parts of India, as for example the towns of Gujarat, the manufacture of macaroni is well understood and fairly largely practised. The use of flour in the production of certain sweetmeats has originated a demand for the commodity. In the Panjáb, as already mentioned, wheat becomes the staple food and is consumed in the form of large cakes cooked over the open fire. All over India, therefore, the chakkiwala or grinder may be met with plying his craft, either by employing women to work the ordinary hand-mill (chakki) or, where a fall in the water-level can be obtained (as for example on the hills), by using the water-driven flour mill. But in addition to such indigenous methods, within the past twenty years or so flour mills after the most improved European fashion have been established and very superior flour may now be procured everywhere, and of such quality as to have checked the imports.
of the foreign article. In a further paragraph, particulars will be found of the imports and exports of flour, but it may be added that the growth of the Indian flour traffic is one of the most encouraging indications of the birth of industrial enterprise. So far, the exports of Indian flour have gone to Indian Ocean ports, but the day is perhaps not far distant when the problem of the exports of clean versus adulterated wheat may be solved, as already stated, by the export of flour (see p. 1089).

Flour Mills.—According to the Financial and Commercial Statistics (1906, 399) there were 42 mills, employing 3,016 persons in 1904, but the statement is said to be defective. These were distributed thus:—The Panjâb 21, with 1,281 employees; Bengal 9, with 755 employees; Bombay 4, with 562 employees; United Provinces 4, with 273 employees; Madras 2, with 58 employees; Sind and the Central Provinces, 1 each, with 52 and 35 employees respectively.

INDIAN TRADE IN WHEAT AND FLOUR.

For many years it was an accepted belief that Indian wheat appeared on the markets of Europe chiefly in order to supplement deficiencies. In 1899, the author of The Wheat Problem (S. William Crookes) practically excluded India from consideration in his study of the world’s supply, on the ground of the insignificance of the surplus available for export. In a most emphatic manner that view has been disproved by recent returns. In 1904, for example, India actually headed the list of countries that contribute towards England’s demands—a circumstance that at once placed it in an altogether new position, notwithstanding that the very next year it fell far short of its record. But what it did one year may be repeated and even exceeded. The explanation of this new state of affairs may be learned from a study of the causes that have brought about India’s extended wheat production. Nearly 75 per cent. of the wheat grown is raised in the Panjâb and the United Provinces. And in these provinces vast tracts of fertile land have been brought under cultivation, through the improved and increased canal and well irrigation accomplished by the Indian Government. Indeed fully half the wheat area of the provinces named is ordinarily under irrigation wheat. Howard (Note Prod. of Wheat, in Agri. Journ. Ind., 1906, i., pt. iv., 399–401) regards the irrigation wheat as securing the internal consumption and as thus releasing a large proportion of the dry crop for export. The expansion of the irrigation wheat area is, therefore, a matter of superlative importance to the British Empire, in addition to being of vital interest to India itself.

Prices of Wheat in India.—These are expressed by the number of seers (=2 lb.) procurable for Rs. 1 (=1s. 4d.). A higher figure, therefore, denotes cheap wheat (more being obtainable), and a low figure dear wheat. It is perhaps only necessary to select three centres, Calcutta, Bombay and Delhi, to exemplify the fluctuations in price. During the twenty years ending 1905, the cheapest wheat in Calcutta was in 1887, when 14'17 seers (28'31 lb.) were obtained for the rupee. So again the dearest wheat was in 1897, when only 8'05 seers were given. The quantities procurable for the past four years were 1902, 10'68 seers; 1903, 12'1 seers; 1904, 11'42 seers; and 1905, 10'67 seers. In Bombay, the record year for cheapness during the twenty years was in 1896, when wheat sold at 11'84 seers to the rupee, and the dearest year 1900, 6'06 seers, while for the following years

1101
it sold at—1902, 7'37 seers; 1903, 8'12 seers; 1904, 8'31 seers; and 1905, 8'33 seers. Wheat in Bombay during the term of years mentioned has manifested much more violent fluctuations than in Calcutta. Thus in 1895 it sold at 13'18 seers, and in 1897 at 6'66 seers. In Delhi, wheat is naturally very much cheaper than in either Calcutta or Bombay; and its record years were, for cheapness 1885, 22'5 seers, and for dearness 1897, 9'91 seers to the rupee, while during the last four years ending 1905 the prices were—1902, 15'14 seers; 1903, 15'26 seers; 1904, 15'0 seers; and 1905, 12'95 seers. The price in Delhi is representative of all towns within the wheat-producing areas, such as Lahore, Lucknow, Cawnpore, Raipur, Patna, etc. A careful scrutiny of the returns of the wheat production and trade for India gives no sort of justification for the opinion that the exports to foreign countries are raising the price of wheat to the people of India, while on the contrary the annually increasing surplus has even now assumed the position of a valuable safeguard against famine.

**PRODUCTION AND EXPORT TRADE OF WHEAT.**—The wheat exports of one year are very nearly entirely drawn from the area of production of the year previous. Similarly it is often the case that the area of production in the British provinces is spoken of as that from which the foreign exports are drawn, thus neglecting the Native States, which undoubtedly contribute considerably to the amounts shown as exported. A mean average yield per acre for all India would be a perfectly misleading figure, since the range between irrigated manured land and dry land without manure (without taking into consideration the difference in yield between pure and mixed crops) would be perhaps three of the former to one of the latter. But accepting the official returns as they stand, we obtain an average for the ten years ending 1905-6 of 24,299,149 acres, with a yield of 7,170,551 tons (or 143,411,020 cwt.) of grain, while the actual figures for 1905-6 were 26,226,200 acres and a yield of 8,560,340 tons (or 171,200,000 cwt.). The decennial average is perhaps the safer figure to employ in all comparisons, since it is considerably below the actuals for the past few years and errs on the side of under-rather than over-stating production. It would, however, serve no useful purpose to strike averages for the exports from India, since these are open to none of the errors mentioned. The following abstract table exhibits the exports from India for the years 1902-7, and contrasts these with the chief items of wheat imports into Great Britain:

**Exports from India to Foreign Countries.**

The table exhibits many instructive features, some of which may be here dealt with. For example, of the exports from India by far the most important purchasing country is the United Kingdom. The next important countries are—Belgium, France and Egypt. In 1905-6 these three together took 3,089,881 cwt., or little more than one-fifth of the supply consigned to the United Kingdom alone. And what is perhaps even more significant, the demands of all countries (other than Great Britain) have practically remained stationary for some years past, while the supply to the United Kingdom has gone forward in a most significant manner.

So also the figures of shares taken by the ports of shipment from India exhibit a remarkable parallelism with recent extensions in irrigation and facilities in transport. The port of Karachi taps the Panjāb, Rajputana and to some extent also Central India and the United Provinces. The expansion of the Karachi traffic has been phenomenal, and the extension of railway communication toward Calcutta must to some extent account for the progress made by that port.

Reverting to the decennial standard, it may now be shown what proportion the exports bear to production. The average production of the ten years ending 1905-6 has been shown as 143,411,020 cwt. The exports from India in 1905-6 came to 18,750,467 cwt. (valued at Rs. 8,53,43,996), or 13 per cent. on the average standard; but if the figure of actual production for the year named be accepted, viz. 171,206,800 cwt., the exports would represent only 10.9 per cent. of the supply. The year 1903-4, as also 1904-5, was notable in the wheat trade. India exported in the former 25,911,312 cwt. (valued at Rs. 11,08,89,546), which expressed to the decennial standard would be 18 per cent., and to the actual crop of 1903-4 13.4 per cent. In 1904-5 the exports were 43,000,502 cwt. (valued at Rs. 17,90,60,692 or £11,937,379), or 30 per cent. on the decennial standard and 28.2 per cent. to the recorded actual production.

An examination of the table given reveals the further fact that in 1904-5 India headed the list of countries concerned in the supply of wheat to Great Britain. In that year it furnished the United Kingdom with wheat valued at close on 8 million pounds sterling. India’s contribution was then close on 29 million cwt., while Russia supplied 23½, the Argentine 21½, Australia 10, the United States 7, and Canada 6 million cwt.

**PRODUCTION AND TRADE IN FLOUR.**—The proportion of flour exported from India gives, of course, no evidence of the magnitude of the

1103
total production. There would seem little doubt, moreover, that by far the major portion of the flour annually produced in India is turned out by the indigenous hand- and water-power mills and thus escapes registration of any sort. No more particulars can, therefore, be afforded of the consumption of flour than are implied by the annual production of wheat and the balance of that cereal that remains in the country over and above the foreign exports.

Exports of Flour.—There is, however, a considerable trade in exporting wheat flour, and this has manifested recently a noteworthy expansion, although the traffic of last year showed a decline from the returns of the years immediately previous. In 1900–1 the exports were 497,346 cwt., valued at Rs. 35,83,176; 1901–2, 529,328 cwt., valued at Rs. 37,12,876; 1902–3, 718,077 cwt., valued at Rs. 46,54,631; 1903–4, 810,422 cwt., valued at Rs. 52,98,843; 1904–5, 1,031,495 cwt., valued at Rs. 69,21,610; 1905–6, 899,056 cwt., valued at Rs. 63,83,264; and 1906–7, 818,462 cwt., valued at Rs. 58,57,116. The great bulk of these exports goes from Bombay, viz. 661,368 cwt. in 1906–7, the balance being divided between Bengal and Sind, while the chief markets are Arabia, Aden, Ceylon, Mauritius, British East Africa, the Straits Settlements and Egypt. A considerable export trade in wheat flour to the United Kingdom appeared for the first time in 1904–5, amounting to 52,523 cwt., but contracted to 1,500 cwt. in 1906–7.

Imports of Wheat and Flour.—A certain amount of foreign Wheat is imported into India, and according to Noël-Paton (Rev. Trade Ind., 1906, 31), "in times of shortage it is taken in considerable quantities even by ports from which grain is commonly shipped." The quantities have been:—1900–3, 783 cwt., valued at Rs. 4,757; 1903–4, 18,852 cwt., valued at Rs. 97,764; 1904–5, 129 cwt., valued at Rs. 432; 1905–6, 454,614 cwt., valued at Rs. 22,53,648; and 1906–7, 209,696 cwt., valued at Rs. 11,38,976. Of the total for 1905–6, Australia supplied 395,696 cwt. and Turkey-in-Asia 58,798 cwt. Noel-Paton points out that "this total was exceeded only in 1896–7 and in 1900–1, when 601,356 cwt. and 559,351 cwt. respectively were imported; but in each of the famine years, 1877–8 and 1878–9, the imports exceeded 400,000 cwt." Small quantities of wheat flour, subject to duty, are also imported, and have averaged for the years 1902–7, 18,500 cwt.

Internal Traffic.—Rail and Riverborne Traffic.—The total transactions by these routes on the average for the years 1902–7 were 31,874,712 cwt. wheat and 1,699,091 cwt. flour. In 1906–7 the figures were 28,556,137 cwt. wheat and 2,350,388 cwt. flour. Of wheat, the Panjāb exported that year 20,537,369 cwt., viz. to Karachi, 14,959,915 cwt.; to Rajputana and Central India, 1,594,477 cwt.; to Calcutta, 1,217,100 cwt.; to the United Provinces, 1,119,578 cwt.; and to Bombay, 1,025,751 cwt. It will thus be seen that the bulk of the railborne traffic is from the Panjāb to Karachi. But Karachi obtains wheat also from Sind province and from the United Provinces, the grand total of its supplies having been in the year under notice 17,018,238 cwt., an amount which it will be seen would have sufficed to meet the foreign exports of 15,434,060 cwt. Of course it is not always safe to assume that the actual amounts shown in the internal traffic appear again in the foreign transactions, but the average of several years would overcome the overlappings that take place. It is sufficient, therefore, to show that the wheat exported from Karachi to foreign countries is drawn mainly from the Panjāb.
THE WHITE DAMMAR TREE

VATERIA INDICA

After the Panjáb come the United Provinces; in 1906-7 these consigned by rail 2,982,862 cwt., of which Calcutta took 1,812,924 cwt. Next come the provinces of Sind and Baluchistán, which exported during the year in question 2,085,224 cwt., almost entirely to Karachi. Lastly, the Central Provinces and Berar supplied 1,683,016 cwt., of which Bombay took 494,405 cwt., Calcutta 299,686 cwt., while the United Provinces drew 418,108 cwt., and Rajputana 267,333 cwt. The total receipts by rail at Calcutta came to 3,407,430 cwt., at Bombay 1,749,615 cwt., quantities that allow for a large local consumption and still leave a balance sufficient to meet their foreign exports. The local consumption of Calcutta and Bombay, unlike that of Karachi, is more important than the foreign exports.

The railborne traffic in flour is from Calcutta 759,586 cwt., to Bengal province and Assam; from the Panjáb 802,423 cwt., to the United Provinces, Bengal and Calcutta; from the United Provinces 314,101 cwt., to Bengal and Calcutta; and lastly, from Bombay (port) 292,154 cwt., to Bombay Presidency, Mysore and the Nizam’s Territory.

Coastwise Traffic.—The traffic by this route is not as a rule very extensive. For the period 1901-6 it averaged 1,321,912 cwt. wheat, valued at Rs. 64,75,711, and 462,681 cwt. flour, valued at Rs. 32,28,418. The exports are mainly from Sind to Bombay, Kaeh and Kathiawar; from Bombay to Káthiawar and Madras; from Bengal to Madras; and from Burma to Bombay and Madras. The corresponding traffic in flour is largely to Burma, and from Bombay to Madras and Burma. [Cf. Twenty Years' Wheat Imports, in Journ. Board Agri., 1904, xi., 534-42.]

V

VATERIA INDICA, Linn.; Fl. Br. Ind., i., 313; Gamble, Man. Ind. Timbs., 1902, 85-6; Talbot, List Trees, etc., 1902, 35; Cooke, Fl. Pres. Bomb., 1903, i., 86-7; Brandis, Ind. Trees, 1906, 72-3; DIPTEROCARPACEAE. The White Dammar of South India, Piney Varnish, Indian Copal or Malabar Tallow, saféd dámár, kahruba, sandras, rdî, vellai-kunurikam, painippishin, kungiliyam, piney maram, gugli, dupa maram, dhupada, payani, etc. A large evergreen of the forests at the foot of the Western Ghats from Kanara to Travancore, ascending to 4,000 feet, often planted as an avenue tree.

This tree yields a true Resin of considerable value known as White Dammär or Piney. It is said to occur in three forms—compact piney, cellular piney and dark-coloured piney resin. The names sufficiently indicate their respective characters, which are said to be due to the mode of collection and the age of the tree. The resin is obtained in the usual way by incising the trunk. It is only slightly soluble in alcohol, but dissolves at once in turpentine and drying oils, and, like copal, is chiefly used for making VARNISHES. It has been recommended for use in pharmacy in place of the officinal pine resin. Gamble states on the authority of Mr. J. H. Broughton that in certain localities the resin is mixed with coconut oil and rolled into candles. The Natives also employ it to make imitation amber beads. The seeds contain a large quantity of a solid Orr, known as “piney tallow,” or vegetable butter of Kanara. In South Kanara this is used for lamps, for flavouring food, as a substitute or adulterant for ghi, as well as for medicinal purposes. According to Bidie, it is valued locally as an application in rheumatism. It has been employed in the manufacture of candles, which were at one time introduced into England. Hooper (Agri. Ledg., 1902, No. 1, 16) states that a sample of the fruit was found to contain 25 per cent. tannin. The bark is also very astrin.ent. Bourdillon (Notes on Trees in Travancore, 30-1) says that it is used in Ceylon to keep toddy from fermenting. Hooper

Khas-khäs.

VETIVERIA ZIZANIIOIDES, Stapf, Kew Bull., 1906, 346-9, 362; Anthericum muricatum, Beauv.; Andropogon muricatus, Retz.; A. squarrosus, Linn., f.; Fl. Br. Ind., vii., 186; Vetiveria odorata, Virey; Rheede, Hort. Mal., 1703, xii., 137, t. 72; Watt, Ind. Art at Delhi, 1903, 161, 198; GRAMINEÆ. The khas-khas or Vetiver; the khas, bæna, panni, balé-kd-ghän, shanadër jhar, sîrom, tin, vâlo, vetti-vër, lâvanchâ, etc., etc. Is found throughout the plains and lower hills of India, Burma and Ceylon, up to 4,000 feet, occurring on moist, heavy soils, more especially the margins of lakes or streams.

The root or khas-khas is extensively made into the aromatic scented mats which are hung in doorways and kept wet to cool the atmosphere during the hot season. It is also used for making fans, ornamental baskets, etc., which are very largely produced at Savantvadi, Poona, Chanda and elsewhere. The raw material is exported to Europe chiefly from Madras ports. Gildemeister and Hoffmann (Volatile Oils, 289) say, "The root is of a reddish colour and often contaminated with red sand. A half-distilled root is frequently found in commerce, and can be recognised by its light colour." It seems more than probable that much of the so-called half-distilled root is in reality the roots that have been used in tatties for a season and are bought back by the traders to be exported. The constant application of water and exposure to the fierce sun might easily exhaust a large proportion of the oil and bleach the roots in the manner described. According to certain inscriptions, taxes were levied on khas-khas in 1103 to 1174 A.D. (As. Soc. Beng., 1875, 161). The roots when distilled with water yield a fragrant oil (known in European trade as Vetiver, which is used as a perfume and for flavouring sherbet. It commands a high price in Europe, being employed in many favourite scents. It is the most viscid of essential oils, and hence its sparing volatility is taken advantage of in fixing other perfumes. The oil is hardly, if ever, exported from India; European supplies being either locally made from the Indian roots or derived from Réunion. According to Piesse, the yield is about 10 oz. per cwt.; other observers have found it to vary from 0.2 to 3.5 per cent. Rheede, who was perhaps the first European author to allude to this plant, calls it ramacciam, and says that with the Brahmans it was bocalo. It was in his time both wild and cultivated in Malabar on account of its roots, which were used medicinally.

In MEDICINE the root has been regarded by European physicians as a diaphoretic and as a preservative against cholera (Pereira, Mat. Med., ii., pt. i., 132). In The Bowier Manuscript (which appears to date from the 6th century) frequent mention is made of usira or virana, which Hoernle renders as the present odoriferous grass; it was an ingredient of a plaster beneficial to the complexion. A paste is rubbed on the skin to relieve excessive heat; an aromatic cooling bath is made by adding to a tub of water a powder of the root with that of Pteronia odorata (red sandal-wood), and the wood of Phoanus Cañatum. The grass (leaves, etc.) is suitable for paper-making, and it is said that 60,000 to 70,000 maunds are annually available in the Hissar district of the Panjáb alone. When young, the grass affords good fodder, and is also in universal demand for thatching purposes. [Cf. Talfef Sherekf (Playfair, transl.), 1833, 14; Taylor, Topog. and Stat. THE COW PEA

1904, 178; Leguminosae. The Garden Bean, báli, andhú, máthban, kálú, chastang raiûn, saín, etc. De Candolle considers its introduction into India to be quite recent, though this would seem to be true only of the plains. In the higher Himalaya it is not unlikely that its cultivation has passed down from the most ancient times.

At the present day it is cultivated in the plains here and there in European gardens, and chiefly in the United Provinces. There are two distinct forms, the long-podded and the broad-podded, the latter originating the name "Broad" or "Windsor bean." The former is said to succeed best in India, though Firman-ger recommends the "broad bean" for garden cultivation. The seed should be sown about the middle of October, and previous to sowing should be steeped in a basin of hot water for twelve hours or more. [Cf. Bentham, Rev. of Terroni-Tazzetti, in Journ. Hort. Soc., 1855, ix., 138; De Candolle, Orig. Cult. Plants, 1884, 316; Church, Food-Grains of Ind., 1886, 132; Ase Gray, Scient. Papers, 1889, i., 349; Pharmacog. Ind., 1890, i., 485–6; Howe, Rep't, on Prov. of South W. 1904, No. 5, 12.]

VIGNA CATJANG, Wurtz.; Fl. Br. Ind., ii., 205; Duthie and Fuller, Field and Garden Crops, ii., 12, tt. xxi.—xxx.; Prain, Beng. Plants, 1903, 1., 389; Duthie, Fl. Upper Ganj. Plain, 1903, 227; Légumino- sae. The Cow Pea, Chowlee (India), Tow Cok (China); lobía or lobbiá, chowli, rianish, barbati, qhangra, urohi, souta, rawin, chaunro, hurree, chavli, caramunyy-pyre, boberli, tadagunny, etc. A sub-erect herb cultivated in the hotter parts of India. Var. sinensis, Prain; Dolichos sinensis, Roxb., Fl. Ind., iii., 302; the Asparagus Bean; a climbing herb cultivated in most parts of India.

It has been pointed out, under Dolichos Lablab (p. 508), that the name lobía (of the Greeks) is commonly applied to that plant and loosely by Indian market gardeners to any pulse, but more especially denotes the present plant. The word lobiya may be, however, derived from the Sanskrit lobhāya (==alluring); it occurs among the list of autumn (kharî) crops known to Akbar, and since Vigna Catjang comes into season in the autumn it is probably the plant referred to. The crop, as a rule, is grown in fields for its seed, and used as a pulse. It may be cultivated alone, but is generally a subordinate crop. Various races exist, one of which, with long pods, is raised by market gardeners as a vegetable and sold as a substitute for French beans.

CULTIVATION.—In Cuttack Bengal, where it is cultivated alone, Banerjei (Agri. Cuttack, 1893, 81–2) states that "it is grown on high loamy lands, and in rotation generally follows bâli and mandia." The soil is prepared and the seed sown broadcast in September—October. In December—January, when thoroughly mature, the plants are plucked up by the root. "The variety raised for vegetables begins to yield fruit in November—December." Basu remarks that in Lohardaga it is "always grown as a second crop along with mârud (Eleusine coracana) and occasionally with gotâ or upland paddy." In July the seed "is thinly scattered over the fields at the rate of 1½ saccs per acre. The pods when they ripen are hand-picked at the same time, or just before harvesting mârud. The average outturn is one maund per acre, the heaviest yield never exceeding 2 maunds; the value of the produce is about Re. 1–8 in a year of common prices." In the United Provinces there were 1,062,783 acres under urd, mung, moth and lobia during 1904–5. Later figures are not available. "It is less frequently grown as a sole crop than either mung (Phascolus raviatus) or urd (P. Mungo), and the area which it occupies by itself is quite insignificant except in the Rohilkhand Division. On the other hand it constitutes a distinct feature of the undergrowth in a large proportion of kharî millet and cotton fields, with which it is associated at the commencement of the rains. It ripens in October or November, and yields a produce of about the same quantity as that of urd" (Field and Garden Crops, i.c.). In the Season and Crop Report for 1905–6 it is stated that the area under this pulse was 32,703 acres, of which 1,706 were raised in the robi. With regard to Bombay, Mallison says "it is grown with other pulses subordinate to bojri in light alluvial soils in the Kaira district. It does better in moderately light soil than in soils of heavier or denser consistence. It is

as a food auxiliary, as a preservative for certain articles of diet, as a medicine, and lastly for certain industrial purposes. It is produced by (a) what is known as acetous fermentation of a mixture of malted and unmalted grain (forming malt vinegar), and (b) the oxidation of white or red wine (yielding white or red wine vinegar). Chemiclly it is a dilute solution of acetic acid with certain organic substances derived from, and peculiar to, the material from which made. It is, in other words, a weak solution of acetic acid, produced by the fermentative action of a vegetable organism (Mycoderma aceti), the process of transference being called acetous fermentation.

History.—Mr. F. W. Thomas informs me that sukta is the most general Sanskrit name for the true or fermented liquor. This occurs in the Brähmanas, Suśruta and elsewhere. Sauktika is an adjective form of the word mett with in Charaka (1st century A.D.). It denotes very possibly the vinegar prepared from a sweet liquid, such as sugar-cane juice, palm-juice, etc. But malted vinegar seems also to have been understood, and is possibly denoted by the word kānjika (sour or fermented), rice gruel (see the account under Burma, p. 1111). The Bhāvaprākāsā defines vinegar as a substance fermented from bulbs, roots, and fruits with oil and salt, and this use of oil and salt will be found frequently alluded to. The Rājānirghanta alludes to the employment of grain in the production of cukra. Lastly, cukra or cukraka is applied to sour substances (such as the fruits of the tamarind and the sorrel) which are used as substitutes for vinegar. These occur in Suśruta, Harivamsa, etc.

Vinegar is known all over India by its Hindustani name sirka. In the provinces the following vernacular names are given to it:—kadi in Tamil; pulla nila in Telegu; chuka in Malayam; and pon-ye in Burmese. While thus doubtless a substance of universal knowledge to-day and one which bears a fairly ancient record, it is significant that most works on India, both ancient and modern, have remarkably little to say about it. Writers on Materia Medica, as well as most of the standard authors on travel, etc., in India, are silent regarding vinegar. Even the Institutes of Manu makes apparently no reference to it. With the Muhammadans, however, vinegar always has been a more important dietetic luxury than with the Hindus, and to this circumstance perhaps is due the scant attention paid to it by early writers. It is, however, alluded to by Thevenot (Travels in Levant, Indostan, etc., 1687, pt. iii., 16) and one or two other European travellers.
MANUFACTURE.—Most of the Indian vinegars are prepared from sweet liquids derived from palm-juice, sugar-cane juice, crude sugar, honey, makhua flowers, grapes, raisins, and other fruits. They are thus not malted, though of course fermented and mostly by the slow process. Each kind of vinegar is named after the substance from which it is produced; thus tári-ka-sirka would be the vinegar of toddy, etc.

_Bengal._—N. C. Chaudhury, Travelling Inspector, Department of Agriculture, writes that in Calcutta there are some twelve shops where sherka (sirka) is manufactured. Each shop turns out about 300 maunds annually on the average. No sherka is imported into Calcutta from Bengal districts, though it is known to be prepared on a small scale in Bihar. It is made chiefly from cane-juice (see p. 952), but also from gur (raw sugar), and occasionally from the fruits of the jámán (Eugenia Jambolana, see p. 526). The manufacture from cane-juice may be briefly indicated:

—Cane-juice is kept in a big earthen pot (jala) (sunk in the ground up to the middle) in an open place and exposed to the sun. The mouth is covered with an earthen basin (gamia). The jala may contain 10 to 16 maunds of juice. Ordinarily it takes three or four months, sometimes six, to complete the operation. After a month or two, when fermentation has taken place briskly, the juice is transferred to a fresh jala till the fermentation is finished. The liquor (sherka) is then conveyed into smaller jalas and is ready for sale. Out of 40 seers of juice, 30 seers of sherka are obtained. In the case of gur or date sugar—'' to one maund of gur or sugar, 4 to 5 maunds of water are added, and the solution thus prepared is treated just as with cane-juice. It takes a little longer time—say about fifteen days more—to finish the preparation of the vinegar from the materials named. Forty seers of the sugar or gur solution yield about 34 or 35 seers of sherka. No special details are furnished regarding the production of vinegar from jámán fruits. Cane-juice sherka is sold at Rs. 5 per maund, the gur sherka at Rs. 4, the sugar sherka at Rs. 4–8 per maund, and the jámán sherka at Rs. 12 per maund.

_Eastern Bengal and Assam._—Information has been received from the Deputy Commissioner, Sylhet, and the Collector, Dacca. The former writes that vinegar is prepared on a very small scale and for home consumption only. It is made from the juice of (1) bhūti (? Garcinia paniculata, see p. 555), (2) blackberries (Eugenia Jambolana), (3) pine-apples (Ananas sativa, see p. 69), (4) imbaki (Phyllanthus Emblica, see p. 887), and from that of sugar-cane and date-palm. The Collector, Dacca, states that in the town the vinegar sold is chiefly imported from abroad. "In Dacca there are only two firms who carry on the manufacture, and in both the business done is very small. The process is exceedingly simple. In one case the substances used are (1) the juice of the date (see p. 886) or palm tree (see p. 170), (2) bread (see p. 1100) and (3) gram (Cicer arietinum, see p. 300). The earthen jar is filled with date or palm juice, and then a few slices of bread and a few handfuls of gram are thrown into it. The mouth of the jar is closed with a cover, and the liquid allowed to ferment in that state for a month or six weeks or until the fermentation is complete. It is then passed through a clean cloth and put into bottles. The vinegar thus manufactured is sold at 2 or 3 annas per bottle.

In the other manufacture the ingredients are (1) cane molasses, (2) putrid apple and (3) gram, while the process of manufacture is exactly the same. The addition of bread and gram, and the utilisation of the waste materials and wild apple-pieces are interesting features of this special Eastern Bengal industry.

United Provinces.—Hoey (Monog. Trade and Manuf, N. Ind., 1880, 180–1) tells us that the chief material used in the manufacture of vinegar is _shirā_ (see p. 952). "When sugar-cane is crushed it gives out the juice called ras. This is boiled and gur and rdb are made. The froth is skinned off and put aside. The crushed stalks of the cane are laid in a vat (_hauz_) with a small outlet below and the froth is thrown on them with a little water. The substance which comes trickling off is boiled and becomes _shirā_. This is the stuff which is purchased by the vinegar-makers and tobacco manufacturers" (see p. 807). In a long and highly interesting communication, the Assistant-Director of Agriculture in these provinces relates that there are a great many substances employed in the preparation of vinegar, but that the liquor is chiefly obtained from cane-juice and cane-juice products. The other better known sources are palm toddy, grapes (see p. 1119), raisins, jámán, barley (see p. 643), etc. The methods of

manufacture are essentially similar to those already detailed in connection with the Lower Provinces. “Fresh cane-juice is obtained from the mills, strained through a piece of coarse cloth and filled into earthen vessels which have been well washed and dried for the purpose. The mouths of the vessels are then closed with stoppers to prevent foreign matter getting into them, and they are removed to a place of safety, where both sun and air can have free access. This naturally takes place at the beginning of the summer, towards the end of the crushing season, and the jars are allowed thus to stand till the commencement of the rains. Throughout the rains damp is avoided as much as possible, as it affects vinegar injuriously. The jars are placed in a dry and warm corner and exposed to the sun at intervals. If kept in a damp place, a thick scum develops upon the surface of the liquid—a mould which appears all in one piece. This bears different names in the localities of vinegar manufacture, the most common term for it is sahír. In Bijnor it is called biláit and in Meerut bhadder. The development of this mould is generally considered ruinous to the vinegar and the material is thrown away, but the more economical advocate curing it. They remove the scum carefully, filter the liquid, change the vessels and add various preparations consisting of Chenopodium (p. 293) seeds and chillies, or of asafetida (p. 533), garlic, chillies, and common salt. They also add raw bel (Ejfe Marnelos, see p. 28), munj (Saccorhuma arundinacea, see p. 920), and a small quantity of sugar. If no attention be paid to the mould, the vinegar after some time altogether disappears.”

Vinegar from toddy is said to be largely used for medicinal purposes, and sells at Rs. 10 to Rs. 12 a maund. Grape and raisin vinegar (see p. 1119) are more costly, selling at Rs. 15 to Rs. 20 a maund. Grape vinegar is thus described:—a solution is made of sugar in water, about 18 seers of sugar to a maund of water, and grapes are then crushed into this solution and the mixture set aside. In time it turns into vinegar. Being expensive, grapes are, however, not very largely used for this purpose on the plains. Jáman vinegar (see p. 520) is made chiefly in Lucknow and costs Rs. 10 a maund, while vinegar from barley costs Rs. 15 a maund. A highly refined form of vinegar termed arak-náná is obtained by redistilling ordinary vinegar along with a small quantity of mint (5 seers dry mint to the maund of vinegar). The substance is said to be extensively manufactured in Lucknow and to be used for pickling. It sells at Rs. 5 to Rs. 10 per maund.

The chief centres of the vinegar trade are stated to be the large towns and cities, notably Lucknow, Gorakhpur, Benares, Meerut, Bijnor, Agra and Shahjahanpur. Lucknow prepares all sorts of vinegars, both edible and medicinal, and these are conveyed all over the Provinces and even to Calcutta.

Panjáb.—In connection with the correspondence above indicated, communications were received from Lahore, Delhi, Multan, Jalandhar and Rawalpindi. Of Lahore, it is stated that vinegar is prepared in the usual way from sugar or sugar-cane juices (rarely from molasses), but in combination with grapes, with alum (phitkári), or with salt as adjuncts. The price per maund of one-year-old vinegar is Rs. 20, of vinegar six months old, Rs. 10. In Delhi there are four principal manufacturing centres, and sugar-cane is almost solely employed. A maund of cane-juice gives 30 seers vinegar. The vinegar in greatest demand is arak-náná (or -náná) already described, namely that made from crude vinegar by adding mint and subsequently distilling the mixture. Vinegar is also occasionally made from grape-juice, raisins, jamans and oranges (see p. 327). The total output of vinegar in Delhi is estimated at 1,200 maunds a year. In Multan three kinds are made—anguri from grapes, kishmash from raisins, jamans from jamans, but it is prepared only in small quantities for local consumption.

The Deputy Commissioner of Jalandhar gives the method of preparation pursued there. To one maund of sifted rae (sugar-cane juice) are added five bottles of superior country vinegar and placed in a jar polished inside with lakh. The mouth is closed and the jar set on one side for three or four months. It is then filtered through a cloth at intervals “to rid it of worms or insects which collect in it.” A quarter-seer of ground tej pat (Cuminum cumminum Tumala, see p. 313) leaves and half a chittaek of ground kaulanjí (Nigella sativa, see p. 811) and chillies (see p. 268) are added, the mixture being left for a month or so more. It may now be ready for use. The vinegar prepared from cane-juice is reddish in colour, but this may be corrected by the addition of alum (see p. 61).

In Rawalpindi district, according to Robertson (Setif. Rept., 1880-7, 1893, appi, xxiv.), the manufacture of vinegar is a fairly important industry, the exports being carried by river from Attock to Sukkar. In the town of Rawalpindi only one vinegar-maker exists, who prepares it either from raisins (see p. 1114) or from gür.
PROVINCIAL PRODUCTION

A large earthen pot polished on the inside with goat’s-grease is charged with one part raisins and four parts water, and the mouth closed as tight as may be and placed “in a room where there is little air, since there is a possibility of its being spoiled otherwise. After twenty days a tola of Peshawari salt and a tola of mercury in the ratio of a seer of raisins used, is mixed with it and the mouth of the vessel is again sealed. Twenty days after this operation the vinegar is ready for use (i.e., in forty days) and is then filtered and kept either in bottles or jars.” Price Rs. 2–8. or 3¢ per maund.

Central Provinces.—Very little vinegar is made in these provinces. In a communication from Seoni it is observed, “The vendors of vinegar, and the confectioners who use it, in making up chutnies and other preserves, procure their stock from outside: from Nagpur, Jubbulpur and even from Delhi. The Deputy Commissioner of Betul speaks of a small manufacture from sugar-cane juice, as also from the berries of the jamun tree (Eugenia Jambolana). The berries are placed in an earthen jar along with some common salt and left for a few days. The juice is then squeezed out and placed in the sun for a short time. Mr. Sadashio Narain of Gadarwara describes three forms of vinegar as prepared from sugar-cane juice, from jamun fruits and from raw sugar.”

Madras.—In the series of Official Papers mentioned above, a report issued by the Board of Trade, Madras, gives the particulars regarding that Presidency. The producers are the toddy-shopkeepers, and they convert their unspent toddy into vinegar in either of the following ways. The toddy is placed in a closed earthen pot and kept there till fermentation is complete and the liquid has become sour. The pot is either kept above ground for a month or two, or is buried underground for three or four months or more, and then taken out. The longer the pot is kept closed and underground, the better the quality of the vinegar. In either case pure vinegar is obtained when the pot is opened and the sediment has been removed. Vinegar is also made by heating fermented toddy either by fire or by exposure to the sun. It is procured in a shorter time by this method, but the quantity is less than by the slow or natural fermentation. The vinegar thus obtained is, however, used both for medicinal purposes and in cooking. There is no shop or bazaar in Madras where country-made vinegar is specially sold, and the trade is not so extensive as that in either English or German vinegar (see p. 170).

Burma.—The information procured from the various districts show two main classes of vinegar as made, namely, from grain or from sweet fluids. The substances chiefly used in the manufacture are rice, peas, toddy, jaggery, sugar, dates and plantains. The observations regarding the preparation of vinegar from rice and peas are interesting, and amplify the Indian knowledge already exemplified. The rice (see pp. 826, 840) is boiled and then cooled for about three hours; it is then mixed with congi or water obtained from previously boiled rice. The mixture is then put into a pot of clean water and kept for three days in the shade. Some salt is now added (1 tola to 1 viss of liquor). The liquid may be seen to have turned slightly green and to have become sour. This is called san-pony, and may be described as the domestic vinegar of the province. It is a crudely formed malt vinegar.

With the peas (see p. 903) the process is similar. They are boiled till they turn soft and the water becomes reddish. This is strained off and put into another pot or jar, the month of which is tied up with a cloth. The fluid is boiled again, salt (3 tolas to 1 viss) added, and the boiling continued till the fluid is reduced by one-third, the result being crude vinegar. Speaking of the manufacture of vinegar from sweet fluids such as palm wine (toddy), mention is repeatedly made by the Burmese correspondents of the advantage of adding a few slices of bread so as to facilitate fermentation. In Mergui, vinegar of local manufacture is largely employed in preserving fish. It is prepared from stale toddy, chiefly the produce of the Nipa palm. Vinegar is said to be improved by placing a hot brick in it.

Trade.—There is no export trade in vinegar from India, and imports of vinegar, together with pickles, sauces and condiments, were recorded in the Official Returns for the first time in 1905–6, when the total quantity received amounted to 14,878 cwt., valued at Rs. 4,13,653; and in 1906–7, 16,300 cwt., valued at Rs. 4,77,033. The bulk of this import traffic is shown to come from the United Kingdom.
VITIS VINIFERA

Hindu Knowledge

V. vinifera, Linn.; Semler, Trop. Agrik., 1892, iv., 8–186. The Vine or Grape, angūr, dākh, buri, tanaur, newala, māmre, gandeli, lāning, quvar, kodi-mun-dirrip-pasham, draksha-pondu, baaangūr, sabi-si; raisins = kismis, manakkā, zirshk, mītha, kurk uzum, kisumisuchettu, zāhib, etc.

Wild Grapes.

The Grape Vine is said to be indigenous in the temperate regions of Western Asia, Southern Europe, Algeria and Morocco (De Candolle). According to the Flora of British India (i., 652) it is "perhaps wild in the North-West Himalaya; cultivated extensively in North-West India, rarely in the Peninsula and Ceylon." Gamble (loc. 190) says, "Has been introduced and successfully cultivated in Kashmir and other parts of India." Lawrence (Valley of Kashmir, 351) remarks that in the old days Kashmir was famous for its grapes, but now, if a few vineyards at the mouth of the Sind Valley be excluded, it is difficult to obtain a good dessert grape in the country." " Everywhere one sees giant vines climbing up poplars and other trees, but they are often wild, and their fruit is poor and tasteless."

History.

History.—Grapes have been known in India from a very remote period. In Sanskrit works the best-known names for the fruit are drākṣā and mridvāk, while a spirit distilled from grapes (madādhika) is distinguished from that from sugar-cane, rice, barley, etc. As showing the antiquity of the knowledge in grapes, Dutt mentions that they are alluded to by Charaka and Suśruta. Prior to the Muhammadan conquests of India we possess, however, no very precise information as to the cultivation of the grape in India proper.

Stein (Ancient Khotan, 1907, 448) tells us that while working in the ruins of Kara-Dong (8th century), he came across a cupful of "large black currants dried perfectly hard." In other passages (l.c. 253, 255) he invites consideration of the fact that in one of the paintings of Dandān-Uiliq, instead of the conventional fig-leaf, the vine-leaf had been substituted, and in still another passage (l.c. 245) he draws attention to the frescoes of Dandān-Uiliq, which manifest a vine-leaf and grape pattern. It is thus quite clear that the grape was well known at these early times, just beyond the north-western frontier of India. In The Bower Manuscript (Hoernle, transl., 1893–7), moreover, numerous references are found to the use of raisins in various medicinal preparations.

But the medicinal uses of the vine recorded in Hindu literature are mostly concerned with the dried fruits or raisins and the spirit (madādhika), so that it is probable that prior to the Muhammadan conquests, both the fresh fruit and the various forms of raisins were, as at the present day, imported from across the northern frontier. Many writers (Hehn, Kulturf. und Haust, 1894, 65–94) have dwelt on the influence of the faith of Islam on vine-growing in the...
MUHAMMADAN INFLUENCE

East, seeing that the drinking of wine is contrary to Muhammadan law. Sirajul-Hasan (Journ. Roy. Hort. Soc., xxix., n.s., 671-4; xxxii., 222-6) furnishes, however, many useful particulars regarding the vineyards of Daulatabad. These, he thinks, date from the time of Tagluq (1335 A.D.), but on Tagluq’s death the capital was transferred to Delhi, and that event had a disastringous effect on the gardens. The following passages, perhaps, sufficiently indicate the ‘Syed’s views:—

‘During the time of the Bahmani Kings (1430 A.D.), Daulatabad became a military station under Parwiz-bin-Karaniul. Once again the people began to pay attention to gardening, however, only those kinds of vines were had survived the neglect of previous years.’ Then, in another passage, he remarks, ‘A great stimulus to grape cultivation was given by the Portuguese Christian Missions located at Aurangabad, which were liberally endowed by the early Bijapur or Ahmadnagar Kings in 1550. Their monasteries grew both purple and white grapes. Ibn Batuta, the Moors’ traveller who visited Daulatabad in 1430, and the French traveller Thevenot, who made an extended tour in 1667, were much struck with the gardens that met their eyes throughout the Sarkar of Daulatabad.’ ‘This state of things continued till 1685 A.D., when Aurangabad became the capital of Aurangzeb. The city grew rapidly, and with it the demand for all sorts of luxuries.’ ‘In Daulatabad itself, the passion for cultivating vines knew no bounds. Places of recreation provided by noblemen in their own gardens were entirely covered with vines. Even Fakirs looked upon the vine as a gift from Paradise, and had their mosques and monasteries adorned with it.’

The Emperor Baber (Memoirs, 1519 (Leiden and Erskine, transl.), 205) gives a full relation of the first occasion on which he tasted wine. His grandson Akbar, however, fostered and encouraged grape cultivation, and, by his direct aid, grapes of high merit were successfully acclimatised in the Panjáb and throughout the greater part of Northern and Western India. But on accession of Akbar’s grandson the order went forth for the destruction of the vineyards of Kashmir, and grape culture in India shared in the neglect that followed. The seventeenth and eighteenth centuries, therefore, witnessed a decline of interest in vine culture, sufficient to account for the low position the industry now occupies, and naturally the references either to the vine or to wine in the works of the early travellers are few, and mostly of a negative character. Nicolo Conti, who travelled in India early in the 15th century, speaking of a town called Phanonia (supposed to be Pegu), says, ‘This is the only place in which vines are found, and here in very small quantity: for throughout all India there are no vines, neither is there any wine.’ This, doubtless, was not a very accurate statement, since shortly after other writers speak of grapes as seen by them in various parts of India and Burma. Thus of Gujarat, Mandelslo (1638-40) says, ‘They want nothing but wine; but to supply their want of that, they have Terri, taken out of the Cocos-tree’; but Tavernier (1676) says that in Assam ‘There are quantities of vines and good grapes, but no wine, the grapes being merely dried to distil spirits from.’ Thevenot (Travels in Levant, Indostan, etc., 1687, pt. iii., 16) tells us that the Dutch made wine from the grapes of Suratt; and that in Golconda they made white wine (I.c. 104); also that wine-drinking was punished in Kandahar (I.C. 56). Ovington (1689) observes that Bannians, though they ‘are under restraint from the blood of the grape, yet will they freely taste the grapes themselves luxuriously with their juice, while it is innocent and harmless. We have grapes brought to Suratt, from the middle of February till towards the end of March; some from Amadavat, some from a village called Napotre, four days’ journey distant from Suratt.’ These would doubtless be described as the Deccan grapes of the Bombay shops to-day.

There is thus no doubt that large tracts of Upper and Western India are eminently suited for grape cultivation. Many quotations might be furnished to prove the extensive and diversified nature of the knowledge that exists in India and its chief frontier countries regarding the vine. Kanáwar, for example, is one of the Indian localities where what may be described as indigenous viticulture is recognised industry, and Kashmir as an area of both acclimatised and wild grapes, so far as the present-day cultivation is concerned, and lastly the trade in the produce of the vineyards of Afghanistan, Baluchistan and Kashmir is of no mean importance, and moreover capable of indefinite extension. To that category there seems every prospect in the near future of being added, namely as an important centre of grape cultivation.” [ Cf. Paulus Aegineta (Adams, transl. and Comment), i., 172-8; iii., 271-3: Januensis, 1113]
VITIS
VINIFERA
Kashmir

VITICULTURE AND WINE AND RAISIN MANUFACTURE.

According to Woodrow (Gard. in Ind., 1903, 227), “The favourite varieties of grape that are grown in Europe have been introduced many times into India, but with few exceptions fail to become established.” He then mentions the following forms as having been acclimatized and as being cultivated successfully in India generally:—White Mascarde (safed angoor); White Portugal (Cashmereco or White Tokay, valayati angor); Black Monukka (bae-danae angor); Black Hamburg (hubshee angor); and Faquira. Details regarding the methods of propagation, etc., as applicable to India, are given in detail in the same publication, but space does not permit of full treatment in this work. Perhaps one of the most important points to which attention should be paid, is the influence of atmospheric moisture. The fruit will not ripen when once the rains have broken, so that early maturity stock in direct adaptation to climatic conditions is essential. Firminger (Man. Gard. Ind., 1904, 271) states that “the driest and hottest period of the year is when grapes ripen finest. This will be March in the Deccan, May in the vicinity of Calcutta, and June in the Upper Provinces.”

Panjáb.—Henderson remarks that “in many parts of the Panjáb, the vine thrives quite as well as in Europe,” and Baden-Powell (Pb. Prod., 271) enumerates twelve different forms recognised there. Practically no information, however, is available regarding viticulture in recent years in the Panjáb. The reports of the experiments carried on at the Agri-Horticultural Gardens of Lahore contain little information, and are mostly a record of failure. While that is so, there are several very distinctive grapes regularly sold in the larger towns (such as the small seedless grape of the Delhi market) that seem well worthy of special study. Sly (Agri. Journ. Ind., i., pt. iii., 268-9) discusses the fruit culture of the North-West Frontier Province. He says that 4,000 acres are under orchards, of which 2,700 are in Peshawar. He then discusses the grapes of Peshawar, Kohat, Kuram and Bannu. (For raisin Vinegar, see pp. 1110-1.)

Wines of Káshmír.—But the interest in Upper India centres very largely in the vineyards of the State of Káshmír. “In the time of the Emperor Akbar, as already indicated, wine production was a very general industry, and held then a much more important place than at the present day. During the time of the Emperor Jähangir, the grapes of Káshmír were improved, but shortly after the decline set in which has been already alluded to. Coming down to modern times, the subject next assumed interest in 1876, when the late Maharajah Ranbir Singh took up the enterprise of vine-growing, and in 1885 had 352,523 plants in his various vineyards. At the Calcutta International Exhibition of 1884, red and white wines and also brandies made in Káshmír from the pure juice of the grape were exhibited, and obtained a gold medal and were highly commended for purity and excellence. This circumstance has often been overlooked, and the old tradition of India not producing wine been every now and
KASHMIR AND KANÁWAR

again commented on. It can and does produce wine, and no one can say that its wine industry of the future may not become one of its commercial triumphs. In spite, however, of the great expenditure lavished on them, the vineyards of Kashmir have not as yet proved the success anticipated, and in 1890 it became evident that the vines were suffering from Phylloxera. With reference to this, Lawrence (Valley of Kashmir, 1895, 351-2) states that "American vines were at once imported, and are now gradually replacing the unhealthy Bordeaux plants."

Commenting on the decline of the production of the eating grape, Lawrence observes that the people cut down their good vines in order to avoid the exactions of officials. "The grapes, white and red, from the State vineyard at Raipur in the Sind Valley are delicious, and efforts are being made to reproduce the Raipur vines in other parts of the valley. With the decline of the eating grapes, there has been an attempt to introduce the wine grape, and at present there are 389 acres of vineyards on the shore of the Dal Lake. The vines were introduced from the Bordeaux district." "Perhaps the vines of Burgundy would have been more suitable to Kashmir. Costly distillery plant was imported and set up at Gupkar on the Dal Lake, and vines of the Medoc and Barsac varieties, sometimes good, sometimes bad, have been manufactured year by year."

"Besides the Medoc and Barsac, which are sold at Gupkar, a large amount of apple brandy is distilled and finds a ready sale." "The vineyards are under the direct management of the State, and in spite of supervision, the vines do not receive the sedulous cultivation which alone can give success." "The business in present circumstances does not pay." [Cf. Smythies, in Agri. Ledg., 1894, No. 15, 24-5, 27-8; Coldstream, Vine Cult. in Kanawar, in Ind. Gard., Aug. 14, 1898; Repts. Agri.-Hort. Gardens, Lahore.]

United Provinces.—Practically nothing of a definite nature has been written regarding grape cultivation in these provinces. The vine is said to fruit well in most districts throughout the plains, but the grapes are quite unsuited for wine manufacture. On the hills, however, it is otherwise, since at Kumaon, Kanávar, etc., a fairly large industry exists in vine cultivation. In Kanávar the vine has been cultivated since the early classic period, and several writers have spoken in high terms of the vines of Dehra Dun (Ind. For., 1889, xv., 313-5). In the Reports of the Botanic Gardens at Saharanpur will be found some information regarding the experimental cultivation of foreign, mostly Afghan, varieties.

"In Upper Kanawar," says Cleghorn (Journ. Agri.-Hort. Soc. Ind., xiii., 382), "the vine is extensively cultivated and ripens its crop at an elevation of from 6,000 to 9,000 feet. The first plants are seen at Nachar, but the climate there is not suitable; beyond the Miru ridge which intercepts the heavy clouds, the smaller amount of rain favours the ripening of the grapes. The vineyards occupy sheltered situations, generally on the steep slope facing the river. The vines are supported on poles three or four feet from the ground, connected by horizontal ones. The fruit hangs below the shade of the leaves, never exposed to the sun. A considerable portion of the crop is dried on the house-top and stored as raisins for winter use, but without care, and many grapes are spoiled in the process. For several years the crop has been deficient, the grapes dropping off before they were ripe from unseasonable falls of rain and snow. This year, 1864, the rainfall was moderate, but the Oidium or vine disease appeared in the valley, and destroyed many vineyards. The fresh fruit is exported to Simla for sale in kilas or large hill baskets, and the small seedless grapes dried are also sold there as "fine Zante currants" at 2 rupees per pound. At Akpa and Poari the
price of fresh grapes is about one rupee for a kilta-full." "Sungnam is the highest point in the valley where the vine thrives."

In Kanawar, says Mr. Atkinson (a later writer), the fruit is called dakhang and the plant lanang, and there the vine is extensively cultivated as a field crop, and ripens its fruits at an elevation of from 6,000 to 9,000 feet. He then adds that a spirit called rak or ark is prepared from the juice, and also a wine called sheo.

According to Hoffmeister (Travels, 1848, 377-8) there appears to have existed a large trade in carrying fresh grapes from Bashahr to Simla. This traffic can hardly be said to exist to-day, though the exports of raisins may be considerable and, moreover, capable of infinite development. The available information regarding the Kanawar industry is, however, both meagre and contradictory. But with a community of cultivators possessed of an ancient tradition and centuries of experience as vine-growers, much might be expected were viticulture organised on more scientific principles, and with sufficient capital and commercial enterprise.

The earliest definite information regarding the cultivation of the vine in the Deccan would appear to be that already briefly alluded to in the paragraph above on history, viz. the passages from Ibn Batuta, Thevenot, Mandelslo and Ovington, etc. Syed Siraj-ul-Hasan (I.c. 224) says, "Looking at the present condition of the fruit trade at Poona and Nasik, one realises what treasure lies buried in Aurangabad and its vicinity. These two places send fruit to the value of many lakhs of rupees to the Bombay market. The writer has personally seen thousands of acres of lands under vine cultivation around Nasik. One merchant alone—a Bohra—exports as much as £33,000 worth of fruit. Why should not Aurangabad compete with the other cities on equal terms? The soil is excellent, as proved by the experience of centuries."

The moist climate of the Konkan is not suitable for vine-growing, but in parts of the Deccan, e.g. Ahmadnagar, Aurangabad, Poona, and especially Nasik, grapes of fair quality are grown for the Bombay market. The vines are usually trained on live posts cut from Erythrina indica, a tree known in the vernacular as the pangara. The account of cultivation given by Woodrow, which has been already referred to, has special application to Bombay, and should be consulted in this connection. More recently P. S. Kanetkar, Superintendent, Empress Gardens, Poona, gives a full account of viticulture in Poona and the Deccan (Ind. Plant. and Gard., April 21 and 28, 1906). He names five distinct varieties which are cultivated there, viz. abhi or bhokri, jakhdi or jakiri, habshi or kali, golkali and sahebi. The field selected "has a kind of garden soil that is neither black clay nor light red (murrum), but is a mixture of these, and contains a fair proportion of lime." In the hot weather it is ploughed four or five times and during the rains is left fallow, or Crotalaria juncea (tag) is grown and ploughed in as a green manure in September. The young vines are reared in nursery beds and then transplanted. The season for transplanting the vine stocks is the month of January. The stock is prepared from the cuttings of the October prunings. "The cuttings, about a foot long, with four eyes or buds upon them, are chosen from ripe wood and are planted in beds; the soil of which is manured with ashes or well rotted farm-yard manure." They are put down in twos, and by January throw shoots about 6 to 9 inches long and become fit for planting out. Previous to planting out the young vines, the field is ploughed along and across, the points of intersection of the furrows being 7 feet apart. At the points where the furrows cross, pits are dug, in each of which a basketful of manure is placed. A pair of young vines is then planted in each pit.
DECCAN GRAPES

The furrows between the pits serve as water-channels, and water is applied immediately after planting. A second and third watering are given at intervals of four and six days, and later the plantation is watered every eight days till June. When the vines are established, karvi stakes (Strobilanthes callosus) are driven into the ground and two of the healthier shoots tied to them, while the others are cut off. In this way the vines grow till April, during which time half a basketful of farm-yard manure, or preferably poudrette, should be given twice to each vine and all side-growth removed. When the vine has grown over 5 feet (towards April), the ends are nipped off. As a consequence, side shoots are thrown out near the top. About three or four of these shoots are kept and all the lower ones are removed. Stronger stakes of the pangara (Erythrina indica) are now supplied in place of the karvi. "The three or four shoots kept at the top of the vine continue growing till October next, when the pruning for the mitha bar (sweet crop) becomes due." After pruning, the ground between the rows of vines is ploughed. No water is given till the shoots blossom, and form small fruits. "About four weeks after pruning the blossoms appear and the fruit sets in a short time afterwards." The bunches are ready to be gathered in March, about six weeks after the grapes begin to get soft. "A well-established plantation about ten years old yields about 10 or 12 lb. of grapes per vine." After the fruit is gathered (in March), no water is given for about a month, and in April the hot-weather pruning is done. "At this pruning the spurs or kalam which had three or four buds left on them at the cold-weather pruning for giving the fruit-bearing shoots, are shortened and cut back to two buds, from which alone one or more shoots will spring up to bear the sour fruit of the rainy season." After the hot-weather pruning, the land is again ploughed, harrowed, and manure applied. Water is then given and continued weekly till the rains. In October pruning commences again, as already explained. [Cf. Repts. Dept. Land Rec. and Agri., Bombay.]

Diseases.—Very little is known regarding the diseases of the vine in Western India. Recently, however, Butler (Agri. Journ. Ind., ii., pt. i., 94–5) furnished a brief report on the subject and identified two out of the four diseases mentioned by Mr. Kanetkar. The four diseases are—(1) kharda rog (red or brown rust), (2) buri (mildew), (3) khajalya rog (black rust), and (4) karpa rog (drying-up disease). The second and the fourth are well-known diseases of the vine. Buri is Oidium Tuckeri, one of the most destructive of mildews; while karpa rog is anthracnose (Sphaceloma ampelinum). Both can be controlled if not checked by flowers of sulphur. [Cf. Maxwell-Lefroy, An Insect attacking Grape-Vine, in Agri. Journ. Ind., 1907, ii., pt. iii., 292.]

Baluchistan and Sind.—One of the many surprises that meet the visitor to Quetta is the profusion and superior quality of the grapes that are offered for sale. On inquiry these are found to be frequently raised in vineyards where there is practically no rainfall and where few or no streams are seen to carry surface water. Underground, however, the people have excavated drains that communicate from one well to another, until a fairly good flow is established from the upper (often rocky regions) to the more fertile lower plains, where vineyards and fruit gardens abound. The system of subterranean drains (or tunnels) has been adopted as a matter of economy, since the great dryness of the surface soil and
high temperature of the atmosphere would absorb all the water long before it reached the orchards.

Little information exists as to the methods of cultivation or of manufacture of raisins, but Mr. R. Hughes Buller has furnished some interesting particulars regarding the chief varieties of grapes grown in the Quetta-Pishin district. He enumerates some eighteen, but the most widely distributed are known as haïta and spin kishmishi, followed by kalamakk, husaini, tor, sra kishmishi, and tandán. The rest, he says, are only met with occasionally. Haïta is a large oval-shaped grape, with hard skin, of a green colour tinged with yellow. It is very lasting and is the grape commonly packed in wool and sold in Indian bazârs. It is obtainable from August to the end of November. In Kandahâr haïta grapes are made into raisins (âbjosh) by dipping them in boiling water mixed with lime and carbonate of soda, and then drying in the sun. Spin kishmishi is a small green grape, oblong in shape, found in all parts of the district, especially in Quetta and along the Khwâja Amrân. It begins to ripen in August and lasts till the end of October. Kalamakk is green, oblong, of medium size, larger than spin kishmishi and smaller than haïta. It ripens from September to 15th November. Husaini is a soft fruit, distinguished by its loose growth and by the narrowing of each grape in the centre. It grows in Gulpistán, Mazarri, Kamálzâi, Arambi and Sâriâb, begins to ripen in August, and lasts till the end of October. Tor is described as an oval grape, dark in colour and fairly sweet. It ripens early, about the middle of July. Sra kishmishi is a small grape, light purple in colour, with soft skin. The Kandahâris make raisins from it. It begins to ripen about the 25th of August and lasts to the 15th of October. Tândán, the last mentioned, is a large round, green grape of inferior quality. It contains a large quantity of juice which is extracted in Kandahâr, boiled and kept for use as a relish. It ripens in September.

Traffic.—The traffic in grapes (preserved in wooden boxes), arranged layer upon layer, with sheets of cotton-wool between, constitutes one of the characteristic features of the so-called Kabul (Afghan) trade of India. The wandering fruit traders carry grapes, raisins, pistacio nuts, almonds, and pomegranates all over India; and, barring the traffic in Kashmir fruit into the Panjâb and of Deccan grapes into Bombay, the Kabuli traders practically supply the grapes and raisins consumed in the whole of the rest of India. The traffic is, therefore, by no means an unimportant one, and the share taken by the Quetta-Pishin district perhaps the most valuable single contribution.

Pedley wrote an interesting paper (Agri. Ledg., 1893, No. 7) on the possibility of a raisin industry being organised in Sind. He contrasted the Fresno district of California with the Schwan Sub-division of Karachi, and came to the conclusion that with its cheap labour Sind might easily do a large trade in this dried fruit.

Bengal and Assam.—The annual rainfall of the province is too high for vine cultivation to be of much importance. In the upper divisions of the province, however, e.g. in Bihar, where the climate approximates to that of the United Provinces, greater success has been attained than in Bengal proper, and fairly good grapes are often produced, as at Dinapore and Tirhut. [Cf. Repts. Dept. Land Rec. and Agri.]

Madras and Mysore.—On the plains of Madras the vine can be grown only under careful garden cultivation, and viticulture can never
MYSORE GRAPES

therefore become an established industry. On the mountains and tablelands, on the other hand, it is grown with complete success. An account of an interesting experiment at present being conducted in Mysore by an Australian (Mr. M. Paul), is given in the Indian Agriculturist (Jan. 1, 1907). Mr. Paul appears to consider the Mysore climate an absolutely ideal one for the vine, and he hopes in a few years to place on the Indian market some twenty varieties of the finest grapes grown in Australia, and equal to any produced on the Continent of Europe. The cuttings imported from Australia were kept partly on the Nilgiri hills and partly in a small nursery at Bangalore, but have now to a large extent been planted out, and are said to be doing very well. In a year it is asserted by Mr. Paul, that he will have a good show of grapes; in two years his little Bangalore vineyard will produce some tons. These grapes, he considers, will sell at a few annas a pound, and he declares that they will be equal to grapes sold in London at five or six shillings a pound. [Cf. Cameron, For. Trees of Mysore and Coorg, 1894, 74–5; Rice, Mysore Gaz., 1897, i., 83; Repts. Govt. Bot. Gard., Bangalore.]

Uses.—It is chiefly as a fruit that grapes are cultivated on the table-land of India. But they are at the same time largely eaten in a dried state as raisins or currants, and at one time constituted a fairly important article of food with the people of Kanāwar. The industry of drying grapes is not practised, however, to any very great extent anywhere in India. According to Dutt (Mat. Med. Hind., 1900, 138) raisins have for many centuries been employed medicinally by the Hindus, and he adds that they enter into the composition of numerous demulcent and expectorant medicines in use at the present time. The other products manufactured from the grape are wine, brandy and vinegar (see pp. 1109, 1110).

TRADE.—In the internal trade returns, wines are classed along with spirits (see p. 1047). The foreign trade consists chiefly of imports and re-exports. The exports of Indian produce are quite unimportant, and when compared with the immense population, the imports also are remarkably small. The following table shows the foreign imports of wines of all sorts for the five years 1902–7.——

From these figures it will be noted that the imports do not show much tendency to increase. The chief supplying countries and the shares taken by the various provinces may be exemplified by the following analysis of the trade of 1906–7. Of the total quantity (329,342 gallons) imported in
that year, 150,899 gallons came from the United Kingdom; 99,587 from France; 15,982 from Italy; 11,672 from Belgium; 11,782 from Germany. The quantities from other countries were comparatively insignificant. The shares received by the various provinces (in gallons) were as follows:—Bombay, 105,200; Bengal, 99,308; Madras, 52,360; Sind, 38,230; Burma, 33,968. The shares (in gallons) taken by the chief importing countries in the different sorts of wine may be similarly exemplified by the figures for 1906–7:—CHAMPAGNE—United Kingdom, 13,292; Belgium, 7,819; France, 6,658. CLARET—France, 27,353; United Kingdom, 8,084. PORT—United Kingdom, 77,080; Germany, 7,544. SHERRY—United Kingdom, 18,023. OTHER SORTS—France, 63,416; United Kingdom, 34,420; Italy, 11,418; Spain, 7,022, etc.

**W**

*W. coagulans*, Dunal. The Cheesemaker or Indian Rennet, akri, *panir, ashugandhá, spin bajia, shápinang, khamazora, kýkñají, amukkura, pennérú-gadda*, etc. A small herb common in the Panjáb, Sind, Afghanistan and Baluchistan.

The fruit, both fresh and dried, is used medicinally, but is chiefly important as possessing the property of coagulating milk, and is used for that purpose instead of rennet in Sind, North-West India, Afghanistan and Baluchistan. This property was first noticed and made known by Stocks in 1849 (*Journ. As. Soc. Bomb.*, 56). Mr. S. Lea published an account (*Proc. Roy. Soc.*, 1883, xxxvi., 55–8) of experiments made on the seeds for the purpose of ascertaining whether they contained a definite ferment with the properties of ordinary rennet. The seeds were subjected for 24 hours to the action of various solvents which were then added to milk. A 5-per-cent. solution of common salt in water was found most effective in extracting the ferment, which rapidly curdles milk. In summarizing up, Lea states that the results of the experiments proved "that the seeds of Withania can be used as an adequate and successful substitute for animal rennet." [Cf. Pharmacog. *Ind.*, ii., 569–72; *Agri. Ledg.*, 1893, No. 17, 114: 1895, No. 5, 64–6; *Kew Bull.*, 1903, 27–8.]

*W. somnifera*, Dunal; Prain, *Beng. Plants*, 1903, ii., 750. The *panír, asgandhá, ashugandhá, kátilál, tili, ghodá, amukkura, pennérú-gadda*, etc. An erect shrub found throughout the drier parts of India; frequent in the west and in Hindustan, rare in Bengal.

Leaves, seeds and root are used in *Native Medicine*, being reputed to have diuretic and narcotic properties. The root, however, according to Dymock (*Mat. Med. W. Ind.*, 1885, 643) " has universally been confounded with a root met with under the same names in the bazars, but which bears no resemblance to the root of *W. somnifera.*" The *asgand* of the shops is the tuber of a convulvis, which, though much smaller and different in habit, does not appear to differ botanically from *Ipomoea digitata* (p. 658). In Bombay the seeds of this species are employed to coagulate milk in the same way as those of the former, already detailed, and both plants accordingly often bear the same vernacular names. [Cf. The Bower Manuscript (Hoernle, transl.), 1893–7, 18, 87, 108, etc.; Mathioli, *New Kreuterbuch*, 1563, 465; Bruce, *Travels in Africa*, 1790, v., 54–6 (the Wanzey); *Paulus Aegineta* (Adams, Comment.), 1847, iii., 359–60; *Pharmacog. Ind.*, ii., 566–9; Banerjei, *Agri. Cuttack*, 1893, 190; *Agri. Ledg.*, 1896, No. 28, 282–3; Dutt, *Mat. Med. Hind.*, 1900, 210–1.]

WOOL AND PASHM

dhuva, dhai, dawai, dhui, dhátaki, icha, santha, dahiri, chungkyek-dám, jatiko, jace, pitta, gul, daur, thávi, phubatti, dhavudina, jargi, yet kyi, etc. A large deciduous shrub found throughout India, ascending the Himalaya to 5,000 feet, rare in the south and not extending farther than to the hills of Karnul; Shan hills and other forests in Upper Burma (Gamble).

It yields a Gum, known as dhauru or dhau-ka-gond of Harauti and Mewar, which is said to resemble gum-tragacanth. The most important part of the plant is, however, the flowers. They appear from February to April, when they are gathered and dried. Throughout India these are employed as a Dye either to produce a colour by themselves or as an adjunct to mordant chiefly with dál (Morinda citrusfolia). Prof. Hummel found them to contain 20-6 per cent. tannic acid and they have long been used as a Tan to a small extent, though far this purpose the flowers have been neglected in favour of the leaves. Medicinally they are employed as an astringent. In the Central Provinces they are said to be eaten as Food, and in Bengal are utilised in the preparation of a cooling drink. The wood is used only for Fuel. The plant is a common ornamental shrub in gardens, being easily propagated by cuttings or seed.

The chapter devoted to Live Stock has dealt so very fully with the wild and domesticated goats and sheep of India (pp. 743-9) that there practically remains only the task of reviewing in this place the trade in raw wool and of furnishing a brief summary of the Indian woolen manufactures. But though many of the sheep of India produce fleeces of hair rather than of wool, still fairly good wool is obtained here and there, as, for example, from the black-headed sheep of Coimbatore, the woolly sheep of Mysore, and the sheep found in large tracts of the Deccan, Rajpautana, the Panjáb, the United Provinces and Bihar (Patna sheep).

History.—Wool was known to the very earliest of the classic writers of India and by the injunctions of the Institutes of Manu it is assigned as the material of the sacrificial thread of the Vaijaya. In the Rig Veda, moreover, there are hymns to Pashan, the god of the shepherds, which make mention of the bleaching and spinning of wool. Wool is regarded as ceremonially pure, and can accordingly be worn while eating or even performing religious functions. With the Vaishnavas the śrāth observance should, in fact, be performed only when clad in woollen.

Kirmani Wool.

Conditions of Merit.

Characteristics of the Fibre and Trade Classification.—The nature and value of the fibre depends first upon the breed of animal from which obtained; next, the climate, soil and herbage of the country in which reared, and lastly, the method and care with which the fleece has been removed from the animal and sent to market. But it is well known that with every precaution observed, departures and irregularities occur. From the standpoint of buying and selling wool, its merit turns on softness, soundness, fulness and freeness. The individual hairs may vary in length, thickness, and number of scales to the inch very greatly, even within the most carefully selected breed, and moreover they are different on the various parts of the body or during the various seasons of the year, and may even be irregular side by side on the same animal. Mr. N. Burgess, for example, gives the measurement of one hair in a sample of Saxon wool as \( \frac{37}{120} \) of an inch, while another lying by its side measured \( \frac{37}{72} \) of an inch. But to compare with these, he records hair of Southdown with a measurement of \( \frac{1}{10} \) of an inch and another \( \frac{1}{15} \), the coarsest fibre being \( \frac{1}{15} \) of an inch.

As with cotton, so with wool, the merit of the fibre is generally expressed by lengths to which it can be spun. 32's would be the lowest and 80's the highest average yarn. That is to say, in the former 32 hanks of 560 yards each can be spun from the pound of wool, and so 80's would mean that the wool was so fine that one pound could be spun into 80 hanks of the length mentioned, or 44,800 yards. But if the wool be harsh and devoid of elasticity, while in length of staple it may be suited for a certain count, a much lower yarn may actually be possible. Much, therefore, depends upon the condition or texture of the fleece.

Pashm.

As mentioned above, the under-fleece of the Tibetan goats yields the finest of all Indian wools—pashm. That is used for the most expensive and artistic purposes in the Indian woollen industries, more especially the shawls and chadars presently to be described. It is imported across the land frontier and almost exclusively through Kashmir. Waddell (Lhasa and Its Mysteries, 1905, 476-7)

WOOL

affords some interesting particulars of the pashm of Southern and Eastern Tibet. He remarks that the Kashmiris have a monopoly of the trade in Upper Tibet, whence they export it all by way of Rampur on the Sutlej, Kashmir and Ladakh, and canvass for it chiefly in the tracts adjoining there. "In Southern Tibet, however, most of this important product, the felted silky underwool, which should amount to hundreds of tons annually, is wasted, as the Tibetans do not know its great value, and do not collect it from either the yak, when shedding its winter coat in spring, or the goats and sheep."

Imported Kirmani wool and the still more inferior wakat shahi pashm (from Persia and Afghanistan), after being treated in a special manner, is extensively employed as a substitute for or in admixture with Tibetan pashm in the production of much of the pashmina of modern commerce. A more recent and even more pernicious practice is the use of foreign, mostly English, woollen yarns in the fabrication of Indian textiles, for which both the colours and the quality of the yarn are unsuited.

Indian Wool.—The best wool is that of the Panjáb and Frontier Province, of which perhaps Hissar would take the foremost place, but Ferogpur, Lahore, Jhang, Shahpur, Peshawar, Dera Ismail Khan, Amritsar, Multan, Rawalpindi and Jhelum each produce wool in fair quantity and quality. In the United Provinces the most useful wool comes from the Himalayan tracts—Garhwal, Almora, and Naini Tal—while the important districts in the plains are those of Agra and Mirzapur. A large drain is, however, made on the Panjáb, Rajputana and Sind, and also on foreign countries, to meet the manufactures of these provinces. The best-known local wools of Western India are the black Deccan and Khandesh and the white wools of Sind, Gujarat, and Kathiawar. Sind and Baluchistan wools are exported from Karachi, along with the fine wool obtained from Bikanir. The rearing of sheep in the Central Provinces is fairly important, especially in Jabalpur, Nagpur, Chanda, Wardha and Raipur. In Rajputana and Central India, Bikanir, Jodhpur, Jaipur and Ajmir produce wool, and that of Bikanir is much prized all over India, especially for carpet-weaving. In Southern India the wools of Bellary, Kurnul, Coimbatore and Mysore are well known; but the sheep of most other districts of Madras, like those of Bengal, yield hair rather than wool.

Prices.—In an official report from the Director of Land Records and Agriculture in the United Provinces, the following occurs regarding prices. The price depends upon the purity of the wool, but 2½ seers per rupee may be assumed as a fair average. Bikanir wool (white) fetches from under Rs. 20 to over Rs. 35 per maund, according to fineness and freedom from burrs. Goats’ hair costs 10 to 12 seers per rupee and camels’ hair 5 seers per rupee.

INDIAN WOOLLEN MANUFACTURE.

Mr. J. E. O’Conor (Rev. Trade Ind., 1893, 51) made the somewhat significant comment: "The trade is as yet quite unimportant and is likely to remain so for a long time to come, unless the Indian mills are able to find markets in Asia for coarse blankets and horse-clothing, the only descriptions of goods for which there would be a fair demand in the regions we could hope to supply and the only kinds we could manufacture with profit to compete outside India with European goods." In 1895, however, the imports from Great Britain had fallen off by 9½ per cent., while those from Germany had increased sixfold, from France threefold, and from Austria twofold. It had thus almost immediately been demonstrated that the attractively got up cheap shoddy and mixed woollen goods of the Continent of Europe (more especially of Germany) were not only outing the superior manufactures of England, but had undermined the ground which
the Indian mills were believed capable of holding. In Calcutta, for example, there has existed for many years past a large demand for coolie blankets and shawls, and this has recently been entirely usurped by cheap foreign supply. It is hardly to be wondered at, therefore, that the pioneer woollen mills of India, such as the Cawnpore Woollen Mills Co., Ltd., should have been driven to turn their attention almost exclusively to the production of high-class goods of pure wool in direct competition with the British supply, since their woollen blankets could no longer compete with the cheap low-grade foreign articles. Similarly it has been realised that there was a more profitable market open to the Indian mills in the production of ordinary average quality and even high-class woollen goods than in contracts with the Army Clothing Department of India. Thus it may be said that recent years have witnessed a complete revolution, and a wholesome one, since the date when the original Dharival Woollen Mills Company was established, almost exclusively, it might be said, to meet official contracts.

The Dharival and Cawnpore Mills may be regarded as favourably placed to tap the supplies of India's finest wools, such as those of Kangra, Simla, Garhwal, Kumaon and Nepal, the South-East Panjab (Shahpur, Dera Ismail Khan, etc.) and South-Western Afghanistan. In some cases these wools have to be carried by road for 200 to 300 miles before they reach the nearest railway station. This is the chief drawback to the Indian mills—the long road transit and consequent heavy charges.

Mills and Woollen Manufactures of India.—In 1876 the Cawnpore Woollen Mills were established, and ten years later (1886) there were four woollen mills in India with a combined capital of Rs. 18,00,000. These gave employment to 1,372 persons, had 242 looms and 5,420 spindles under use. They produced goods to the extent of 798,062 lb., valued at Rs. 5,27,420. Still a decade later (1896) there were 6 mills at work in India with a capital of Rs. 32,50,000, and these gave employment to 3,017 persons, had 530 looms, 18,658 spindles, and produced 2,345,570 lb. of goods, valued at Rs. 24,96,751. During 1904 there were 6 mills with a capital of Rs. 46,25,000, employing 3,468 persons, 737 looms and 25,931 spindles, with a production of 3,508,700 lb. valued at Rs. 36,74,678. That is a record of thirty years' progression of which India has no cause to be ashamed, yet it should be viewed as giving but a foretaste of still greater advancements.

It may perhaps suffice to complete this reference to the Indian power-loom woollen mills to repeat that, as a rule, they concern themselves with the growing demand for goods on a European pattern and style, such as serges, broadcloths, flannels, tweeds, blankets, travelling rugs, etc. They have also given attention to the production of worsted, knitting yarns, Berlin wool, as also knitted goods of all kinds, such as socks, cardigans, jackets, jerseys, caps, gloves, etc., etc. They use pure wool: for the lower grade goods, Indian wool, and for the higher, the finer imported wools, either alone or mixed with Indian. They do not attempt the imitation of Indian special textiles, nor have they as yet engaged in any branch of the European carpet industry.

Indigenous Woollen Industry.—But the official returns of mills take cognisance only of factories that each employ not less than 25 persons and keep these at work mainly, if not exclusively, on the production of woollen goods. Scattered all over India, however, more especially in
the upper provinces, there are small hand-loom workshops in woollen manufactures, and these each employ only one or two hands. In the aggregate they are important, though out of the large number that exist, recognition is made officially of only some 10 or 12, because, though not woollen mills in the strict sense, they are weaving establishments that employ annually from 4,500 to close on 6,000 hands. These larger wool-weaving indigenous establishments are all located within the Panjáb and are concerned for the most part in the production of shawls, chadars (see next page), pashmina, jamawar (or patterned alwans), pattu, etc., etc. But here and there throughout India there is a fairly large industry in Oriental carpet-weaving (see Carpets and Rugs, 272–5) and in felted rugs (namdas), and this does not appear to be included in the official returns above indicated. But if the study of the Indian woollen industries be extended so as to include the production of mixed fabrics, that is to say those in which wool constitutes but one, and perhaps the least important ingredient, an extensive assemblage of textiles would be thereby embraced, such as the himrus, mashrus, ghattas and the like. These are mostly made of silk and cotton mixed, but occasionally of wool and silk combined. The name mashru (i.e. permitted textile) gives the key apparently to the explanation of the richly varied assemblage of fabrics so designated. Pure silk was forbidden to be worn by Muhammadans except on special occasions, and thus the weavers conceived of numerous methods by which an admixture, perhaps of but a small amount, of silk might be thrown on the surface of a woollen or cotton textile to give it the rich effect of being constructed almost entirely of the more expensive and luxurious material. The word himru literally means a textile intended to be worn in the cold season. It is woven of cotton so treated as to give it the effect of wool, and is usually brocaded with silk. Occasionally such textiles are made entirely of silk, and are, strictly speaking, amrus, but when, in place of cotton, wool is used, they are commonly designated jamawars. These are pieces of a fixed length, such as would be required for the preparation of a choqa or coat, or suitable for a lady’s dress. They are simply brocaded woolen goods with the pattern either in very fine pashm or in silk, or they may be in cotton, with pashm or silk ornamentations. In the jamawars of Kashmir, the end pieces are woven straight on, but in Amritsar and Ludhiana they are sewn on. A large percentage of the Kashmiris settled in British India have abandoned the shawl trade and concentrated their attention exclusively on the production of plain pashmina or of jamawars. They found a lucrative field in the larger towns, especially where these possess a fair percentage of Muhammadans, such as Lucknow, Hyderabad, etc., and in time the weavers adapted themselves to the requirements of their markets and produced himrus and other brocaded textiles in which wool was largely replaced by cotton or silk. Within recent years a soft form of wool has been imported into India (and in increasing quantities) originally from Kirman in Persia, more recently from Australia and Afghanistan. So also by special treatment soft staple can be produced from almost any wool. These special wools are worked up alone or in admixture with pashm in the production of pashmina, a textile imitated in Europe by a fabric known as “Kashmir,” which, needless to say, is not made in Kashmir nor in India, any more than a tithe of pashmina sold in India and exported to Europe and America is made of pashm. [Cf. Imp. Gaz., 1907, iii., 212–8.]
Shawls and Chadars.—Some years ago the Indian supply set the fashion of wearing these special articles and gave the name shawl (shal) to Europe. These textiles are woven of the finest wool (usually the under-fleece of the Tibetan goat), known as pashm, an extremely fine hair (which in Europe is called shawl-wool, the textile being pashmina). The Rampur chadar is usually white or of some plain colour. It is woven of a woollen (pashm) warp and a specially prepared silk, sometimes even cotton weft, though occasionally the weft also is of pashm. In manufacture, chadars are twilled or damasked, but they may be embroidered in the shal-stitch fashion, and may even be possessed of narrow ornate borders or be embroidered in pale-coloured or white silk. A large proportion of the soft shawls sold in India to-day as Rampur chadars, and which are often carried away by visitors in good faith as being genuine, are made in Europe and sent to India on purpose to meet the demand that exists for these goods.

Much has been written on the Kashmir shawls. Perhaps the earliest account of any note is that given in the Ain-i-Akbari, 1590 (Blochmann, transl., 91–2). “His Majesty encourages, in every possible way, the manufacture of shawls in Kashmir. In Lahore also there are more than a thousand workshops.” Bernier, who travelled in India in 1656–8, gives some interesting particulars regarding the Kashmir shawls and the woollen manufactures of the Panjáb generally (Travels, in Constable, Or. Misc., 1891, 402–5). Great pains, he says, have been taken to manufacture shawls similar to those of Kashmir, in Patna, Agra and Lahore, but, notwithstanding every possible care, they never have the delicate texture and softness of the Kashmir article. Vigne (Travels in Kashmir, 1842, ii., 125) affords many useful facts, but Moorcroft (Travels, ii., 164–217) produced what might be described as a full technical report of the materials used, methods of fabrication, and trade in Kashmir shawls during the period of his special studies. Lawrence (Valley of Kashmir, 1895, 375) carries the story down to the present position of the craft—a tradition, a memory of the past, a degraded industry starved through the loss of the European demand. Dr. A. Mitra, in a pamphlet on the Arts and Industries of Kashmir State, says the time was when 60,000 persons were employed in shawl-weaving and brought into the State fifty lakhs of rupees a year. Now, instead of prosperity, the people are sunk in the most abject poverty. [Cf. Ind Art at Delhi in 1903, 338–65.]

Kashmir shawls are classified according to size, shape or purpose for which made, e.g. plaids, shawls, handkerchiefs, table-covers, curtains, scarves, etc., but it may be said there are two chief modes employed in their artistic ornamentation—(a) tili or kanikar (patterns elaborated on the loom), and (b) amlikar (patterns worked by the needle). The one is woven, the other embroidered, but curiously enough and contrary to what might have been anticipated, the needle (or hand-work) is less expensive and at the same time less artistic than that produced by the loom. A sort of intermediate condition, however, also exists in which the imperfections and shortcomings of cheap loom-work are removed, or made up for by subsequent needle embroidery. But the loom commonly used is hardly more than a few inches in diameter. Strips (braids) or patches are thus woven, then pieced together with the necessary pieces of pashmina cloth to form the shawl. The unions are next cleverly obliterated by needlework that can hardly be distinguished from the loom-work. The ground material is usually the finest and purest pashm, and

1126
KASHMIR AND PAISLEY SHAWLS

The chief centres of the Kashmir shawl manufacture to-day are Kashmir, Amritsar, Sialkot, Ludhiana, Gurdaspur and Lahore. The returns given below of the exports of Indian woollen goods afford the only indication available of the extent of the traffic. But for centuries past expensive Kashmir shawls have been much sought after by the princes and nobles of India. The possession of one or more of priceless value was an admitted mark of nobility, and accordingly such shawls were treasured and handed down from generation to generation. Some of the finest known examples of Kashmir shawls are, accordingly, those belonging to the older families. It was perhaps an unfortunate circumstance when the French nobility sought out these expensive garments. French traders visited Kashmir to purchase their annual supplies and year by year dictated the changes in style which they deemed necessary to meet the ever changing fashions of Paris. An incalculable injury to the art conceptions of the Kashmir people was a necessary consequence of this new trade, and when the Franco-Prussian war put a complete check on the demand, the Kashmir weavers who had become dependent on their French customers were ruined. Meantime Paisley had imitated completely and successfully the Kashmir shawls, and at a price far below what the hand-weavers could accept. Although these imitation shawls had the severity of all power-loom fabrics, they reproduced every detail of the originals and were marvellously woven and extremely beautiful and delicate in texture, so much so that by many they were preferred to the more clumsy though more artistic shawls of Kashmir. The cheapening process soon, however, effected its own ruin. Paisley shawls became so common as to cease to be popular. The demand terminated and the Paisley new industry had to be abandoned, its expensive and ingenious machinery sold as old iron, and its weavers converted into sewing-thread spinners, just as the bulk of the Kashmir shawl-weavers had to become either carpet-weavers or agriculturists. But Paisley has recovered from the loss of its shawl-weaving industry: Kashmir has not. And this is ever the story of art and industrial instinct. The latter lives by conquest, the former dies by contest. [Cf. Andrew Blair, The Paisley Shawl, 1906.]

INDIAN TRADE IN RAW WOOL.

Prof. Clapham of Leeds, in an address to the Yorkshire Association for Promoting Commercial Education, gave some striking facts regarding the wool trade of Great Britain. In 1840 the imports from Australia were 40,000 bales; in 1850, 140,000 bales; in 1860, 200,000 bales; and in 1870, 500,000 bales of wool. If by "bales" was meant "sacks" of 364 lb., the imports mentioned for the last year would have been 182,000,000 lb., or just one-half the amount recorded thirty years later.

Up to the opening of the Suez Canal, London was the world's chief emporium for wool, but the establishment of steam shipping and of cable communication, when taken in conjunction with the quick route through the Canal, had the natural effect of bringing the sellers in Australia into
direct touch with the buyers in Europe, and hence London lost its supremacy in the traffic. In modern returns of the British trade, wool is dealt with under the following headings:—(1) Alpaca, Vicuna and Llama; (2) Goats’ Wool or Hair, Mohair (Angora goats’ hair); and (3) Sheep or Lambs’ Wool. Of the last mentioned, the following statement for the past five years may be given: the countries that supply 10 million pounds and over being alone mentioned and the last three figures omitted as a matter of convenience:—

Statement of Wool Supplies into Great Britain (omitting last three figures).

India’s Contribution.

It will thus be seen that the supply of wool drained from British India, when compared with that from Australia and New Zealand, is unimportant. From the Indian point of view, however, it is very considerable, since it represents an amount that might with great advantage have been worked up locally and been thus employed to contest the import traffic in foreign manufactured woollen goods.

Raw Wool. RAW WOOL.—Little or no information can be furnished as to the total production of wool in India. According to the Agricultural Statistics, there were estimated to have been in India during 1905–6, 18,029,181 sheep and 25,172,701 goats. It has further been ascertained that a yield of one seer (2 lb.) of wool per annum would fairly represent the yield of each plains sheep, and something like three seers that of the hills. But it may be added that the returns just mentioned ignore the sheep and goats of the alpine tracts, more especially those across the frontier, from which a large portion of the finest wool of India is derived. And moreover, in the tropical portions of the plains, the sheep yield very little true wool: in fact their fleeces are so poor that they are often not even clipped, the animals being reared purely and simply as sources of mutton. On the other hand, many of the goats yield hair of such a quality that it may be used for some of the purposes for which wool is employed, if indeed goats’ hair be not sometimes mixed with wool. And, of course, the under-fleece of the Tibetan goat constitutes the pashm or wool, of which repeated mention has to be made in this article. It thus seems safe to assume that one seer per sheep, on the herds actually registered, might be ac-
excepted as fairly representing the annual supply of wool in India, or say 36,058,362 lb. But that estimate may be checked by reference to various records of actual transactions:

Trans-frontier Traffic.—The imports of wool into India for the latest years of official returns were—1902–3, 92,990 cwt., valued at Rs. 23,91,242; 1903–4, 97,125 cwt., valued at Rs. 27,10,041; 1904–5, 105,934 cwt., valued at Rs. 30,89,138; 1905–6, 141,771 cwt., valued at Rs. 42,45,286; and in 1906–7, 171,783 cwt., valued at Rs. 57,86,817. The chief countries that contribute wool to India are South-Western Afghanistan, which in the last-mentioned year gave 105,686 cwt., and Tibet, 34,869 cwt., while the supply from Khelat came to 13,071 cwt. To allow of comparison with other returns, the total imports may be expressed in pounds, viz. 19,239,696. The growing importance of the Trans-frontier wool traffic is one of the most encouraging aspects of the modern trade.

The exports of wool across the frontier are unimportant, and consist chiefly of foreign wool sent to Southern and Western Afghanistan and to Kashmir—the total exports in 1906–7 came to 92,960 lb.

Internal Traffic—Rail and River.—The totals carried during the past six years have been as follows:—1901–2, 197,341 cwt.; 1902–3, 249,797 cwt.; 1903–4, 284,680 cwt.; 1904–5, 359,700 cwt.; 1905–6, 354,725 cwt.; and 1906–7, 383,102 cwt. If the last figure be expressed in pounds to allow of ready comparison, we learn that 42,907,424 lb. were distributed by the railways during the year in question. Of that amount 19,239,696 lb. would doubtless correspond with the supply received across the land frontier from foreign countries, thus leaving a balance of 23,667,728 lb. as derived from the sheep of India proper—a figure that, on estimated production, would leave a balance to meet purely local or homestead requirements of 12,390,634 lb.

In an official report of the Department of Land Records and Agriculture in the United Provinces, it is estimated that the local production in these provinces for the year under review (1896–7) may have been something like 2,624,000 lb. The balance available for local consumption (chiefly at the Cawnpore Mills), after adjusting imports and exports on local production, would have been 2,333,556 lb. This view would be in accord with the returns for rail and river traffic, and is perhaps a fairly representative statement of one of the chief provinces in the wool trade of India.

Foreign Exports.—The following were the total exports from India to all foreign countries during the past six years:—1901–2, 19,592,630 lb., valued at Rs. 79,38,259; 1902–3, 27,892,898 lb., valued at Rs. 1,16,53,204; 1903–4, 33,234,775 lb., valued at Rs. 1,37,73,957; 1904–5, 38,571,968 lb., valued at Rs. 1,89,16,747; 1905–6, 42,514,498 lb., valued at Rs. 2,11,47,283; and in 1906–7, 45,909,898 lb., valued at Rs. 2,42,65,349. Last year's exports thus show an expansion of 8 per cent. in quantity and 14.73 per cent. in total value on the figures of the year preceding, and of 134 per cent. quantity and 205 per cent. in value on the exports of 1901–2. At the same time they maintain a continuous record of progress for the sixth year in succession. Of the total exports in 1906–7, Great Britain took 43,184,135 lb., the United States coming next with 1,573,903 lb. Another significant feature is the rise of the Karachi traffic. In 1901–2 the share taken by that port came to 61 million pounds, but in 1906–7 it stood at 18½ million pounds. Karachi is today about co-equal in im-

1129
WOOL
Trade

WOOL AND PASHM

Imports.

Foreign Imports.—The demand for foreign raw wool may be accepted as contributing toward the higher class woollen goods, both hand- and power-loom, though in the former case the foreign wool appears to be largely employed as an adulterant or even a substitute for the more expensive pashm. In 1896–7 the imports were returned at 4,725,899 lb., valued at Rs. 14,02,284; in 1898–9 they were 3,283,905 lb.; in 1900–1, 2,871,319 lb.; in 1902–3, 2,756,071 lb.; in 1904–5, 2,117,734 lb.; in 1905–6, 2,908,036 lb., valued at Rs. 9,18,395; and in 1906–7, 2,451,237 lb., valued at Rs. 8,64,505. Practically the whole of these imports are drawn from Persia, with smaller quantities from Mekran and Sonmiani, and are imported into Bombay and Karachi, a fair portion being thence carried by rail to the Panjab and the United Provinces. The traffic by sea would seem to have improved steadily up to 1896–7, since which date it might be described as having declined. In 1876–7 the imports of raw wool were valued at Rs. 5,32,116; fifteen years later (1890–1) they stood at Rs. 11,56,154, and attained their maximum five years later still (1896–7), but have ever since almost steadily declined. Against this shrinking demand, however, for foreign wools (brought by sea) has to be placed the expansion of the Trans-frontier traffic already dealt with, especially that across the north-western frontier, which may be regarded as bringing Kirmani wools to India by land routes, to some extent doubtless an expression of increased railway facilities within India itself. [Cf. Kermanshah Wool, in Dipl. and Cons. Rept., 1903-4, ii., No. 3189, 25–7.]

MANUFACTURED WOOL.—Imports.—The encouraging conception of the Indian woollen industries receives a somewhat severe set-back by an inspection of the foreign traffic. It is not possible to give the returns in pounds, since most of the articles are sold by number or by the yard. The value may, however, be accepted as a sufficiently satisfactory standard. In 1896–7 the Imports of woollen manufactures were valued at Rs. 1,69,24,447; in 1898–9 at Rs. 1,52,37,310; 1900–1 at Rs. 2,11,25,756; 1902–3 at Rs. 1,40,59,122; 1904–5 at Rs. 3,07,64,281; 1905–6 at Rs. 2,42,51,878; and in 1906–7, Rs. 2,05,21,666. Thus in the past eleven years the imports of manufactured wool have expanded from a valuation of £1,128,296 in 1898–9 to £1,368,111 in 1906–7, but if the study be carried still further back, the expansion becomes more marked. In 1876–7 the imports of woollen goods came to only £541,101, whereas the highest record during the past thirty years was in 1904–5, when the supply drawn from abroad by sea was valued at £2,050,952. The Indian mills are thus seen to be securing but a small portion of India's demand for European manufactured woollen goods. But by way of contrast, it may be here mentioned that the exports of Indian woollen goods (mostly Oriental carpets and shawls) rarely exceed £120,000.

Turning now to the nature of the imports and countries of supply, the chief item is "piece goods." Out of the total of Rs. 2,05,21,666, the share taken by piece goods alone came to Rs. 1,39,52,624. Of that amount the United Kingdom supplied Rs. 1,03,31,105 and Germany Rs. 26,76,231. [It is to be noted that the above figures relate mostly to goods exported in cloth form, and are, therefore, not strictly comparable with the imports.]

Kirmani Wool.

Manufactures.

Imports.

Shawls and Carpets.

Piece Goods.
WOOLLEN MANUFACTURES

Fully half these imports are consigned to Bombay, one-third to Calcutta, and the balance to Burma, Sind and Madras. Following the “piece goods” come “shawls.” During the five years ending 1906–7 these have manifested an average valuation of Rs. 33,07,815 (or, say, £220,521). They come chiefly from Germany, from which the average annual amount consigned to India for the five years ending 1906–7 showed a valuation of £159,324, while from Great Britain the quinquennial average came only to £42,658. What is, however, far more significant, the supply from the United Kingdom contracted from a valuation of Rs. 14,57,354 in 1901–2 to Rs. 81,272 in 1906–7, while from Germany it expanded from Rs. 14,74,562 in 1901–2 to Rs. 46,86,246 in 1904–5, and contracted to Rs. 24,35,951 in 1905–6 and to Rs. 13,04,494 in 1906–7. The shawl traffic is almost entirely with Calcutta, and is very largely the expression of the demand made by the coolies employed in the tea industry for shawls and blankets, so that Germany has not only driven the Indian mills, but the British as well, out of this particular market.

The imports of woollen carpets and rugs into India have for some years past manifested a continuous expansion. In 1896–7 these were valued at Rs. 4,67,836, and during the past six years the traffic has been as follows:—1901–2, Rs. 8,49,168; 1902–3, Rs. 5,76,304; 1903–4, Rs. 8,96,738; 1904–5, Rs. 13,98,640; 1905–6, Rs. 14,47,131; and in 1906–7, Rs. 10,56,679. During the last-mentioned year carpets and rugs to the value of Rs. 7,30,496 came from the United Kingdom, Rs. 2,04,540 from France, and Rs. 72,219 from Germany. It is only necessary to add (in view of the activity of the Indian woollen mills) that the imports of hosiery came in 1906–7 to Rs. 8,05,614, of which Rs. 6,97,490 worth came from the United Kingdom, two-thirds being taken by Bengal and Bombay and the remaining third by Burma, Sind and Madras.

Exports.—The total value of the exports of woollen goods came, on the average of the returns for the five years ending 1906–7, to a valuation of Rs. 23,78,835, but the figures as they stand would seem to indicate a shrinkage, the year 1905–6 showing the lowest valuation of the series. But taking 1906–7, the total exports came to Rs. 22,92,838, of which Rs. 16,04,573 represented the portion taken by the United Kingdom, and this is followed by the United States with Rs. 4,03,973; China with Rs. 33,390; and Germany with Rs. 31,699. Thus while Germany supplies India with a yearly increasing quantity of inferior woollen goods, she takes in return practically none of India’s manufactures of wool. But it may be added that the exports from India to the United Kingdom, the United States and Germany just mentioned, are almost entirely Oriental carpets and rugs. The exports in shawls are made mainly to the Straits Settlements, and the exports in piece-goods (possibly for the most part Native-made pashmina) go to the United Kingdom, Ceylon, Hongkong, the United States, China and Japan.

WRIGHTIA, Br.; Fl. Br. Ind., iii., 652–4; Gamble Man. Ind. Timbs., 1902, 486–7; Cooke, Fl. Pres. Bomb., ii., pt. i., 136–8; Brandis, Ind. Trees, 1906, 461–2; Apocynaceae. A genus of shrubs or small trees of which about six species are found in India, the following being those of economic importance:—

W. tinctoria, R. Br. ; indarjau, hyamaraka, khirni, dakh, kōlakado, pāla, eeypalē, tedlapāl, amkudu, kodmurki, etc. A small deciduous tree of the

Peninsula of India, common in the Deccan and Karnataka and the Bombay Presidency, extending north to Rajputana and Banda, in deciduous forest; also in Burma.” (Gamble).

It yields a crude rubber, which was found to give the following analysis:—water, gum, etc., 25.8° per cent.; resin, 45.8°; caoutchouc, 28.4°. [Cf. Ind. For., 1903, xxix., 406-7.] The seeds are said to be used as an adjunct to other materials in dyeing, while from remote times the Natives of Southern India have employed the leaves as a source of blue dye or indigo. The root-bark and seeds, though of no value medicinally, have been the cause of considerable confusion in the literature of Indian Materia Medica, being frequently mistaken for and used to adulterate those of Holarrhena antidysenterica (see p. 640). The wood is of good quality for carving and turning, and is fairly extensively used for both these purposes. It is said to resemble ivory in colour and texture, and according to Rice (Mysore Gaz., 1897, i., 81) is employed for making the celebrated Chenapata toys and for wooden idols. [Cf. Pharmacog. Ind., ii., 397-8; Cameron, For. Trees Mysore and Coorg, 1894, 166-7; Pharm. Journ., 1901, lxvii., 690.]

W. tomentosa, Roem. & Schult.; Prain, Beng. Plants, 1903, ii., 674. The dudhi, dharauli, sandi-huya, atkura, karingi, selemnyok, kal kurvan, harido, tellouk thein, etc. A small deciduous tree “throughout India, chiefly in deciduous forests, extending in the Sub-Himalayan tract westwards to the Beas, eastwards to Sikkim; mixed forests of Burma.” (Gamble).

Every part of the tree discharges, on being wounded, a yellow milky juice, said to yield a good yellow dye when diluted with water. The seeds are reputed to afford a medicinal oil, and both stem and root bark are said to be useful in cases of snake-bite and scorpion sting. The leaves are eaten as a pot-herb by the Santals. The wood is even-grained, easy to work, and used for making combs, and in carving and turnery, etc. [Cf. Cameron, loc. cit. 187; Duncan, Dyes and Dyeing Assam, 1896, 55.]

Z

A tall annual grass, according to De Candolle originally native of New Granada, but now cultivated almost throughout the world. The cultivated races are very numerous and show great power of adaptation to local environment, so much so that efforts to introduce American forms into India have generally resulted in degeneration towards the existing (now often called indigenous) forms. There seems no doubt that maize came to India from America, and was possibly brought thence directly by the Portuguese. But it appears to have been cultivated in India for at least a hundred years before forms were evolved, for each tract of country, of sufficient merit to justify extensive production. When, however, India had obtained its own special forms, maize moved rapidly over the whole continent, assuming tropical conditions in some parts, temperate and even arctic in others.

History.—The admirable account of the origin of this plant furnished by De Candolle (Orig. Cult. Plants, 387-97) leaves little that can be here added of any material value. Maize was unquestionably introduced into India just about the time of the advent of the East India Company, and the first mention in their Proceedings, of what may possibly be this grain, occurs in a letter of date October 1621, addressed to the Surat agent by Capt. John Weddel, in which he suggests that a warehouse be hired at Swally for the temporary housing of the “chanderouze” (khadur = an Arabic name for maize) (Foster, Engl. Factories Ind., 1806, 286). It is, however, highly likely the khandarous in question was judar and
not maize—that Arabic name being now applied to both grains. Baber (Mémoire (portion written 1520-9)) makes no mention of having seen maize on his arrival in India, though he carefully describes all the animals and plants new to him. Moreover, the early European travellers in India, including the botanists Rheed and Rumphiuss, are silent regarding this cereal. Abul Fazl (Ain-i-Akbari—the Administr. Rept. of the Emperor Akbar for 1590 A.D.), in his long list of grains and pulses grown in India during the 16th century, does not include maize, but he remarks under kâru (Pandanus, see p. 777) that its leaves are like those of maize (Blochmann, transl., 83). The word “maize" is of course furnished by the translator, and must be an incorrect rendering. It is interesting to note, however, that Mendoza (Hist. China, 1555) mentions amongst the plants observed by him "the plant called maize, which constitutes the principal food of the Indians in Mexico" (Brederode, Hist. Europ. Bot. Disc. in China, 1898, 10). In the 18th century Burnham published his Thesaurus Zeyalicus and his Flora Indica, but in neither does he allude to Zea. Hove, who at the close of the 18th century (1787) visited Bombay in order to study its cotton, wrote a report full of information on all the crops seen by him, but does not mention Indian-corn. But it would perhaps be unsafe to assume that, although the pine-apple was fully known in the 16th century, so extremely valuable a plant as the maize had not reached India until after the date when Rumphiuss wrote his great work (Herb. Amb., 1750), which to some extent figures and describes the plants of India. If we can accept the passage above indicated from Foster as satisfactorily establishing the existence of the grain in India, it must have been an article of commerce nearly a century previous to the date at which Rumphiuss wrote.

The most general vernacular name in India for this corn is makkai (Maeean corn), which may be regarded as manifesting the association of the grain with the Muhammadan rulers of India and at the same time accepted as strongly suggestive of the Portuguese influence at the court of the Mughal. The dissemination accomplished by the new cereal, or rather its appropriation of names formerly given to certain forms of Sorghum, may be viewed as denoting the innate propensity of Asiatics to contrast all new ideas with previous conceptions. The origin of its other most general name, bhuta, is more obscure, but is probably derived from bhutta or bhutta to eat. Both names are clearly modern, however, and do not occur in any classic works of even the most recent date. So very little progress had, however, been made with maize cultivation that Roxburgh wrote, about the beginning of the 19th century, that Indian-corn was "cultivated in various parts of India in gardens, and only as a delicacy; but not anywhere on the continent of India, so far as I can learn, as an extensive crop." Buchanan-Hamilton (Kingdom of Nepal, 1819, 284, 312), while dealing with the ancient State of Yumla (its capital Chinha-chin) says that they had maize. In a further page, he remarks of Kangra—"The poor live mainly on maize." Very shortly after the appearance of Roxburgh’s Flora Indica, however, Graham (Cat. Fl. Bombay, 1833, 240) wrote of Western India that maize was "commonly cultivated." Dalzell and Gibson (Fl. Bomb., 1801 (suppl.), 100) some thirty years later (1861), said that it was "extensively grown in the early part of the rains, especially near large towns." These authors also add—"The grain is seldom used in India as a flour." But as illustrative of the extremely local character of the information often furnished by Indian writers, it may be added that Stewart (in 1862) wrote of Bijounur that "much of the maize was ground into flour and made into bread, although very much less is here used in this way than in the Panjab." It is thus very probable that in Upper India (a region, comparatively speaking, unknown to Roxburgh) maize was much more extensively grown at the beginning of the century than might be inferred from Roxburgh’s words. At the present day it would be more nearly correct, at any rate, to speak of maize as of equal value to the people of India collectively with wheat, instead of its being grown purely as a garden “delicacy.” It is a field crop upon which at least the bulk of the aboriginal tribes of the hilly tracts of India are very largely dependent for subsistence. Thus its diffusion over India, during the present century, might almost be said to be one of the most powerful arguments against the statement often made that the Natives of India are so very conservative that they can scarcely be induced to change their time-honoured customs, even when these can be shown to be inimical to their best interests. So completely has India now appropriated the makkai that few of the village fathers would be found willing to admit that it had not always been with them, as it is now, a staple article of diet.

INTRODUCTION INTO INDIA

Grown as a Luxury.

Extensively Grown.

An Important Grain.
THE INDIAN-CORN PLANT

CULTIVATION.—Though grown practically all over India, the area of maize cultivation as a ripe grain may be said to be the central tableland, the northern extremity of the plains, and the Himalayan slopes and river valleys up to an altitude of 9,000 feet above the sea. On the lower or Gangetic plain it is grown chiefly as a green vegetable. In the vicinity of large towns the sale of the unripe cob is so remunerative that by peculiar systems of cultivation and selection, special forms have been matured that could scarcely be eaten in the condition of ripe grain. On the other hand, within the region where maize is grown for its ripe grain, it is hardly possible to procure green cobs as a vegetable. But adaptation to local conditions is perhaps more strikingly seen in the fact that in many parts of India there are forms of maize that require six months to mature, others not more than three months. In some parts of the country, indeed, both kinds may be seen growing separately or as mixed crops. Further it may be added that where the transition of the seasons into kharif and rabi crops allows of tropical cultivation during the former and temperate during the latter, two widely different forms of maize may be found. In the greater part of the plains of India, maize is a kharif crop, but rabi maize is by no means unusual, i.e. maize sown in autumn and reaped in spring along with wheat and barley.

Area.—According to the Agricultural Statistics, the area under the crop in British India for the six years 1900–1 to 1905–6 averaged 6,083,484 acres, and in the last year, 1905–6, was 5,790,543 acres. In the Native States the area during a similar period averaged 269,017 acres, and in 1905–6 was 221,687, giving a total for all India in that year of 6,012,230 acres. Bengal had the largest average area during the period in question, viz. about 2 million acres; followed by Agra with about 1¾ million; the Panjáb, from 1 to 1¼ million; Oudh, ¾ to ¾ million; the North-West Frontier, ¾ million; while the Central Provinces and Bombay had 130 to 160 thousand acres under the crop. But it should be here recorded that the above areas do not include production as a green vegetable, an important admission, since nearly every peasant grows a few plants near his homestead, which of necessity escape registration in agricultural statistics.

Diseases.—Barclay described a species of Rust found by him on Indian-corn (Agri. Led., 1895, No. 20, 284–5); a species of Smut (Ustilago) has also been recorded (L.c. 278). More recently Maxwell-Lefroy (Agri. Journ. Ind., 1906, i., pt. ii., 97–113; also Mem. Dept. Agri. Ind., 1907, i., No. 2) discusses the Moth-borer of the sugar-cane, maize and sorghum.

Bengal.—The area in 1905–6 was 1,825,400 acres and the yield, according to the Season and Crop Report, 448,670 tons. The largest areas were Patna Division with 820,500 acres, Bhagalpur with 657,800 acres, and Chota Nagpur with 307,800 acres. The yield per acre varies considerably, but the provincial average for the years 1901–2 (Agricultural Statistics) shows so little difference between the returns for unirrigated as compared with irrigated, that the latter may be disregarded. The yield for unirrigated land comes to 1,522 lb. to the acre. The districts that show the highest yield are Santal Parganas (2,739 lb.) and Manbhum (2,447 lb.). Mukerji (Handbook Ind. Agri., 1901, 249–53) states that “5 to 8 maunds of grain per acre is considered a fair yield, but 30 to 40 maunds are sometimes obtained.”

Maize cultivation may be said to manifest three phases:—(1) the homestead cultivation in Lower Bengal, to produce green cobs; (2) the cultivation...
tion as a staple food-grain on the hilly tracts, such as Chota Nagpur; and (3) the cultivation in Bihar, which differs in no essential from that in the greater part of the United Provinces. The method of cultivation described by Basu (Agri. Lohardaga, 1890, pt. i., 66-6) may be considered typical for the hilly parts of the Lower Provinces. Two varieties are there distinguished, a dull yellow and a red. It requires a rich soil and is usually grown for two to three successive seasons on the same plot, followed by some cold-weather crop like mustard. In June-July the land is ploughed and the seed sown broadcast, 4 to 5 seers per acre, and buried by a light ploughing. The field is then weeded and hoed two or three times from June to August, and the cobs ripen from the middle of August to the middle of September. If they are to be roasted and eaten, they are picked a fortnight before ripening (Basu). According to Mukerji, "the value of a 5 to 8 maunds' crop is only about Rs. 10. An acre (if ravages of jackals are prevented) may produce 20,000 green cobs. If these are sold at an average price of 8 cobs per piece, the produce of one acre may come up to Rs. 35 to Rs. 40." [Cf. Grierson, Bihar Peasant Life, 1885, 223-4; Banerjei, Agri. Cuttack, 1893, 77; Roy, Crops of Beng., 1906, 51-4; Subpur Exper. Farm Repts.]

**Assam.**—The area in 1905-6 was 1,300 acres, chiefly in Nowgong and Sylhet, but it is nowhere grown to any appreciable extent. In Cachar, Darrang and Sibsagar it is said to be grown in small patches, chiefly by foreigners. In the Khasia, Jaintia, Garo and Lushai hills, B. O. Allen states that "it is either grown in garden ground or is sown in the potato fields at the time when the tubers are earthed up. It is usually sown in April and May and ripens in August and September. The maize fields are well hoed and treated with manure" (Assam Dist. Gaz., 1906, x., 72-3).

**United Provinces.**—The area in Agra in 1905-6 was 1,374,267 acres, and in Oudh 796,976 acres. The average outturn for the provinces for the years 1897-1902 is stated to have been 950 lb. per acre. The acreage in the chief districts during 1905-6 was as follows:—Agra—Meerut, 121,307; Districts Balandsbahr, 120,481; Gorakhpur, 115,587; Aligarh, 97,905; Jaipur, 88,216; Saharanpur, 83,054; Bareli, 78,936; Etah, 65,745, etc. In Oudh—Bahraich, 256,914; Gonda, 206,471; Kheri, 96,487, etc. Maize is one of the crops which has for many years been systematically studied at the Cawnpore Experiment Station, and much valuable information relative to the varieties grown, the manures used and the seasons of sowing and reaping, will be obtained by referring to the voluminous annual reports. The account given by Duthie and Fuller (I.c. 22) may, however, be considered typical of the ordinary Native methods. It is a kharif crop sown, as a rule, when the rains break, and harvested at the end of August. If the cobs are to be sold as vegetables they are pulled while green; otherwise they are left till the leafy envelopes surrounding them are dry and shrivelled. Generally it is cultivated alone, but sometimes "cucumbers are grown between the lines. It is not uncommon, too, to mix a certain proportion of the lesser millets (kakum and mandva) and a little pulse (urd)." The average outturn for the provinces, Duthie and Fuller estimate at 10 maunds for unirrigated and 14 maunds for irrigated maize.

With regard to the Cawnpore experiments, an interesting summary of these is given by Mr. Subbiah, Principal, Cawnpore Agricultural School (Dept. Land Rec. and Agri. Bull., 1901, No. 14), to which the reader is referred. He there states that "since 1895 outturns ranging from 30 to
ZEAA MAYS
United Provinces

THE MAIZE PLANT

35 maunds of grain have been repeatedly obtained on a number of plots, and occasionally as much as 40 maunds and more.” Regarding varieties, he remarks that “about eighteen American and the two common North Indian varieties have been tried at the station with a view to test their merits as regards hardihood, productiveness and suitability to the climate of North India. The results of these trials showed that American varieties could be grown without any difficulty the same year the seed was imported; that one or two Americans might excel the Indians in productiveness; but that, taking everything into consideration, the two country varieties are the best for our present local conditions; that much better practical results could be immediately achieved by improving these two varieties by a careful selection of seed, etc.; and that with the light-yellow country variety as improved at Cawnpore the best results that the North Indian climate and soil would admit of might be attained within a few years.” Subbiah further states that to secure yields approaching those obtained at Cawnpore, the agents at the cultivator’s disposal are (a) regular spacing of each individual plant; (b) selection of seed or using Cawnpore maize seed; (c) two diggings between the crop in addition to the usual weeding and earthing; (d) one or two waterings during breaks in the rains that occur in most years; (e) liberal manuring; (f) either deep ploughing or digging with phaora before sowing.”

By the ordinary method of cultivation he estimates the cost per acre to be Rs. 13-13 and the normal produce 13 maunds, worth Rs. 22-12, giving a profit of Rs. 8-15; by the Cawnpore method, the cost is Rs. 31-12, outturn 35 maunds worth Rs. 61-4, giving a profit of Rs. 29-8.

Central Provinces and Berar.—The area in 1905-6 was 134,329 acres in the Central Provinces, and 2,445 acres in Berar. The chief districts in the former are Chhindwara, Mandla, Betul, Bilaspur and Jabalpur; in the latter, Wun and Buldana. Practically no information is available regarding the cultivation of the crop. The Nagpur Experimental Farm Reports deal only with the efforts to acclimatise American races and races from other parts of India.

Panjâb and North-West Frontier.—The area in 1905-6 was 896,241 acres in the Panjâb and 341,862 acres in the North-West Frontier. In the Panjâb the area would appear to be declining. For the five years ending 1901-2 the average outturn for the Panjâb is stated to have been 1,133 lb. per acre irrigated and 841 lb. unirrigated; in the North-West, 1,665 lb. irrigated and 583 lb. unirrigated. From returns submitted from various districts it was calculated in the Dictionary that an average yield for the province would be about 886 lb., or 10½ maunds per acre. In the Panjâb the districts with largest acreage were Kangra, 140,585; Hoshiarpur, 118,853; Jalandhar, 83,204; Gurdaspur, 59,808; Sialkot, 54,482; Ludhiana, 54,228; Ferozpur, 52,627; Ambala, 52,405; Lahore, 42,070; Amritsar, 42,013, etc.; in the North-West—Hazara, 162,699, and Peshawar, 130,002.

In a volume entitled Selections from the Records of the Financial Commissio-ner’s Office (1887, No. 36, 780-836), the subject of maize cultivation in the Panjâb was fully discussed. The periods of sowing and reaping vary
greatly. Speaking generally it is a kharif crop in the plains, sowing being dependent on the rains taking place, usually from June to August. The crop begins to bear green cobs (from the earliest sowing) in August, and ripe grain (from later sowings) in September, October or even November. On the hills the sowings are generally much earlier, and the higher reaches are earlier than the lower. In Hazara, Kullu and Simla, for example, early sowings are in April and May. While these are the general principles, remarkable variations occur in some districts, such as Rawalpindi, where there are two widely different crops that correspond very nearly to the kharif and rabi seasons. [Cf. Lawrence, Valley of Kashmir, 1895, 336-7; Settl. Repts. and Dist. Gaz., Panjab and N.-W. Frontier; Repts. Govt. Agri.-Hort. Gardens, Lahore.]

**Bombay and Sind.**—The area in 1905-6 was 158,115 acres in Bombay; 1,400 acres in Sind. In Bombay, Panch Mahals claims two-thirds of the total area, 110,950 acres, and in Sind about two-thirds of its total are confined to Karachi. Mollison (Textbook Ind. Agri., iii., 52-3) describes the cultivation in Panch Mahals and the Deccan. In the former, he says, "it is grown either as a rain or late irrigated crop." With sufficient rainfall it does best on the rich brown soils of the district, recently brought under cultivation, but rice land also suits the crop. It is usually grown alone, and requires a soil deeply and carefully tilled. The land is liberally manured, usually in May. "The crop tests of the Presidency show that 10 to 15 lb. per acre of seed is the ordinary rate." It is harvested when dead ripe. "In the Panch Mahals an average crop may be estimated at 1,200 to 1,500 lb. per acre." In the Deccan it is often grown for fodder. "A heavy crop will yield over 20,000 lb. of green fodder per acre." The cost of cultivation Mollison estimates at Rs. 13-6 per acre. [Cf. Exper. Farm Repts., Bombay.]

**Madras and Mysore.**—The area in 1905-6 was 76,377 acres in Madras; 231 acres in Mysore, but this represents a great contraction, the average being about 2,000 acres. The area in Madras also shows a decrease on previous years. The largest acreages were in Guntur, 37,297; Tanjore, 14,059; and Kistna, 12,897. Maize does not appear to be a crop of much importance in South India, and it is better described as a plant of gardens rather than of fields. [Cf. Cox, Man. N. Arcot, 1895, i., 269.]

**Burma.**—There were 94,942 acres under the crop in Upper Burma in 1905-6; 18,003 in Lower Burma. In Upper Burma the chief districts are ordinarily Magwe, Pakókku, Myingyan, Minbu, Yaméthu and Meiktila; and in Lower Burma, Thayetmyo. There is little information available regarding cultivation. It appears to be most frequently grown as a mixed crop. Parlett (Settl. Rept., Sagaing Dist., 1893-1900) states that it is "common all over kaing lands, as a rule sown sparsely in among pegga." Harvest, he states, is usually completed by April 1, and the cost of cultivation is estimated at Rs. 2-50 per acre. [Cf. Settl. Oper. Repts.; Repts. Dept. Land Rec. and Agri.]

**ECONOMIC AND INDUSTRIAL.**—The chief uses of this cereal are as an article of human and cattle food—the stems and leaves being also valued as fodder. It is mainly in Upper India that the ripe grain is reduced to a flour and made into bread. In some parts of the country it is ground into meal and eaten as porridge, known as *lapsi* or *gatha* in Bengal. But, as already stated, the green cobs are extensively eaten after being roasted or boiled. The ripe grain is also often parched and eaten as a mid-

day meal. The preparation known in Bengal as *satu* is the parched grain reduced to flour, much as in other parts of India *satu* is the flour of parched grain and barley mixed. The straw of the ripe crop is not of great value as fodder (except for elephants), but reaped in a green state it is very valuable. Both in Europe and America, Indian-corn is largely employed in the production of special articles of food that differ in some cases but little from the ancient *satu* of India; these bear the names Hominy, Maizena, Polenta, Indian-corn flour, etc.

In the United States it is perhaps but natural that a fuller knowledge and more complete utilisation of maize should have been attained than in India. Next perhaps to cotton, maize is the most valuable crop grown in the States, and the utilisation of its various by-products has given rise to numerous flourishing industries. A full account of these is given by Wiley (U.S. Dept. Agri. (Chemistry), Bull., 1898, No. 50). The grain is largely employed in the manufacture of STARCH and STARCH SUGAR or glucose, which in the United States is extensively employed in the manufacture of whisky and alcohol (Hanausek, Micro. Tech. Prod. (Winton and Barber, transl.), 1907, 40-1). A sugar is also prepared from the juice of the stems (D.E.P., vi., pt. iv., 332). Recently the waste material from the manufacture of glucose has been utilised in the production of a RUBBER said to have both the resiliency and wearing power of genuine Para rubber. From the germ of the seed is obtained by expression a valuable OIL, used for lighting, lubrication, soap-making, and as a salad oil. Among minor uses it may be mentioned that the pith of the stalk "has been used with the greatest success in the construction of battleships in the American Navy, the compressed blocks being placed between the two walls of armour." The pith is also "easily nitrated into all the various forms of material commonly made from cotton," and is said to have "many advantages over cotton for nitrating purposes, especially in the manufacture of explosives of all kinds, by reason of its more perfect keeping qualities" (Wiley, l.c. 27). Finally the stems, leaves and spathes are used in the manufacture of PAPER which is spoken of as suitable for bank-notes, while the residues from the manufacture of starch, glucose, whisky and alcohol are utilised in the production of a special article of CATTLE-FOOD. "Formerly it was the custom to employ these waste matters in the moist state, but in most parts of the country this method has been superseded by the method of drying the residues and selling them in the anhydrous condition. In this state they are much more easily transported, the objectionable odours which were the predominant characteristic of the moist foods are removed, and the wholesomeness of the food is in every way promoted." (Wiley, l.c., 25, 30). Similarly a special preparation of the whole plant, except the root and ear, is discussed by Wiley under the name of "Maize Stover." "As has before been intimated, this fodder is often fed in the coarse state without any preparation whatever. In this condition a very large percentage of it is wasted, the cattle eating little except the blades and perhaps some of the smaller and tenderer parts of the stalk. In the older parts of the country, it is now becoming quite general to have the maize stover finely shredded before being fed. This not only increases the quantity which becomes available for feed, but also leaves the manure in a much better condition for spreading on the field."

TRADE.—Unfortunately no information of this nature can be furnished. Jackson (Comm. Bot. 19th Century, 47-8) mentions that the-
BRITISH TRADE IN MAIZE

Imports of Great Britain came to 444,453 cwt. in 1856, and by 1889 had expanded to 36,203,069 cwt. The traffic continued to expand, and in 1899 stood at 66,741,350 cwt., valued at £12,978,025; but in 1903 it declined slightly, to 50,099,328 cwt., valued at £12,465,583; in 1904 to 42,897,880 cwt., valued at £10,247,134; in 1905 to 42,101,210 cwt., valued at £11,034,748; and in 1906 stood at 48,685,200 cwt., valued at £11,972,694. About one-half comes from the Argentine, a little less from the United States, and the balance from Roumania, Canada, Russia and British East Indies, in the order named. The Indian traffic in maize appears under the designation of "other sorts of grain and pulse," but as the foreign exports in these collectively are comparatively unimportant and, moreover, fluctuate extremely, they may be disregarded. In 1904 the total exports under this heading came to 1,691,672 cwt., in 1905 to 112,042 cwt., and in 1906-7 to 21,226 cwt. The imports of maize taken by Great Britain from India are returned as 206,900 cwt. in 1904; 917,700 cwt. in 1905, and 23,800 cwt. in 1906.

The following are the average wholesale prices (minimum and maximum) of maize per 10 maunds in the various provinces of India for 1905:—

**Bengal, from Rs. 18-65 in Bhagalpur to Rs. 21-05 in Patna; United Provinces, from Rs. 18-12 in Shahjahanpur to Rs. 26-29 in Aligarh; Punjab, from Rs. 16-78 in Ferozpur to Rs. 21-58 in Multan.**

**ZINGIBER OFFICINALE, Roscoe:** *Fl. Br. Ind.*, vi., 246; Roxb., in *As. Res.*, 1810, xi., 346; *Semler, Trop. Agrik.*, 1900, ii., 360-71; Prain, *Beng. Plants*, 1903, ii., 1045; *Scitamineae*. Ginger, plant = *adra* add, die, allam, khuyen-seing, etc.; and root = sōnth, sīndhi, adhruka, sīnt, zangzabol, shukku, iniji, vana-sunthi, khasisunthi, chukka, inchi, ginsi-kiav, gin sin, etc. It is not known in a truly wild state, but is doubtless a native of tropical South-East Asia. Introduced into the West Indies (Jamaica), Africa—the warmer parts of both worlds—and now cultivated in most tropical countries.

**History.** Ginger is known to have been cultivated in India and China for many centuries. Its most general Chinese name is *kuang*. Bretschneider tells us that "Confucius was never without ginger when he ate." It is mentioned in the *Li Ki*, among the articles of food there enumerated. Turning to India, the word "ginger" is generally believed to come from the Sanskrit "yangana," through the Arabic "eznabil," and from the same source was doubtless derived the corresponding Greek name "zinger." Knowledge in the tuber seems, accordingly, to have reached Europe via Africa and Arabia, and to have been very ancient in India. Dioscorides describes the country of ginger, and gives the distinctive features of the best kinds. Galen, Paulus Åegineta, and other Greek and Roman authors give full details of the medicinal virtues of the drug, and are followed by the Arab medicinal writers, such as Mosma, Serapion, Avicenna, etc. Coming down to more recent times, Marco Polo (13th century)

(Travels (ed. Yule), ii., 312) was familiar with both the fresh and preserved root; he specially mentions Colum (the modern Quilon) in Malabar as affording the best quality. This appears to have been known to the merchants of the Middle Ages as "Columbo," or "Colombo," and later as "Columbine." Three names that denote countries of supply are constantly mentioned—namely Belledi, Colombino and Meschino. The belledi or balladi came from various districts of India, meschino from Mecca, and colombino from Quilon. The word balladi seems to be an exact equivalent of deesi, and to mean "country," and ultimately denoted a common or inferior article. Raashiduddin speaks of the exports of "balladi" from Gujarat, and Nicolò Conti, who travelled in India in the early part of the 16th century, remarks that in the neighbourhood of Pecamuria and Helly, two cities of the west coast, there "grows ginger, called in the language of the country, belledi, gebeli and nelii." Barbosa mentions ginger as exported from Calicut in the beginning of the 16th century. So also Garcia de Orta, who wrote in 1563, and again Linschoten, in 1598, give long, interesting accounts of it. In the following century Terry (1655) says that it grows "almost in every place" in the southern part of the Great Mughal's territory; Mandelslo (1662) that it is found abundantly in Gujarat; and lastly, Tavernier (1676) refers to its prevalence in the kingdom of the Great Mughul. From these and such-like accounts by travellers in India, it may be inferred that ginger was already well known and a trade established in it—eventually in the early Middle Ages. [Cf. Paulus Egineta (Adams, transl.), iii., 123; Nicolò Conti, Ind. in 15th Century (ed. Major), 6; Vertommenus, Travels, 1503, in Hakl. Voy., iv., 577; Barbosa, Coasts E. Africa and Malabar (ed. Hakl. Soc.), 220-1; Garcia de Orta, 1563, Coll., xxvi.; also in Ball, Proc. Roy. Ir. Acad., 3rd ser., 1889-91, i., 411; Acosta, Tract. de las Drogas, 1578, 259; Linschoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), ii., 78-80; Pyrrad, Voy. E. Ind., etc. (ed. Hakl. Soc.), ii., 356, etc.; Clusius, Hist. Exot. Pl., 1605, 212; Terry, Voy. to Ind., 1655, 92; Boym, Fl. Sin., 1666, v.; Ligon, Hist. Ball), 1788, ii., 13; Milburn, Or. Comm., 1813, ii., 209.]

CULTIVATION.—The plant is cultivated all over the warmer and moister parts of India, up to an elevation of 4,000 to 5,000 feet in the Himalaya. The cultivation is one on which much care and labour are bestowed. The soil must be rich, but neither too heavy nor too light, and the amount of moisture must be carefully regulated. Manure is freely used and weeding carefully and frequently carried out (Nicholls, Textbook Trop. Agri., 1892, 194-6).

Bengal.—Ginger is said to be largely grown in many parts of the province, but no statistics of area are available. Buchanan-Hamilton (Stat. Acc. Dinaj., 186) gives many interesting particulars as to methods of cultivation, yield, etc. In Rangpur it might be said that ginger and tobacco, taken together, constitute the second most important crop, jute being first and rice third. According to Roy, a fine sandy loam is most suitable, and the crop follows a kachu (Colocasia antiquorum, p. 398) or a pulse crop. The land is prepared by repeated ploughings from the 15th February to the 15th April, then levelled and water-channels dug along and across the fields. "Well-rotted cow-dung at the rate of 100 maunds per acre is applied at the time of the first ploughing. In August—September the plants are top-dressed with 6 maunds of mustard-cake and 6 maunds of castor-cake per acre." "The rhizomes preserved from the previous year's crop, cut into pieces about 3 inches long, are planted out at the rate of 12 maunds per acre. They are planted in parallel furrows drawn 15 inches apart and about 8 inches apart in the furrow, at right angles to the subsidiary water-channels." The field is frequently hoed and weeded and irrigated twice a month during the cold season if there be no rain. The rhizomes are dug up.

United Provinces.—Ginger is extensively grown in all hotter valleys in Kumáon. A piece of ground not liable to be flooded is selected and protected from excessive rainfall by trenching round the upper side. The soil is well hoed and manured and the ginger planted in furrows in April. The whole field is then covered with leafy branches kept in place by bamboo or wooden poles. The rhizomes are gathered in February.

Panjáb.—As in the United Provinces, ginger cultivation is carried on chiefly in the lower hot valleys of the Himálaya. The rhizomes selected for planting are preserved in heaps covered with cow-dung. The land is ploughed at the end of June or beginning of July, divided into beds, and saturated with water. Leaves are applied as in Kumaon, but a layer of manure is placed over the leaves in addition. After the rains cease, artificial irrigation is necessary from October to January. In January the rhizomes are dug out and removed to another place for a month, after which they are exposed to the sun for a day, and are then fit for use. A bigha is stated to require 8 maunds of ginger to plant it, and yields 32 maunds in a good crop.

Bombay.—According to the Season and Crop Report, there were 596 acres under ginger in 1905-6, chiefly in Thána, Surat, Sátara and Kaira. Mollison (Textbook Ind. Agri., iii., 182-6) has recently described fully the methods of cultivation. "It grows to great perfection on the deep, alluvial, sandy loams (gordu) of Kaira and Baroda. The garden land of Surat, in which the crop is important, is somewhat heavier, but of the same general character and consistence. In the Thána district, where the rainfall is heavy, the crop is only grown in the strip of deep, sandy soil which fringes the coast in the Máhim and Bassein Tálukas."

"In Thána, ginger is rotated with betel vines, plantains, and sugar-cane. In Northern Gujarát it is rotated with a number of other garden crops, such as sugar-cane, surans, turmeric, onions, garlic, chillies, brinjals, cabbages, methi, etc. Most of these crops are found in different patches in the same garden in a single year."

"Ginger in Thána is grown alone. In Northern Gujarát, a thick sprinkling of guedr is sown with the crop. Yams are planted at the corners of the beds and along the bándhás which separate the beds, or, instead of yams, turmeric may be so grown." Mollison then describes in detail the methods pursued in Kaira, for which the reader is referred to the original. Planting the sets takes place in May or early in June before the monsoon breaks, and Mollison estimates that about 77,000 sets are required per acre, varying in weight from about 1,200 lb. to 2,000 lb. The crop is ready for harvest by November or December. "Under favourable conditions, an acre may yield 12,000 lb. of dry cleaned rhizomes. The sun-dried partially cleaned rhizomes are sold by the cultivators to dealers at 40 to 50 lb. per rupee in ordinary seasons. Selected pieces of rhizomes after storage for several months are worth as sets for replanting about 25 lb. per rupee. A crop test which was taken in the Surat district in good garden-land in 1895-6 gave for a mixed crop of ginger and turmeric the following outturn:—ginger, 8,337 b. per acre; turmeric, 3,364 b. per acre." Mollison estimates the cost of cultivation in Surat at Rs. 183 per acre. In the Pharmacographia Indica mention is made of many qualities.
of ginger. "One variety found in gardens in the Konkan has a darker colour than the ordinary ginger and somewhat of a zedoary flavour; it is known as kala-ala or black ginger." [Cf. Repts. Dept. Land Rec. and Agrt., Bombay; Crop Exper., Bombay.]

**Madras.**—The best Malabar ginger, spoken of so highly by Linschoten, is said to be the produce of the district of Shernaad to the south of Calicut. The soil is a rich red earth, and cultivation generally commences about the middle of May, after the ground has been thoroughly ploughed and harrowed. At the commencement of the monsoon, beds are formed, and on these, holes are dug and filled with manure. Cuttings of the rhizomes are placed in the holes and the beds covered up with a layer of leaves. A fair supply of rain is necessary, but, as inundation entirely ruins the crop, great care is taken in draining. The rhizomes are dug up about November. There are no statistics available relative to area or outturn.

**PREPARATION AND USES.**—The rhizomes are dug out with a small hand-pick and then consigned to a dealer, who sells them as fresh ginger or converts them into *santh* (dried ginger). The pieces of rhizomes are known by spice dealers as "races" or "hands." Nicholls (Textbook Trop. Agri., 1892, 196) describes two methods of drying the rhizomes after they have been dug out, viz. they may be plunged into boiling water for some minutes and then dried in the sun, or they may be scraped with a knife till the black outer skin is removed and then sun-dried. The former is known as "unscraped," "coated," or "black" ginger, the latter as "scraped," "uncoated," and "white." Uncoated Cochin ginger is reputed to be the best kind produced in India. Mollison thus describes the preparation in Surat: "The first operation in *santh*-making is to soak the partially cleaned rhizomes in water. This with rubbing cleans the rhizomes, and also softens them. The soaking facilitates the removal of the outer skin. It is scraped off with a shell or broken piece of earthenware. The scraped ginger is now washed and exposed for three or four days to the sun on an ordinary threshing-floor. The ginger is thus bleached and dried. It is then rubbed by hand. The object is not clear. The operation is done carefully, so that the shoots are not broken. The ginger is then bleached in the sun for three or four days, and again hand rubbed. It is now steeped in water for two hours, and exposed on a clean floor to the sun until it gets dry. When dry it is rubbed on a coarse cloth or coarse sacking. This removes any outer skin not previously removed by scraping. The *santh* is now ready for market. The cost of *santh*-making is about Rs. 3 per *khandi* of 20 maunds of green ginger."

Ginger has long been known both to Hindu and Muhammadan medicine, and its uses in European Medicine are well known. It is sold in almost every bazaar throughout India, and is largely employed as a condiment, especially in the preparation of curries. Gildemeister and Hoffmann (Volatile Oils, 1900, 315–5) give particulars of the ginger orz trade. The rhizome is also pickled and an excellent preserve made by cooking the fresh young rhizomes in syrup. The manufacture of ginger-beer and ginger-ale forms a large portion of the mineral water trade in England and the States. Besides being used as a spice, confection or medicine, ginger is thus used in gingerade, ginger-ale, ginger-beer, ginger-brandy, ginger-wine, gingerbread, ginger lozenges and ginger essence. Soluble essences are required in the manufacture of most of the liquors, etc., in which ginger becomes an important ingredient. The traffic in Jamaica unbleached ginger is very considerable. [Cf. Pharmacog. Ind., iii., 420–5; Waring, Bazar Med. Ind., 1897, 69–70; Parry, Chem. of Essential Oils and Artif. Perfumes, 1899, 136–7; Dhargal Ker, Notes on Therap. of Indig. Veg. Drugs., 1899, 64; Dutt, Mat. Med. Ind., 1900, 253–5; Blyth, Foods Compos. and Anal., 1903, 25; Journ. Agri.-Hort. Soc. Ind., 1902, xii., n.s., 85–7; Ghosh, Treat. Mat. Med., 1904, 656; Leach, Food Inspect. and Anal., 1905, 434–50.]

**Trade.**—The Indian internal trade in ginger is fairly large and important. During the five years 1901–2 to 1906–7 the total transactions by rail and river averaged 90,639 cwt., amounting in 1906–7 to 86,211 cwt. The largest quantities in that year were exported from Eastern Bengal and Assam with 20,009 cwt. (almost all to Calcutta).
THE INDIAN JUJUBE

followed by Bombay Port, 13,110 cwt. (to Bombay Province, Central Provinces and Berar, Panjäb, United Provinces, Rajputana and Nizam’s Territory); Panjäh, 10,728 cwt. (to Karachi, United Provinces, etc.); Madras, 6,648 cwt. (to Madras ports); United Provinces, 10,002 cwt. (to the Panjäb and Bengal).

Similarly, by coast the exports in 1905-6 amounted to 2,634,020 lb., valued at Rs. 3,21,100. The great bulk of these coastwise exports went from Madras, viz. 1,984,040 lb., and were consigned chiefly to Bombay, viz. 1,902,294 lb. Bombay is the only other exporting centre of any importance, from which the exports in the same year amounted to 587,161 lb.

Turning to the foreign trade, the following have been the quantities exported for the six years 1901-2 to 1906-7:—1901-2, 5,758,616 lb., valued at Rs. 13,02,323; 1902-3, 7,397,702 lb. and Rs. 16,59,499; 1903-4, 12,061,517 lb. and Rs. 24,91,055; 1904-5, 11,164,019 lb. and Rs. 19,26,784; 1905-6, 9,869,174 lb. and Rs. 12,52,740; and in 1906-7, 5,415,531 lb. and Rs. 9,67,209. Analysing the figures for the last year, we find that from Bombay there were exported 2,314,778 lb., from Madras 2,032,088 lb., and from Bengal 1,068,620 lb. The chief markets were the United Kingdom, which received 1,565,020 lb.; Aden, 1,517,696 lb.; United States, 960,801 lb.; Arabia, 378,544 lb.; Ceylon, 242,373 lb.; and Germany, 219,920 lb. For a similar period the imports were:—1901-2, 863,837 lb., valued at Rs. 1,68,313; 1902-3, 664,041 lb. and Rs. 1,29,036; 1903-4, 2,104,746 lb. and Rs. 3,41,204; 1904-5, 874,625 lb. and Rs. 1,07,071; 1905-6, 1,089,515 lb. and Rs. 1,35,876; and in 1906-7, 1,028,344 lb. and Rs. 1,70,421. These quantities come almost entirely from Japan and China, which contributed in the last year (1906-7) 875,360 lb. and 117,820 lb., respectively, and go chiefly to Bombay and Bengal, which imported 824,561 lb. and 187,560 lb.

ZIZYPHUS, Juss.; Fl. Br. Ind., i., 632-7; Gamble, Man. Ind. Timbs., 1902, 180-5; Cooke, Fl. Pres. Bombs., 1903, i., 240-1; Prain, Beng. Plants, 1903, i., 333-4; Brandis, Ind. Trees, 1906, 169-72; Rham. N. C. E. A genus of trees or shrubs, of which some 18 species are natives of India.

Z. Jujuba, Lamk. The Indian Jujube or Chinese Date, bér, bor, bür, kül, jumunjan, dedhaori jumun, ringa, jibang, khalia, elandap, yelande, karkandhau, regu, yalachi or jelachi, zi, etc. The cultivated form is known as pweangi, pendi or pendi-boe, the wild form being jharberi (Duthie, Fl. Upper Gang. Plain, 1903, 103). The grafted bér is called powndi. Burkhill (MS. Notes on Tour in Rohat) remarks on four kinds extensively grown, viz. umari, nasuk, pendi and kutia. Lisbon observes of bordi that it is one of the commonest fruit trees of the villages of Western India. A moderate-sized deciduous tree, “distinctly wild in the forests of the Siwaliks and Sub-Himalayan tracts of the Panjäb and United Provinces, and also in the Deccan and in Upper Burma and Ceylon in dry forests. Elsewhere mostly cultivated or run wild” (Gamble).

The bark is said to be used for TANSING in Northern India, Bombay, Madras and Burma. In Chota Nagpur it is similarly employed, but along with the fruit. Occasionally it is thrown into indigo-vaat to aid in precipitating the feclua. Hooper (Agri. Ledg., 1902, No. 1, 20) states that a sample of bark from Madras gave 4-1 per cent. of tannin, and a sample of thick root examined at Dehra Dun gave 2-6 per cent., while some thin roots afforded 9-3 per cent. Most parts of the tree are employed in Native Medicine. The fruit of the wild bér, which ripens in the cold weather—the cultivated one ahoast in any season (Collett, Fl. Sim., 1902, 90)—resembles the crab-apple in flavour and appearance, and is much eaten, as well as that of most species, by the poorer classes;
in fact, in times of scarcity these fruits are specially prized. By cultivation it is greatly improved both in size and flavour, and there is great variety among the cultivated forms. According to Marshall Woodrow, "the best are elliptical, two inches in length by one in thickness and are propagated by inarching or budding on seedlings of the common sort." The unripe fruit is pickled; the ripe pulp is dried, mixed with salt and tamarinds, to form a condiment or is made into chutneys. The kernels are also eaten, and the leaves constitute a useful FODDER for cattle and goats. The Wood is hard and reddish in colour, weighing on an average 48 lb. per cubic foot. It is largely employed in ordinary constructive work and has been recommended for furniture. It is also said to make excellent CHARCOAL. The lac insect is commonly reared on the tree (see Tachardia laccata, p. 1057), and it is one of the food-plants of the tasar silkworm (see p. 1005), while in Assam the eri silkworm is sometimes fed on it as well (see Silk, p. 1012). [Cf. Baber, Memoirs, 1519 (Leyden and Erskine, transl.), 326; Garcia de Orta, 1563, Coll., xxviii.; also in Ball, Proc. Roy. Ir. Acad., 3rd ser., 1888-91, i., 413-4; Prosper Alpinus, De Pl. Aigypti, 1592, 8; Linschoten, Voy. E. Ind., 1598 (ed. Hakl. Soc.), ii., 32; Thevenot, Travels in Levant, Indostan, etc., 1687, pt. ii., 117, and pl.; Milburn, Or. Comm., 1813, i., 138; De Candolle, Orig. Cult. Plantes, 1884, 197-8; Pharmacog. Ind., 1890, i., 351; Moodeen Sheriff, Mat. Med. Mad., 1891, 108-9; Banerjei, Agri. Cuttack, 1893, 191; Cameron, For. Trees of Mysoore and Coorg, 1894, 72-3; Rept. Oper. Dept. Land Rec. and Agri., 1897-8, 19; Agri. Ledg., 1901, No. 9, 213, 221; Kanjilal, For. Fl., 1901, 72; Woodrow, Gard. in Ind., 1903, 236-7; Firminger, Man. Gard. Ind., 1904, 273; Rec. Bot. Surv. Ind., 1904, iii., 35.]

Z. vulgaris, Lamk. The Common Jujube, tün-í- (or phitní-) bér, kandika, singli, bán, bárj, ganyeri, shamor, amlai, relnu, aná, unnáb, rán-bor, etc. A large shrub or small tree "wild in the Panjab from the Indus to the Ravi; much cultivated in the Panjab, Kashmir, Baluchistan, etc." (Gamble). The tree is chiefly important on account of its FRUIT, which is very similar to that of Z. Jujuba, being an oval pulpy drupe about the size of a plum. It varies much and can be greatly improved by cultivation and grafting. The dried fruit is the jujube of Arabian and Persian works on Materia Medica, and has long been known as an article of commerce. The Indian market is supplied from China and the Persian Gulf, the Chinese fruit being preferred as it is larger and sweeter. In Europe it is used in the preparation of syrups, confections and lozenges (pate de jujube) taken to allay cough. In order to ascertain the composition and value of these fruits a consignment was sent to London in 1904, and a report was submitted by Dunstan (Imp. Inst., March 3, 1905). The fruits were chemically examined, but the results showed that they contained no constituents to which definite medicinal qualities could be ascribed. The report further adds that "it was considered possible that confectioners might be able to make use of such materials for the preparation of candied fruit or in some similar way, but the absence of any peculiar flavour and the somewhat mawkish taste of the pulp were considered insuperable difficulties by the firms to whom samples of the fruits were submitted for consideration from this point of view." Specimens of the fruit were also submitted to dealers in cattle-food in the hope that it might be used for mixing with ground pulse and similar products as a sweetening agent. The fruit was considered suitable for this purpose, but experts were of opinion that owing to its bulkiness it could not compete in this direction with similar products such as the carob bean. The report concludes by stating that there appears to be "no immediate prospect of any commercial outlets being formed for these dry fruits, but the inquiry will be continued, and it is possible that some new development in trade may suggest a method for their utilisation in the future." [Cf. Bentham, Rev. of Targioni-Tozzetti, in Journ. Hort. Soc., 1855, ix., 165; De Candolle, l.c. 194; Pharmacog. Ind., l.c. 350; Lawrence, Valley of Kashmir, 1895, 79, 82; Agri. Ledg., 1902, No. 1, 20; Hosie, Rept. Prov. Ssu'ch'uan, China, 1904, No. 5, 17, 50, 54.]
INDEX

This work being alphabetical, a complete index to the subjects dealt with becomes superfluous. In the pages that follow, therefore, will be found all the vernacular and other names mentioned in the text, as also cross references to subjects that might otherwise have escaped observation. Minor products that find positions in collective articles and do not therefore appear in their alphabetical positions are included in the index. Scientific names of unimportant products, such as species of birds, fish, insects, etc., are not included, except their English and vernacular names. Names of places, persons, books consulted and analytical details have been purposely omitted. It is believed the marginal notes and cross references within the text fully meet these requirements. The citations to the Dictionary of Economic Products of India have been uniformly given on the margin as "D.E.P." Vernacular names, as also scientific synonyms (when given), are in italics, English names in ordinary type, and modern scientific names in small capitals.
